The wide breach and fast breach scenarios have an M value (i.e., 1,080,000 m^3/hr and 917,000 m^3/hr) that is between the best estimate and the maximum M value from Equation 2 (i.e., 736,000 m^3/hr and 2,327,000 m^3/hr, respectively) for the example dam. The wide and fast breach scenario has an M (2,170,000 m^3/hr) that is about the same as the maximum M value from Equation 2. The adjustments in the breach width and formation time used for these hypothetical sensitivity cases are not extreme and are less than the typical uncertainties when using multiple empirical equations (Adria et al., 2023a) but result in an extreme outcome when combined. Depending on the project-specific conditions, the wide and fast breach sensitivity scenario may not be physically possible, or it could be representative of a worst-case scenario for an erosional breach.

It is noted that credible non-erosional breach scenarios could still result in a wider and faster breach than a worst-case erosional breach; however, it is also possible that a non-erosional breach is smaller than the erosional breach and may not represent the worst-case scenario (e.g., a decapitation or a shallow surface slip type failure).

Comparisons to case histories

There are numerous uncertainties in TDBAs every step along the way. It is therefore prudent and beneficial to compare the final selection of breach parameters against case histories to assess whether the selections are reasonable and sufficiently conservative. To assess the predicted mobilized tailings volume in a TDBA, the outflow volume can be compared to the impounded volume. This comparison is shown in Figure 5 (reproduced from Adria et al., 2023), which is adapted from Rana et al. (2021a and 2021b).

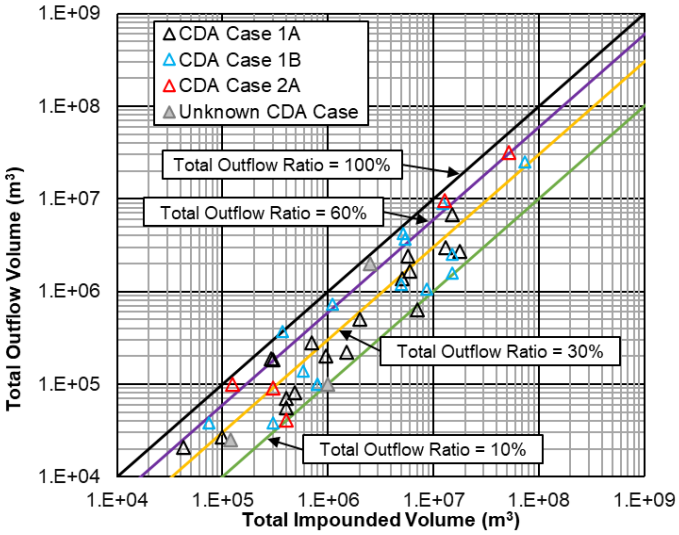

Figure 5: Total outflow ratios for past tailings dam failures (adapted from Rana et al., 2021a)

Other types of comparisons are shown in the Appendix and include scatter plots of: (A) breach heights to average breach widths, (B) eroded dam volumes, (C) mean erosion rates/breach formation times, and (D) mean dam erosion rates. The plots were developed using data compiled by Wahl (1998, 2014), Walder and O'Connor (1997), Rana et al. (2021b), and Adria et al. (2023b). Colored lines that represent relevant ratios are included on these plots for reference. As an example, if the dam evaluated in the TDBA has a broad geometry and is constructed of erosion-resistant materials, it should plot closer to the lower ratios shown with blue lines on the Appendix figures.

Conclusion

This paper discusses the processes that occur during breach formation that need to be understood to prevent

the application of non-analogous case studies or empirical equations to forward-analysis. Two empirical equations from Adria et al. (2023a) are presented that estimate the eroded dam volume and the eroded dam volume rate. These equations can provide additional tools for breach parameter selection, particularly for dam geometries that are outside of the typical conditions in existing dam failure databases. The authors find these equations to be useful tools in their day-to-day practice, as they provide a different measure for checking the reasonableness of the selected breach parameters, given the inherent uncertainties associated with the breach analysis.

Acknowledgements

The authors gratefully acknowledge their clients and colleagues for valuable inputs and support during actual dam breach assessments and preparation of this manuscript. The contributions of Dr Scott McDougall, who collaborated on the CDA 2023 paper, are also greatly appreciated. Various members of the CanBreach Research Program were also instrumental in the development of several key databases used in this paper and contributed thoughtful discussions on several of the themes in this paper over the years. The authors also thank the two reviewers of this manuscript for their constructive comments.-k

Estimation of Outflow Runout Distance in Tailings Dam Using an Artificial Intelligence Technique

Mohammad Rashidi, Stantec, USA
Sam Abbaszadeh, Stantec, USA
Jenisha Chhetri, Stantec, USA

Abstract

There are about 3,500 tailings dams worldwide storing billions of tons of mill and waste tailings from mineral processing activity at mine sites. A number of particular characteristics make these tailings dams more vulnerable to failure than traditional water storage dams, such as multi-stage raising, constructing embankments using mine waste materials, and the lack of regulations in certain regions. More than a third of the existing tailings dams are at high risk of causing catastrophic damage to the downstream communities, socio-economic activities, and ecological systems. The extent of tailings dam failure is often estimated as part of the risk assessment process, utilizing available empirical and semi-empirical approaches. While these methods are helpful, they are not developed specifically for estimating the runout distance for tailings dams. Some critical parameters that affect outflow runout distance, such as break mechanisms, breach size, and the geometry of the downstream valley, are not incorporated in these methods.

This study introduces a new method to predict potential mine waste runout distance using information from historical tailings dam failures. The new method is based on artificial intelligence and uses the Genetic Programming (GP) method. Parameters such as tailings height at the time of failure, volume of tailings released, and slope of the downstream area are considered as the input parameters in the proposed GP models. The results obtained from comparing the proposed artificial intelligence method and existing empirical relationships showed that the proposed method is capable of estimating the runout distance for tailings dams.

Although the accuracy of any runout estimations should be approached with great caution, the proposed method can be utilized as a simple tool to provide an estimation of the runout distance. This information can be used by the project team to better understand the failure consequences and potential risks and impacts to the downstream population.

Introduction

Tailings dams play a crucial role in storing vast amounts of mill and waste tailings generated from mineral processing activities at mine sites worldwide. With approximately 3,500 tailings dams worldwide, storing billions of tons of tailings, these structures present unique challenges and risks to the communities and environment, in terms of their vulnerability to failure compared to traditional water storage dams (Davies et al., 2000). Factors such as multi-stage raising, the use of mine waste materials in embankment construction, and the absence of adequate regulations in certain regions contribute to the heightened risk associated with tailings dams (Adamo et al., 2020).

Alarming statistics indicate that over one-third of existing tailings dams have a high risk of catastrophic failure, which could lead to severe damage to downstream communities, socio-economic activities, and ecological systems (Rourke and Luppnow, 2015). Accurate estimation of the runout distance resulting from such failures is a crucial aspect of risk assessment, as it helps in understanding the potential consequences and impacts on the downstream population, which is required by most guidelines and standards such as GISTM (Global Tailings Review, 2020).

Current empirical and semi-empirical approaches used for estimating the extent of tailings dam failure, although valuable, do not specifically account for the unique characteristics and parameters influencing runout distance of tailings dams. Critical factors such as break mechanisms, breach size, and the geometry of the downstream valley may have been overlooked in these methods.

To address the limitations of existing approaches, previous studies have sought alternative methods to predict the runout distance of tailings dam failures. Rico et al. (2008) proposed an empirical relationship by analyzing historical data on tailings storage facility (TSF) failures. Their approach incorporated parameters such as tailings height, total tailings volume, and released tailings volume, as represented in Equation 1. The study demonstrated the effectiveness of this approach in estimating runout distance. However, an important factor that was not considered in their estimation was the influence of downstream topography. The omission of downstream topography as a parameter in their analysis represents a gap in their methodology.

$$D_{max} = 1.61 \times (H \times V_R)^{0.66} \quad (1)$$

Where D_{max} is maximum runout distance (km), H is the dam height (m), and V_R is released outflow volume ($\times 10^6 m^3$).

In this study, a novel method is presented for predicting the runout distance of tailings dam failures by leveraging historical data from past incidents and utilizing artificial intelligence, specifically the Genetic Programming (GP) method. By incorporating key input parameters such as tailings height at the time of failure, volume of released tailings, and the slope of the downstream area, our proposed GP model aims to provide accurate estimations of the runout distance. By integrating these critical factors, the proposed

method seeks to overcome the limitations of previous approaches and improve the reliability of runout distance predictions for tailings dam failures.

While the proposed method may serve as a simple tool, it can provide valuable insights for project teams in comprehending the potential risks, impacts, and failure consequences to downstream populations. By integrating the estimation of runout distance into risk assessments, decision-makers can make more informed choices regarding tailings dam management, emergency preparedness, and disaster response.

In the subsequent sections of this paper, we will delve into the methodology employed, present the results of the comparative analysis, and discuss the implications of the proposed method for tailings dam failure mitigation.

Study of database

The height at the time of failure (H), TSF capacity (V_T), released volume (V_R), and the distance traveled by the tailings (D_{max}) are inputs in Rico et al.'s (2008) method (Equation 1). Of the 29 tailings dam failure cases analyzed by Rico et al., nine of them did not have complete information, particularly the downstream slopes of TSF (S). Therefore, the remaining 20 tailings dam failures were used to develop and validate the correlation presented in this study, as illustrated in Table 1. Figure 1 indicates the location of the tailings dam failures reported in Table 1.

Genetic programming

Genetic programming is a subfield of artificial intelligence that extends the principles of genetic algorithms (GAs) (Goldberg, 1989). GP begins with an initial population consisting of randomly generated computer programs, represented as syntax trees, composed of functions and terminals suitable for the given problem domain. Functions encompass standard arithmetic operations, programming operations, mathematical functions, logical functions, and domain-specific functions. Terminals, on the other hand, represent constants or variables. Through a supervised trial and error process, the initial functions and terminals undergo adjustments to obtain refined functions and terminals that accurately estimate the desired output.

GP, much like nature, is inherently a random process and cannot guarantee specific results. However, the stochastic nature of GP enables it to escape traps that deterministic methods may encounter. This randomness has proven to be a key factor in the success of GP, as it allows for the evolution of innovative and unexpected solutions to complex problems.

In GP, programs are commonly represented as syntax trees, as opposed to traditional lines of code. For instance, Figure 2 depicts a tree representation of the program "max(x + y, x – 6)," where x and y are independent variables, and 6 is a constant. In GP, the leaves of the tree, such as variables and constants, are referred to as terminals, while the internal nodes, such as arithmetic operations and functions like "max," are called functions. The collective set of allowed functions and terminals forms the primitive set of a GP system.

Similarly to other evolutionary algorithms, GP involves the generation of an initial population of individuals, typically generated randomly. Various approaches exist for generating this initial population, including the full and grow methods, which are simpler and earlier techniques, as well as a widely used combination of the two known as ramped half and half (Koza, 1992). Genetic operators in GP, such as crossover and mutation, are applied to individuals who are probabilistically selected based on their fitness, as determined by the objective function.

By leveraging the principles of GP, researchers and practitioners can explore the potential of evolving novel solutions and addressing complex problems through adaptive and self-improving computational processes.

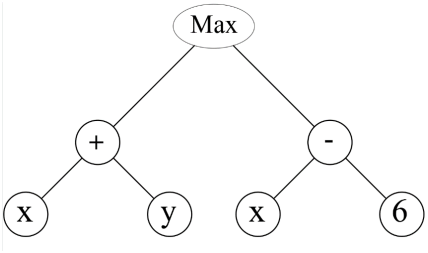

Figure 2: Representation of an expression tree in GP ("Max" represents the maximum function)

The advantage of GP over other soft computing techniques (such as artificial neural networks and adaptive neuro fuzzy inference systems) is that GP is not a black box and outputs are in the form of semi-complex mathematical solutions, which could be applicable to the actual problems. The GP approach is relatively new in the field of dam engineering, although some studies have been dedicated to their application recently (Rashidi et al., 2021; Noorzad et al., 2014).

In this study the data set was divided into training (80%), and validation (20%) subsets to prevent overfitting. The performance of the testing set is critical because it determines the accuracy and generalization capability of the model.

Two statistical evaluation criteria were used to assess the performance of the intelligent methods. These criteria are Root Mean Square Error (RMSE) and determination coefficient (R^2), respectively, given by Equations 2 and 3.

$$RMSE = \sqrt{(\frac{1}{n})\sum_{i=1}^{n}(a_i - p_i)^2} \quad (2)$$

$$R^2 = (\frac{\sum_{i=1}^{n}(p_i - p^-)(a_i - a^-)}{\sqrt{\sum_{i=1}^{n}(p_i - p^-)^2(a_i - a^-)^2}})^2 \quad (3)$$

where a is the actual value and p is the predicted value, a^- and p^- are the mean of actual and predicted values respectively, a is the absolute error, $a_i - p_i$; a- is the mean of absolute error, 1n and n is the number of data sets. Evidently, a model with good performance (i.e., RMSE close to 0 or R^2 close to 1) will be the best model among several candidates.

Results and discussions

Sensitivity analysis

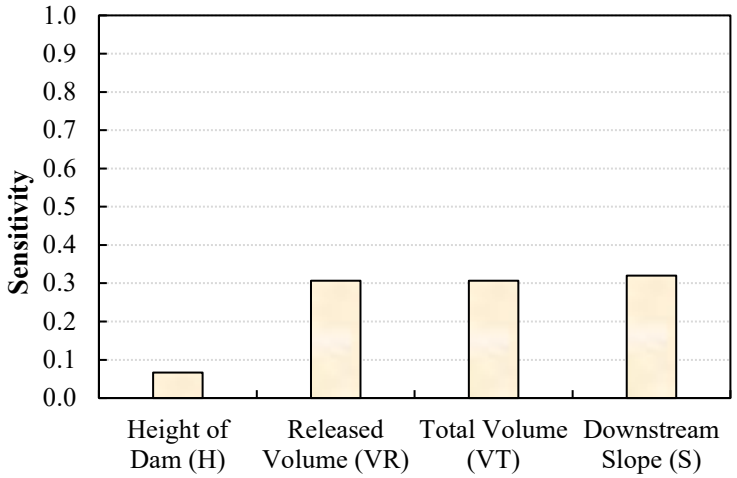

Figure 3: Sensitivity of the runout distance to the tailings dam features

Figure 3 illustrates the results of the sensitivity analysis conducted on the GP model developed in this study. The sensitivity function provides insights into the relative impact of input parameters on the estimation of runout distance. A negligible magnitude of the sensitivity function indicates that the corresponding input parameter has minimal influence on the model's output, whereas a higher value signifies a greater impact of the tailings dam features on the estimated runout distance.

Based on the sensitivity analysis results presented in Figure 3, it is evident that the downstream slope of the tailings storage facility (TSF) exhibits the highest influence on the maximum runout distance of a tailings dam. Following the downstream slope, the total and released volume of tailings were identified as the next most influential parameters affecting the outflow runout distance. Conversely, the height of the tailings dam was found to have the lowest influence compared to the other parameters. These findings highlight the critical impact of the downstream slope in determining the runout distance of tailings dams. Understanding the significant influence of these parameters allows for more informed decision-making and improved risk assessment in the management of tailings facilities.

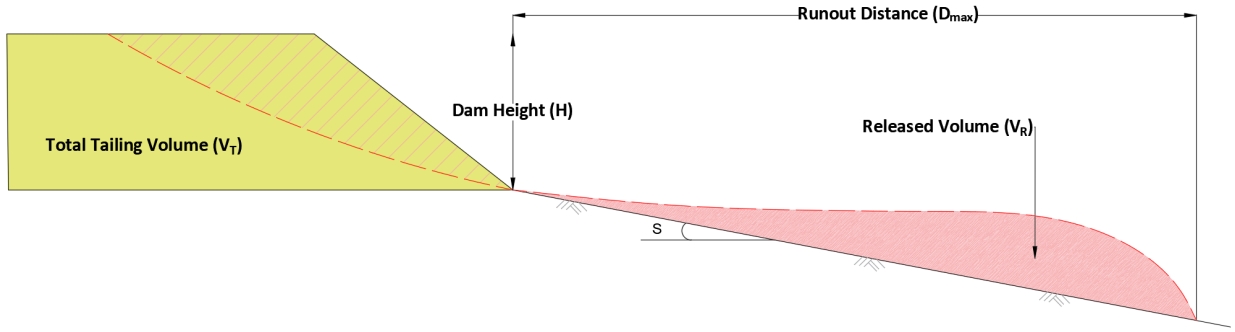

Figure 4: Cross-sectional illustration of the tailings dam failure for a tailing dam

Genetic programming model

Genetic programming was utilized to construct a prediction model for estimating the outflow runout distance of tailings dams. The GP method was employed to develop Equation 4, which incorporated data from 20 case studies and considered three key input parameters: the height of the dam, the released volume of tailings, and the downstream slopes of the TSF:

$$D_{max} = V_T + {V_R}^3 - (\frac{7.21}{S^S} - \frac{113}{V_T + S^{2^S}}) \quad (4)$$

Where D_{max} is maximum outflow runout distance in km, V_R is the released volume of tailings in million m^3, V_T is the total volume of tailings in million m^3, and the S is downstream slopes of the TSF in percentage.

For prediction of runout distance, out of the 20 sets of data, 16 sets (80%) were considered for training and the remaining 4 sets (20%) were considered for validation. The training and validation data sets were selected randomly from the database. Figure 5 shows the relationship between actual runout distance and predictions of GP for Equation 4.

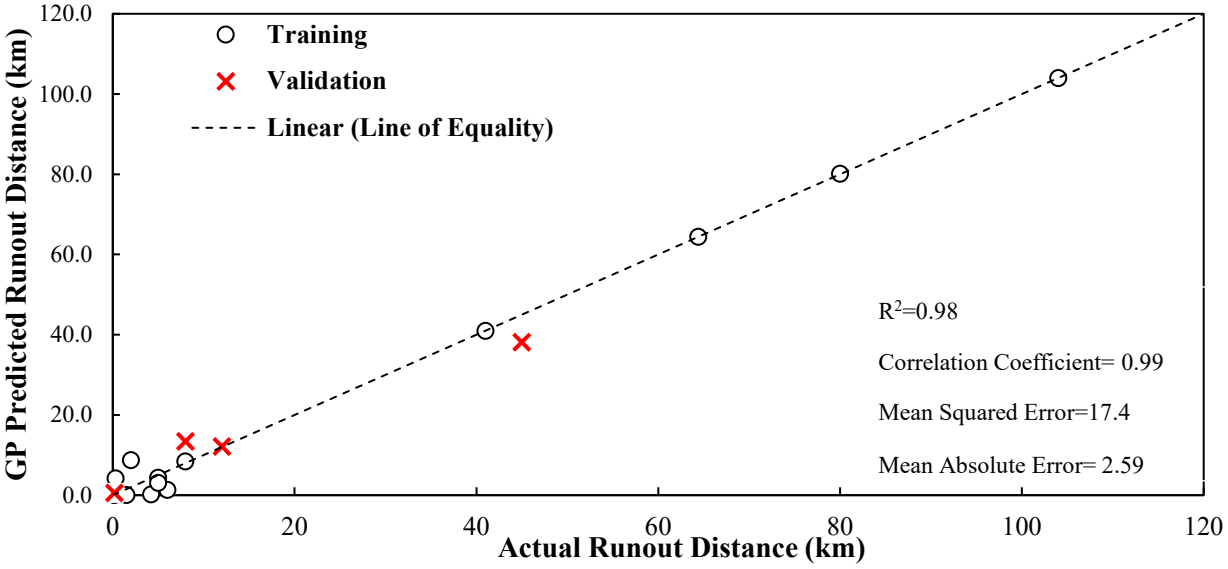

Figure 5: Predicted runout distance using GP versus actual runout distance

Comparison between GP Model and experimental relationships

Figure 6 shows the comparison between the actual runout distance, estimated runout distance using GP model, and experimental relationship developed by Rico et al. (2008). As observed in the plot, the coefficient of determination for empirical relationship was 0.364, which is the indication of low accuracy of this equation in predicting of outflow runout distance of TSF.

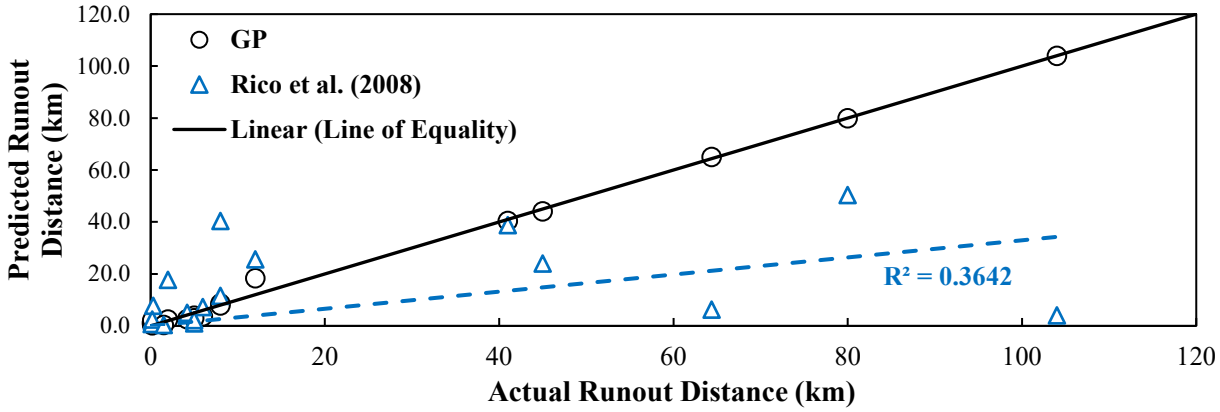

Figure 6: Coefficient of determination between the actual runout distance and predicted intelligent models (GP [Eq. 4]) and experimental relationships [Rico et al., 2008] [Eq. 1])

The limitations of existing empirical relationships can be attributed to their reliance on only two factors: tailings height and size. To achieve more robust and practical equations, it is essential to incorporate additional parameters, particularly downstream topography, which enhances the intelligence and predictive capability of the resulting relationships.

Figure 7 illustrates a comparison of the prediction performance between the GP models developed in this study and the empirical relationship proposed by Rico et al. It appears that the Rico et al. equation mostly underestimates the actual runout distance. These equations exhibit limited ability in predicting higher values of D_{max}. In contrast, the proposed GP model demonstrates significantly improved accuracy when compared to the Rico et al. relationship. By incorporating a wider range of input parameters, the proposed GP equation proves to be more applicable and reliable for estimating runout distance.

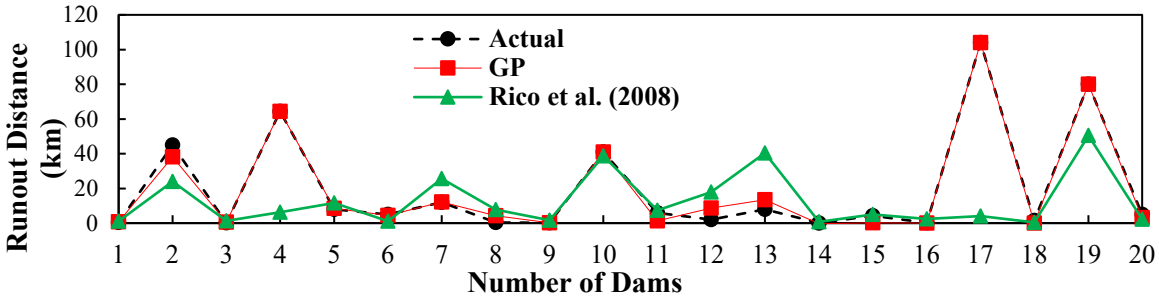

Figure 7: Comparing the actual runout distance and predicted intelligent models (GP [Eq. 4]) and experimental relationships (Rico et al. [Eq. 1])

Validation

The proposed equation using GP was validated using the Dynamic Run-out Methodology (DRUM) on a hypothetical upstream-constructed tailings dam model. This method satisfies Newton's second law of motion and uses an idealized kinematic boundary. In this method, the slide mass is assumed to slide along the slip surface, controlled by shear strength along the interface, as schematically shown in Figure 8.

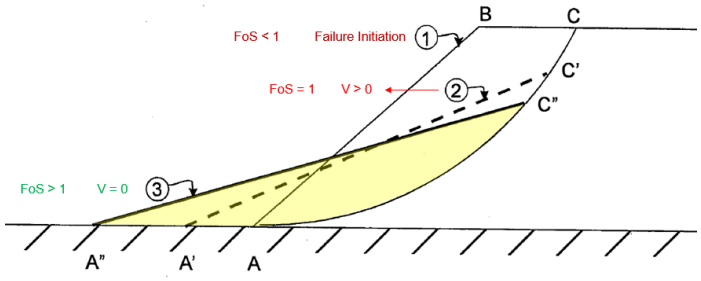

Figure 8: Configurations and conditions during flow slide in DRUM method (Moriwaki et al., 2000)

A hypothetical upstream-constructed tailings dam model was used to perform DRUM analyses and verify the newly developed equation using GP. The model contained three different tailings materials: coarse tailings, fine tailings, and slimes, as shown in Figure 9. Available field and laboratory data from a tailings project in North America were used for characterization, as summarized in Table 1. The Cone Penetration Tests (CPTs) and their dynamic pore pressure profiles were used to establish saturation.

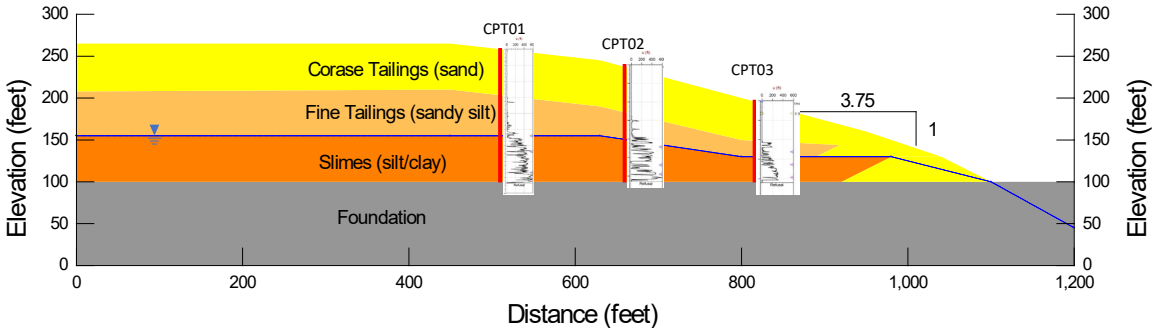

Figure 9: Analyzed cross-section geometry and tailings zone delineation

Table 2: Material properties summary

Materials	Cohesion, c' (pcf)	Friction Angle, ϕ' (degrees)	Residual Undrained Shear Strength	Peak Undrained Shear Strength	Total Unit Weight (pcf)
Coarse Tailings	0	37	–	–	110
Fine Tailings	100	30	–	–	120
Slimes	–	26	0.10	0.25	120
Foundation	1,000	38	–	–	135

Critical slip surfaces for the DRUM analysis were selected based on the results of seismic deformation analyses on the hypothetical model. A large seismic load with PGA=1.0 and M=7.9 was used to trigger liquefaction in the hypothetical model and develop a flow runout. The slip surface and released tailings area were derived from displacement results from the FLAC analysis, as shown in Figure 10.

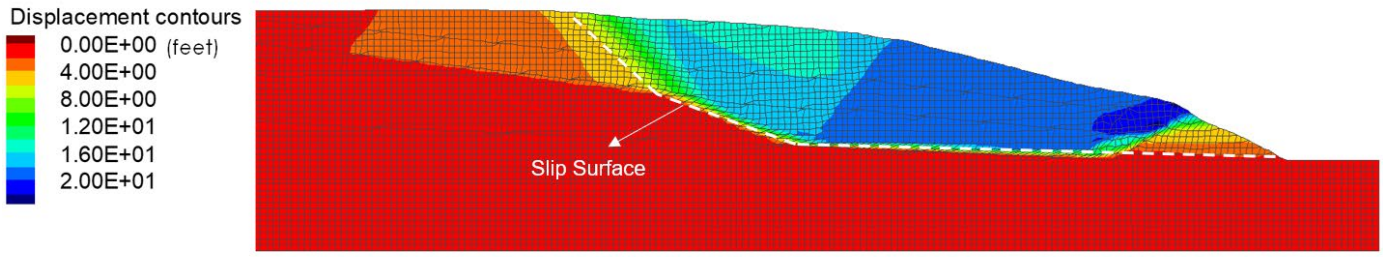

Figure 10: Calculated slip surfaces from seismic deformation

Since FLAC is not effective at estimating large magnitudes of deformation following a flow failure instability, the full flow runout calculation for the hypothetical model was performed using DRUM analyses. Calculations continued until the slide mass velocity approached zero, indicating a dynamically stable slide configuration. The total run-out distance for the hypothetical model was 2,200 ft, with a maximum velocity of 14 feet per second (ft/s). Figure 11 shows the time histories of computed runout distance and velocity.

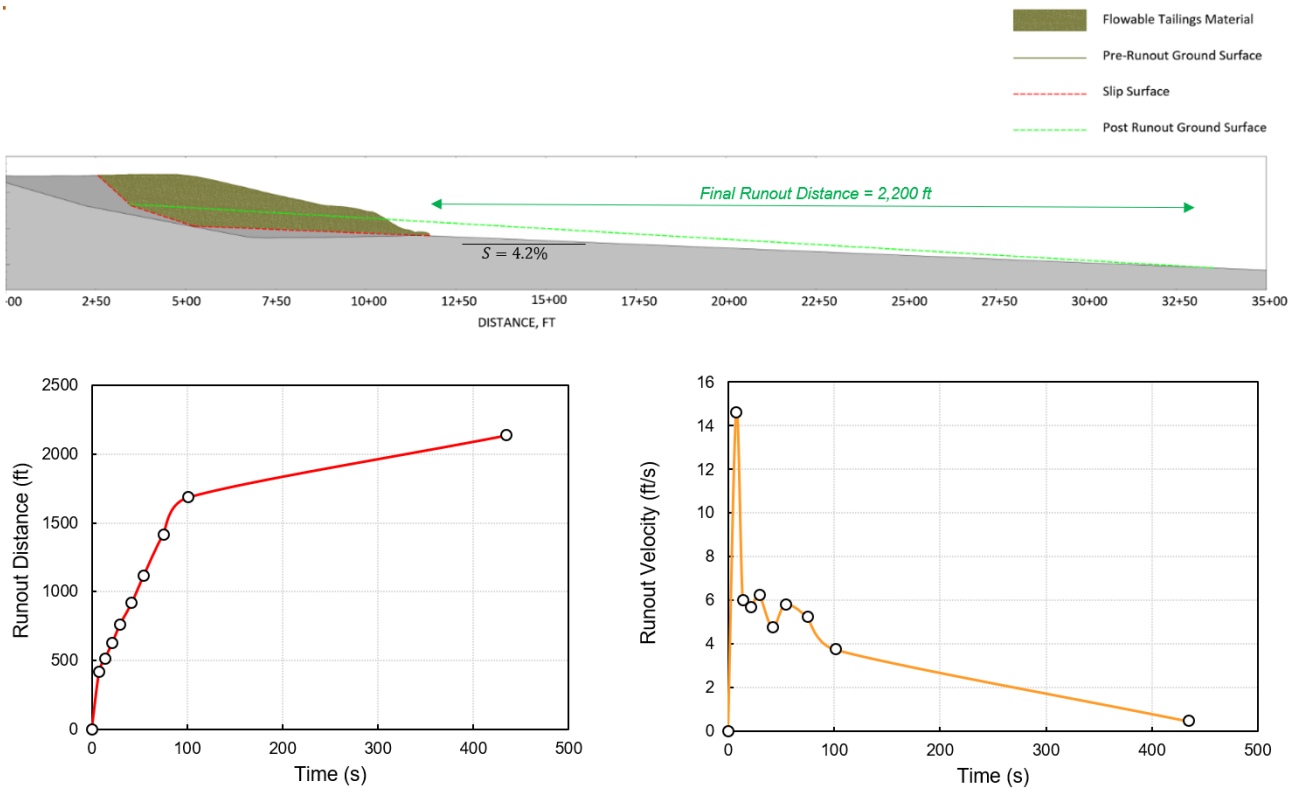

Figure 11: DRUM analysis results

The estimated total and released tailings volume, downstream slope, and dam height for the hypothetical model were 1,000,000 m³, 225,000 m³, 4.2%, and 55 m, respectively. Based on the newly developed GP equation, the runout distance for the hypothetical model should be approximately 2,066 ft, which closely matched the 2,200 feet result from DRUM analyses:

$$D_{max} = 1 + 0.225^3 - \left(\frac{7.21}{4.2^{4.2}} - \frac{113}{1 + 4.2^{2^{4.2}}}\right) = 0.63\ km = 2{,}066\ ft$$

Therefore, this validation shows the newly developed model can roughly estimate the runout distance of tailings storage facilities. The improved accuracy of the GP model, coupled with its consideration of additional input parameters, enhances its runout distance prediction capabilities. The utilization of the GP model in predicting runout distance offers a valuable tool for better understanding the potential consequences and risks associated with tailings dam failures. Although accuracy of any runout estimations should be approached with great caution, the proposed method can be utilized as a simple screening tool to provide an estimation of the runout distance. This information can be used by the project team to better understand the failure consequences and potential risks and impacts to the downstream population.

Conclusion

This study utilized Genetic Programming to predict the outflow runout distance of tailings storage facilities (TSFs) by analyzing data from 20 documented tailings dam failures globally. The models incorporated parameters such as total and released tailings volume, downstream slope, and height of the dam, revealing that downstream topography considerably affects the runout distance. The newly developed GP equation was validated using the DRUM analysis on a hypothetical upstream constructed tailings dam model, estimating a runout distance of approximately 2,066 feet, which is in close agreement with the 2,200 feet calculated based on the DRUM method. This validation shows that the GP models can be effectively used in estimating runout distances.

The findings of this study indicate that intelligent methods like Genetic Programming are well-suited for addressing complex problems involving multiple influential factors, such as predicting runout distances in tailings dams. Despite inherent uncertainties and complexities in tailings dam failures, this method seems to provide reasonable estimations that can aid project teams in understanding potential consequences and risks, and their impacts on downstream populations. This paper demonstrates the potential effectiveness of using advanced AI techniques to improve predictions and risk assessments in the context of tailings dam management.

Good Practices for the Elaboration of Hypothetical Dam Break Studies in Brazil

Caique Simões Renna Costa, AECOM, Brazil
Fernando Pereira Aguilar, AECOM, Brazil
Mônica Torres dos Santos de Almeida, AECOM, Brazil
Vicente Mello, AECOM, Brazil

Abstract

Recently, two catastrophes involving tailings dam ruptures in Brazil occurred: in 2015, the Fundão Dam failure in Mariana City, and in 2019, the B-I Dam failure in Brumadinho City, both in the state of Minas Gerais. These two events resulted in the loss of human lives and severe socio-environmental impacts on nearby communities, thereby necessitating an increase in risk management and dam safety in Brazil, as well as in local legislation and regulations.

The quality of a hypothetical rupture study is directly proportional to the knowledge of the dam structure and the materials deposited in its reservoir. For hydraulic propagation modeling, a precise understanding of the downstream region significantly impacts the flood boundary results, affecting its cross-sectional coverage, the arrival time of the rupture wave, and the distance reached by the flood boundary. The use of robust software and appropriate modeling allows available information to be used for more reliable and representative results.

This paper suggests good practices for studying and modeling hypothetical failures based on the knowledge acquired by AECOM in evaluating more than 220 tailings containment structures in Brazil.

Introduction

Reflecting Brazil's advances in dam safety in recent years, AECOM has been established as an independent technical advisor to the National Mining Agency of Brazil (ANM) in auditing more than 220 mining dams. This has enabled AECOM to understand the sensitivity of information and parameters in the development of dam break studies and, consequently, in estimating the resulting floodplain.

Additionally, as a result of the dam failure events in the state of Minas Gerais, the company Vale, owner of the B-I Dam, signed a Term of Covenant with the Public Prosecutors Office of the State of Minas Gerais (MPMG) to update all its hypothetical rupture studies. To ensure the quality of the studies, Vale

prepared the document “Guidelines for Studies of Hypothetical Rupture of Mining Dams” in 2020, which AECOM audited. Brazilian regulatory institutions have also created more restrictive resolutions to ensure the quality of studies, such as ANM resolution 95 of 2022, later modified by resolution 175 of 2024. These resolutions establish a classification for mining dams based on their associated potential damage, which is categorized as low, medium, and high. This damage is defined as that which may occur due to the rupture, leakage, infiltration into the soil, or malfunction of a dam, regardless of its probability of occurrence, to be graded according to the loss of human lives, social, economic, and environmental impacts.

It has been determined that all mining dams must have an updated hypothetical rupture study with high technical rigor, primary data obtained through direct investigations, and two-dimensional hydrodynamic modeling. It is also worth mentioning that other Brazilian institutions have prepared or are preparing documents to guide hypothetical rupture studies and establish minimum quality standards. As an example, a term of reference has already been prepared by the Minas Gerais State Foundation for the Environment (FEAM) in 2021, and a specific technical standard is being discussed by the Brazilian Association of Technical Standards (ABNT).

At the same time, there have also been advances in the guidelines for preparing these studies outside Brazil, such as the guidelines proposed by the Canadian Dam Association in 2021 in its technical bulletin, which details in depth the aspects related to hypothetical rupture studies. Additionally, there is the role of the engineer of record, who has knowledge of the structure and can validate the failure mode proposed by the designer.

Although Brazilian and international normative/regulatory institutions are evolving in their guidelines and requirements for preparing hypothetical dam break studies, there are still gaps, such as the lack of specification in certain points of the legislation, like the definition of freeboard, where it is not clear if the wind wave height needs to be considered to ensure a 1-meter freeboard. Additionally, designers face challenges in preparing detailed studies due to a lack of basic data, such as adequately precise topographic surveys. Furthermore, small entrepreneurs often lack a robust technical team and do not have specialized professionals capable of developing high-quality studies as required by the legislation. The guideline documents only sometimes reflect the difficulties encountered by designers, as in the case of mining dams in Brazil.

Thus, this article aims to present the main criteria and essential data to be used to prepare the hypothetical dam break studies in accordance with the best Brazilian and international practices. In addition, it considers the experience acquired by AECOM during the audit process in more than 220 mining dams in Brazil.

Discussion

A hypothetical dam break studies (HDBS)'s quality is important for understanding the dam and the materials deposited in its reservoir. Historical information about the structure contributes to understanding its weaknesses and defining failure modes and volumes to be mobilized for the scenarios with the most significant impacts. Thus, the HDBS should be prepared with the best technical knowledge of the structures. For this purpose, the essential data are listed below:

- Documents related to the design and safety of the structure, such as Executive Design, As Built or As Is, Regular and Periodic Safety Inspection Reports.
- Detailed topographic and cadastral survey of the dam and reservoir area, updated topobathymetry of the reservoir, and primitive topography. The developer will be able to use additional information, such as geological-geotechnical investigations of the reservoir and dam, which allows for improving the precision of the primitive topography. Topographic inconsistencies can significantly interfere with the mobilized volumes of the study and, consequently, with the results of the floodplain.
- Complete geological-geotechnical investigations of the embankment and foundation dam to obtain the resistance factors that will support the studies for evaluating the failure modes.
- Geotechnical characterization of the reservoir through geological-geotechnical tests and investigations. The following information must be considered, at a minimum, regarding tailings, residues, or sediments deposited in the reservoir: information on the water table; contact between the deposited material and the natural terrain; angle of repose; Atterberg limits; specific weight of the grains; granulometry; void index and moisture content in situ; and saturation and classification of the material according to the risk to health and the environment. This minimum characterization of the materials is mentioned in the guidelines document elaborated by Vale in 2020, and in the FEAM term of reference and ANM resolution 95 of 2022.
- Rheological characterization of the material disposed of in the reservoir (where applicable).

For tailings accumulation dams, it is essential to know the characteristics of the material disposed in the reservoir in order to know with greater precision about the deformations and flow of the fluid in rupture studies. Fluids composed of a mixture of water and solids may be classified as hyperconcentrated, depending on the calculated volumetric concentration (VC) and the rheological characteristic of the mixture contained in the reservoir. The most common equations for representations of hyperconcentrated flows use the parameters of dynamic viscosity, yield stress, and specific weight. For the proper rheological characterization of a fluid, it is necessary to define the number of samples/assays and their VCs for the

study. It is recommended that the tests be performed for different VC values, allowing correlations among the different conditions of the samples (VC curves versus shear stress and viscosity).

Sensitivity analyses of rheological parameters, input parameters for hydrological studies, downstream topographic surveys, and primitive topography are desirable to understand how a given material will propagate in the downstream valley. In this sense, it is recommended that the designer carry out preliminary modeling to understand the impact of variations in VCs and rheological parameters on the propagation of the rupture wave through the downstream valley. This will contribute to selecting the most critical scenario, as long as it is credible.

Downstream valley investigations are also essential. They should comprise at least the following:

- Precision mapping/topography of the downstream valley.
- Land use and occupation.
- Inventory of the main structures, urban equipment, and population downstream (industrial structures, public equipment, areas of environmental and cultural interest, among others).
- Inventory of structures that can exert hydraulic or synergistic controls with the breaking wave (e.g., dams, tailings piles, bridges, embankments, among others).
- Bathymetry of the downstream valley when there is a watercourse in the region.

Such information should guide the refinement of the simulation model to adequately represent flooding in the regions of interest.

The topographic survey in the valley downstream of the dam must be updated and carried out with adequate precision, preferably with contour lines at a minimum of every meter. For regions with human occupation, very flat topography or other singularities require greater accuracy. It is recommended that bathymetric sections along the downstream river valley be surveyed, ensuring more significant detail in the river channel and a better representation of the geometry in the modeling. It is worth mentioning that the treatment of the topographic survey for the elaboration of the digital terrain model (DTM) is of paramount importance for the study, because hydrodynamic modeling is sensitive to inconsistent or low-resolution topographic data, and the use of inadequate DTMs may generate incoherent and unrealistic results. All topographic surveys must be accompanied by technical reports with information about the applied methodology, topographic landmarks, auxiliary control points, cartographic projection systems, software, and models used to process the geographic product.

Figure 1 presents an example of the importance of data quality. The first image shows a low-resolution digital surface model, while the second image represents the same location with a high-resolution digital terrain survey, adequately processed and with integrated bathymetry.

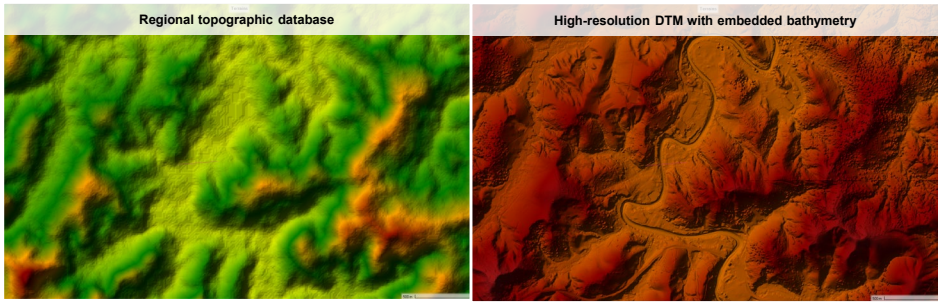

Figure 1: Difference in the quality between DSM and DTM

Evaluated scenarios

The HDBS should evaluate different simulation scenarios, adopting different hypotheses of rupture or extreme conditions. The scenarios evaluated should include at least the following items:

Scenarios without dam break: these must be developed to evaluate the impacts of natural floods in the downstream valley without the influence of the rupture wave, considering different return times:

- Ordinary natural flood: natural floods in the downstream valley can completely fill smaller beds (e.g., floods associated with a 2-year return period).
- Severe natural flood: natural floods in the downstream valley with an extreme return period (e.g., a flood with a 100-year return period, which is the flood assessed for flood insurance in the U.S. and tracked by the Federal Emergency Management Agency – FEMA). For large drainage areas, the flood attenuation of the downstream valley reference can be assessed along the propagation of the rupture wave.

Scenarios with dam break: Two rupture scenarios must be minimally modeled, each of them being associated with one hydrological condition of the downstream valley:

- Dam break – fair weather: rupture scenario associated with ordinary natural flooding in the downstream valley and the reservoir's water level at the spillway threshold.
- Dam break – rainy day: rupture scenario associated with severe natural flooding in the downstream valley and the water level in the reservoir being at least at the maximum maximorum or at the dam crest. These levels should be determined in the reservoir flood study. The reservoir flooding analyses utilized to develop the scenario must be fully documented and presented.

Additional scenarios: for some structures, additional scenarios can be evaluated, such as:

- For reservoirs with multiple embankments, rupture scenarios must be developed for all dams that could be mobilized in a rupture event.

- For structures with upstream tailings piles, synergistic failure scenarios between the dam and pile should be evaluated.
- For structures with long dam crests, different locations for breaches should be evaluated, defining a maximum potential envelope of the impact area around the structure.

Failure modes and rupture hydrograph

The failure mode adopted as a reference should be credible and represent the worst-case scenario, regardless of its probability, as mentioned in ANM Resolution 95/2022. In this context, a sensitivity analysis must be conducted when there are two or more credible failure modes. The sensitivity analysis results must be presented in the study (e.g., compare the rupture hydrographs of the credible modes). Various failure modes can be assessed, including but not limited to overtopping, internal erosion, and collapse (liquefaction, instability, tipping, sliding), among others.

The breach parameters of a rupture are intrinsic to the failure mode adopted. In traditional rupture scenarios such as overtopping and internal erosion in earth dams, the breach parameters determine the peak flow and duration time. This type of hydrograph has classic characteristics of rise, peak, and bust. Conversely, instantaneous ruptures such as liquefaction and destabilization result in hydrographs characterized by an extremely high peak, immediate onset, short duration, and rapid recession. Hydrographs with high peaks often lead to more severe flooding, even when the same volume is mobilized across all rupture scenarios.

The elaboration of the rupture hydrograph for cases of overtopping and internal erosion is usually done with parametric models, which are based on real dam failures and are elaborated by means of mathematical regressions adjusted to the geometric and hydraulic parameters measured during and after the opening of the breach. The most established parametric models for dams are Froehlich (1995), MacDonald and Langridge-Monopolis (1984), Von Thun and Gillette (1990), and Xu and Zhang (2009). The hydrograph developed in these models is based on data such as reservoir volume and dam height.

Conversely, instantaneous breach formations, such as liquefaction, are more accurately defined using hydraulic modeling software. This is because they depend on the immediate topographic features of the valley downstream of the structure.

As an example of the behavior of different hydrographs, Figure 2 illustrates three distinct types: overtopping, internal erosion, and liquefaction/instability hydrographs. It is observed that overtopping and internal erosion hydrographs have similar shapes, while the liquefaction/instability hydrograph exhibits markedly different characteristics from the others. It is important to highlight that although overtopping and internal erosion (piping) hydrographs have similar shapes and peaks, the different failure modes

significantly influence the wave arrival time. This occurs because the development of the hydrograph can accelerate the occurrence of the peak, resulting in a shorter arrival time.

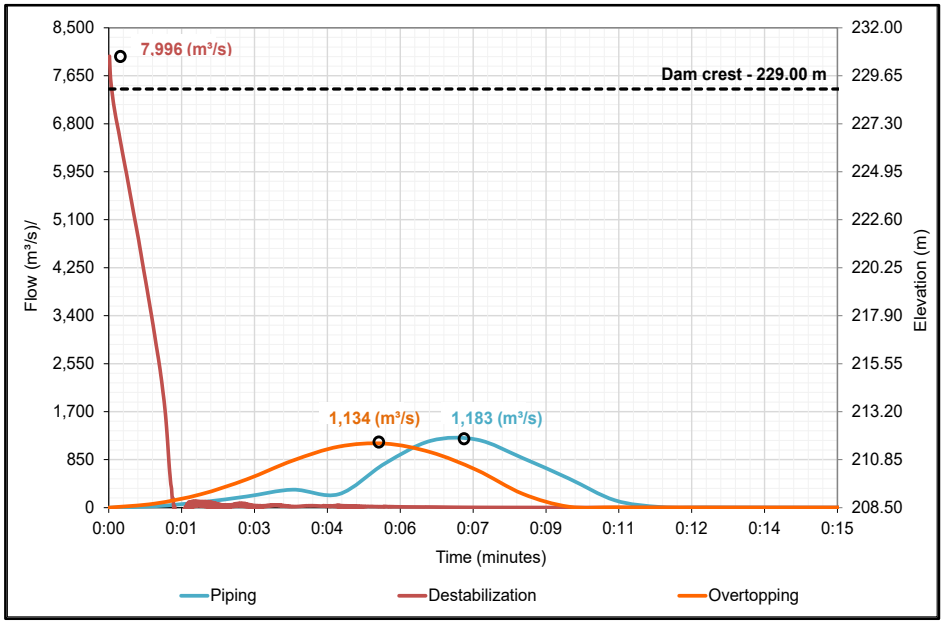

Figure 2: Comparison of rupture hydrographs from different failure modes

Potential mobilized volume

The justification for the mobilized volume should be based on physical and credible processes, aiming to adopt the largest possible mobilized volume. The volume can be defined through geotechnical and rheological parameters of the deposited material (when there are reserved solids). The mobilized volume must be divided into at least three components: volume of water, volume of mobilized solids in the reservoir, and volume of the rupture breach. It is common practice to define the mobilized portions as 100% of the volume of water in the reservoir and the breach. However, the solids portion of the reservoir can vary depending on the rigor of the designer, with the residual angle of repose of the material disposed in the reservoir often being used as a reference. Some of these good practices are further explored in the guidelines prepared by Vale in 2020. The figure presents a summary of the proportions of the potential volume mobilized.

Flood wave propagation

The propagation of the rupture wave must be carried out using at least two-dimensional hydraulic modeling software. Structures in which mobilized volume composition generates hyperconcentrated flows must be modeled in software with non-Newtonian flow modules. Cases in which the rupture wave initially presents a hyperconcentrated flow may present a dilution of the solid contents and a consequent change in the flow parameters. This possibility considers the transport of water transport by natural floods and/or other

downstream flow interferences.

Synergy between structures/dams/piles

Resolutions 32/2020 and 95/2022 of the National Mining Agency (ANM) stipulate that the entrepreneur must evaluate synergistic rupture scenarios if dams are identified in the downstream stretch. However, these regulations do not consider the synergistic effects with other structures, such as stacking and other structures located upstream of the reservoir. It is important to highlight that the synergy between structures can be triggered by factors such as the direct impact of the rupture wave, and earthquakes resulting from an initial rupture, among others. Figure 3 illustrates some possible scenarios where different structures may present synergistic rupture effects with the evaluated structure.

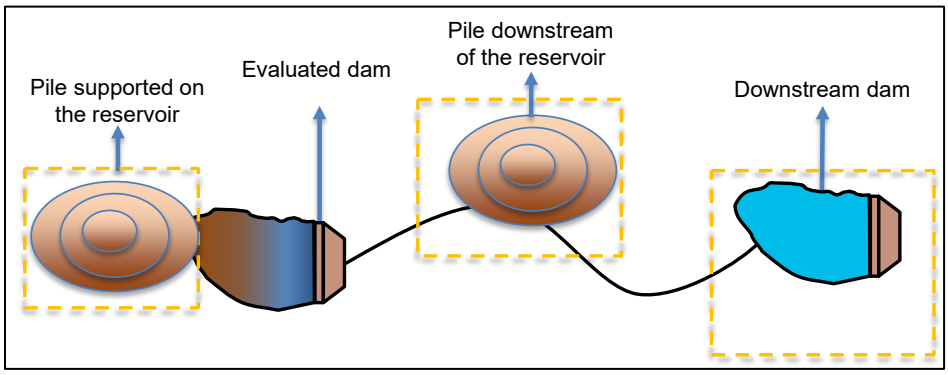

Figure 3: Examples of configurations that may result in synergistic effects

Examples of configurations that may result in synergistic effects include:

- A pile supported by the dam reservoir;
- A pile downstream of the reservoir; and
- a downstream dam.

Synergistic scenarios should be evaluated when structures (upstream or downstream) can be mobilized due to dam failure.

When a reservoir is identified in the wave propagation section, the passage of the rupture wave through the structure (dam) must be detailed to show whether the rupture wave causes elevation above safety levels, such as the crest of the downstream structure, and thus consequent synergistic effect (cascade disruption). For more representative results, it is recommended to evaluate the stability of the downstream structure even in the case of non-overtopping, as well as to perform calibration/sensitivity of the flow under natural conditions in the downstream valley.

Minimal results

The results to be extracted from the model must be represented in maps and tables containing the hydraulic

parameters by cross-sections, as also mentioned in Brazilian regulations, such as ANM Resolution 95/2022. The maps to be prepared must include, but are not limited to:

- Maps resulting from the hydrodynamic model: inundation boundary, maximum depth, and velocity; arrival time of the rupture wave; hydrodynamic risk/ flood hazard.
- The segmentation of the Self-Rescue Zone and the Secondary Rescue Zone: It should be noted that this map is extremely important, as the Self-Rescue Zone is characterized as the region of the valley downstream of the dam in which it is considered that warning notices to the population are the responsibility of the entrepreneur, as there is not enough time for an intervention of competent authorities in emergencies. In Brazil, the Self-Rescue Zone is defined as the greatest distance, 10 km or 30 minutes of propagation of the rupture wave.
- Registration of interferences along the floodplain.

The flow cross-sections complement the maps and must be drawn at an appropriate interval. Locations and elements at risk must have more sections, to guarantee more detailed information in sensitive areas. The cross-section results must be presented in hydrodynamic results tables for each scenario modeled in the rupture study. The minimum information to be presented for each section in the table is: riverbed elevation, maximum depths, and velocities reached for the natural situation and for the situation after rupture, maximum flow achieved, rupture wave arrival time, and rupture wave arrival time (peak). It is worth mentioning that FEAM (2021) and ANM (2023 and 2024b) published a term of reference and resolution and manual, respectively, for the presentation of the results and maps of flood studies.

Termination point of incremental hazard evaluation

The hypothetical rupture study must explain how the termination point of incremental hazard evaluation was defined. That point defines where the increase in downstream water surface elevation, caused by the breach, is not sufficient to cause incremental damage. As a reference, we can evaluate the point where the elevation caused by the rupture wave does not exceed the limit of the gutter and/or natural flood plain and presents velocities and flows close to those of the natural flood, where there is a concentration of buildings or infrastructures or larger rivers, among others.

It is relevant to mention that the Federal Emergency Management Agency (FEMA, 2013) establishes the stopping criterion for the assessment of incremental floods at the point where a 2-foot (0.61 m) rise above the natural flood level is no longer identified. However, a thorough evaluation by the designer is crucial, as a 2-foot (0.61 m) rise can be significant in very flat regions, where even small depths can result in a considerable increase in impact. Conversely, in incised channels, a 2-foot rise can substantially hinder the propagation of the rupture, as it may not result in significant incremental damage.

Conclusion

The objective of this paper was to comment on minimum standards of technical rigor for hypothetical dam break studies according to Brazilian standards and legislation, in addition to the experience in the analysis of more than 220 hypothetical dam break studies conducted by AECOM. It is worth mentioning that the study in question is highly dependent on the available data, the technical knowledge of all the professionals involved, and interdisciplinary interaction. This knowledge makes it possible to establish the most representative and credible failure modes and volumes to be mobilized. It was also important to know the downstream valley through detailed topobathymetric surveys, mapping structures that can exert hydraulic and/or synergistic controls, and determining hydrological conditions in the downstream valley. In addition, appropriate software and calculation methods will allow the entire information framework to be used for solid results, which will be more representative of an eventual rupture, and therefore adequate for the creation of emergency action plans.

However, studies on hypothetical rupture still have a long way to go for improvement. Items to be further refined in the future include:

- More accurate characterization of Self-Rescue Zone and Secondary Rescue Zone.
- Use of robust (3D) computational models.
- Geotechnical aspects of Fault Modes.
- Accurate characterization of tailings rheology.
- Better characterization of hydrological scenarios.
- Relationship between Failure Modes and Deployable Volumes.
- Full characterization of the downstream section.

Good Practices for Hydraulic Safety for Mining Dams in Brazil

Fernando Pereira Aguilar, AECOM, Brazil
Manuelle Prado Cardoso Pereira, AECOM, Brazil
Vicente Mello, AECOM, Brazil

Abstract

This paper presents information and recommendations regarding hydrology and hydraulic issues related to mining dams, based on observations made during audits, as well as on technical safety consultancy work carried out for more than 220 dams throughout Brazil.

It is essential to consider the hydrological routine and hydraulic checks for mining structures, especially tailings dams, in an environment of climate change, in which extreme events of greater magnitude and frequency of occurrence are expected. Insufficient overflow capacity of spillways and decants, inappropriate freeboard, or inefficient surface drainage systems are deficiencies frequently observed in mining structures.

Introduction

Recently, two catastrophes have occurred involving tailings dam ruptures in Brazil: in 2015, the Fundão Dam failures in Mariana City, and in 2019, the B-I Dam failures in Brumadinho City, both in Minas Gerais. These two events caused loss of human life and severe socio-environmental impacts on nearby communities, thus demanding an increase in risk management and dam safety in Brazil and in local legislation and regulations. Despite these occurrences not being caused by failures in hydraulic structures, this aspect is also crucial to ensure the safety of dams against extreme flood events and thus prevent further catastrophic failures.

Brazilian normative and regulatory institutions are evolving in their guidelines and requirements to enhance the hydraulic safety of dams. Despite this progress, there are still gaps in the available standards and regulations. Moreover, the standards merely guide the development of studies and projects, necessitating that the designer uses established methodologies and adopts best technical practices for secure evaluation of the structures. For instance, the available standards indicate return periods associated with risks to be met in the design of hydraulic structures of a dam. However, they do not specify the

methodologies to be adopted in developing studies and the precautions necessary to mitigate risks to people, infrastructure, and the environment.

Furthermore, it is essential to emphasize that nowadays, climate change is increasingly an issue, as extreme events with greater magnitude and frequency are observed, requiring additional care in the assessments of the performances of hydraulic structures, as it is understood that legislations and standards do not always allow for these changes. Thus, there is a growing need for routines to update hydrological studies and hydraulic verifications in mining structures, especially in tailings dams that exhibit dynamic behavior concerning their geometry and uses in their contributing watershed. Insufficient performance of spillways and inadequate freeboards for the dam and other hydraulic structures, including surface drainage systems, are deficiencies frequently observed in mining structures. This paper presents information and recommendations regarding hydrology and hydraulics issues related to mining dams based on observations during audits and technical safety consultancy work carried out by AECOM at more than 220 dams throughout the Brazilian territory.

Discussion

Study of intense rainfall

The study of intense rainfall is one of the inputs in analyzing reservoir flooding, in addition to helping to verify surface drainage structures. As a good practice for studies of intense rainfall, it is important to evaluate rainfall stations located close to the studied structure. The selected stations must represent the hydrological behavior of the study region, being able to assess variables such as distance from the structure, altitude, relief, and extension of the historical series, among others.

Intense rainfall studies include the definition of the hydrological season, a complete annual maximum rainfall historical series, a graph with the various adjustments of probability distributions, statistics from probabilistic adherence tests, trend analysis, and a table with rainfall quantiles for different duration times and recurrence intervals. Essential information and evaluations are expected for each aspect presented, as indicated below.

Historical series: a daily historical series is recommended, with a minimum of 20 years corresponding to the most recent period possible. Data consistency analyses and assessment of possible outliers must be presented.

Adjustments to probability distributions: this consists of plotting the historical data observed in the Weibull distribution using more common methods, such as Gumbel, Gamma, GEV, Log-Normal, Exponential, Pearson III, and Log-Pearson III, enabling visualization of the adherence of each statistical curve to the sample used. It is usual to present adherence tests demonstrating deviations from the studied probabilistic distributions, but not limited to these, since the visual analysis of trends translates into an

important criterion for choosing the statistical distribution depending on the sample data, especially for the curve extrapolation region. Figure 1 presents an example of how to display the probabilistic distribution fitting of the rainfall study.

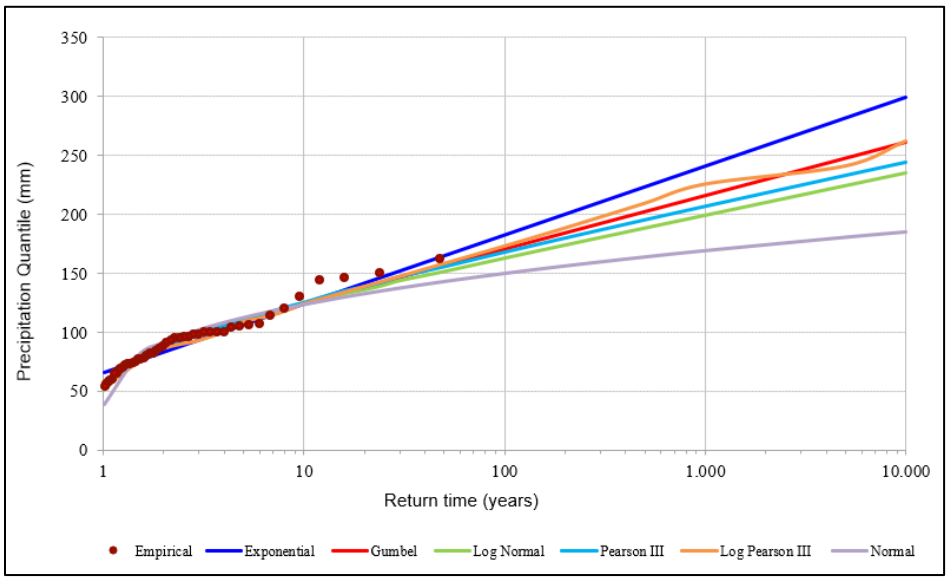

Figure 1: An example of adjustments to probability distributions

Disaggregation of rainfall quantiles: generally, rainfall data comes from daily information obtained from rain gauges, requiring the conversion of daily quantiles into 24-hour quantiles and disaggregation for shorter durations. Among the available disaggregation methodologies we can highlight, for Brazilian conditions, the isozone method presented by Taborga Torrico (1974), the technical note by Silveira (2000), the CETESB Project Manual (1980), or intensity-duration-frequency curves developed for a specific station or nearby and representative stations.

Probable Maximum Precipitation (PMP): hydraulic verification of a dam for the occurrence of a PMP, which represents the maximum rain event physically possible to occur in a given region, can be requested for structures that present high Associated Potential Damage or for decharacterization and closure projects. There are two classic methods for calculating the PMP of a region: the deterministic or meteorological method, and the statistical method. Consistent hydrometeorological data must be used to apply the deterministic method. The statistical method is based on rainfall data series, which must also be properly constituted. The most recognized statistical methodology is recommended by the World Meteorological Organization (WMO, 2009), for which parameters were developed for North American regions. However, several studies in Brazil suggest that calculating the maximization factor using data from rainfall stations in the area of interest would be more representative. The PMP study, however, reflects a

regional characteristic; therefore, it is recommended that a careful analysis be carried out to select stations that reflect the regional meteorological condition.

Reservoirs flooding

The reservoir flooding analysis is one of the main products of the safety analysis of a dam in the face of extreme floods, which consists of defining the greatest surface elevation that will be reached inside the reservoir, associated with the most significant outflow. This study is based on the classic modified Puls method (Butler, 1957), which consists of a balance of inflow and outflow. The main inputs of this study are inflow, storage volume, and the downstream hydraulic control, which define the outflow.

The inflow can be obtained using two approaches, direct or indirect, that should be applied depending on data availability. The direct method allows the calculation of flows through direct measurements of the variable of interest. The indirect method consists of obtaining flow through formulations with correlated variables, such as converting rainfall into flow.

Mining dams are generally found at the headwaters of watersheds, where, in general, there are gaps in flow monitoring. So, indirect methods are used to define the influent flow. The main methods currently used are the NRCS (Natural Resource Soil Conservation Service) method and the Rational method, which is recommended for basins smaller than one km².

To apply the NRCS method, it is necessary to characterize and define the drainage area, time of concentration, land use and occupation, and curve number, among others. The main aspects that must be observed when defining these parameters are described below.

Drainage area: to delimit the drainage area, it is essential to use an updated cartographic base with adequate precision, which also allows extraction of information about its physical characteristics, such as axial length, maximum difference in level, and equivalent average slope, among others. It is recommended that the limits of the drainage area be presented, preferably with contour lines. Based on the physical characteristics of the contribution area, the need for subdivision of the drainage areas must be assessed. In the case of anthropic areas, the direction of the flow and surface drainage infrastructure that can alter the contributions to the reservoir must be carefully evaluated. In these cases, it is important to carry out a detailed local topographic survey in addition to providing a registry of hydraulic infrastructure.

Time of concentration: The methods most used to calculate the time of concentration, which represents the watershed's response time, are the Kirpich method, the G.B. Williams method, and the kinematic method (Pinheiro, 2011). Silveira (2005) also presents numerous methods for calculating the time of concentration in urban and rural basins. It is recommended to evaluate the empirical conditions considered for the development of each methodology and look for appropriate similarities with the case under study.

Curve Number (CN): This is the index of the NRCS method for generating an effective hyetograph from total precipitation, depending on land use and occupation, soil hydrological group (related to soil typology), and antecedent humidity. This index provides great sensitivity to calculations regarding its variation. In the literature, there are tables that present these relationships, as presented by Tucci (2015) and Chow et al. (1988). Figure 2 is an example of a map of land use and occupation.

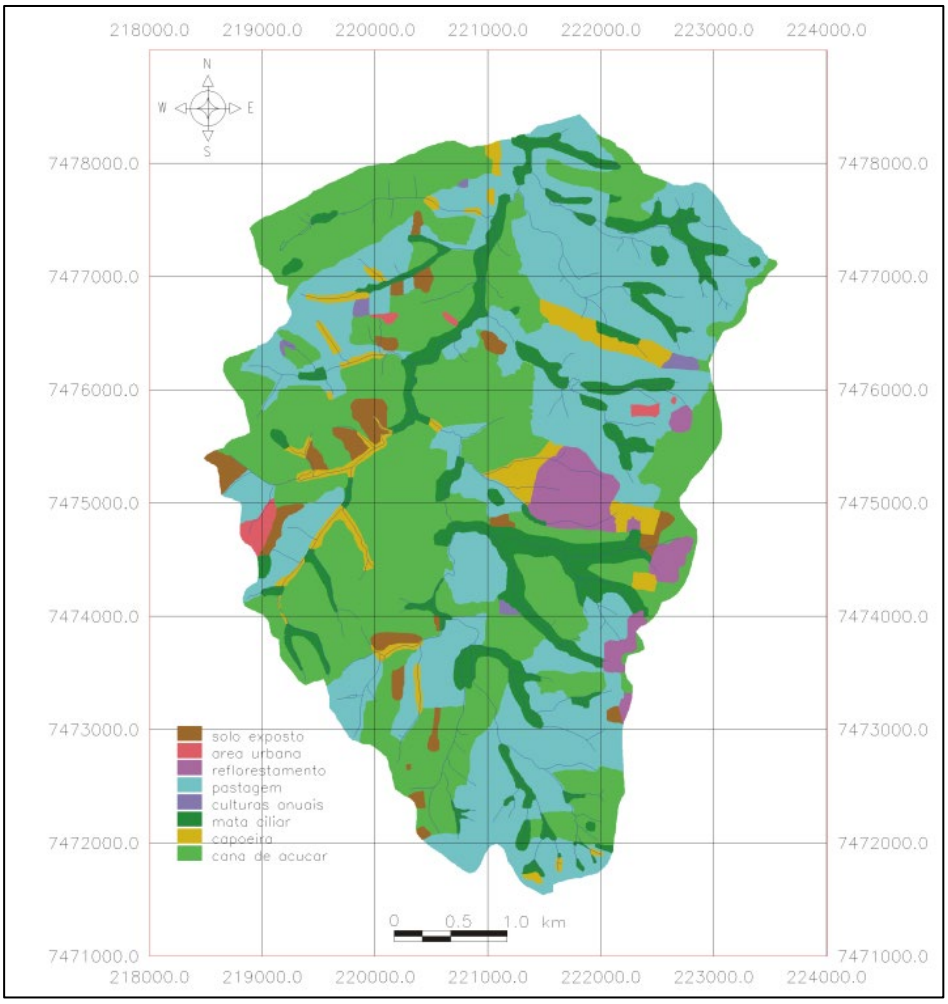

Figure 2: Map of land use and occupation of micro basin hydrographic Ribeirão dos Marins (source: Sartori, 2004)

Hydrologic soil group: Once the types of soil present in the drainage area have been identified, the respective hydrological groups must be associated. To justify the choice of groups, it is recommended to base it on established bibliographical references such as the studies by Sartori (2004 and 2010). For areas affected by anthropogenic activity, where the soil revealed on the surface does not present its natural condition (e.g., tailings pile and pit), it is important to note that the reference mapping may not reflect the current condition for the potential for infiltration and runoff generation. Therefore, the classification of the

soil hydrological group must take the altered condition into account. Figure 3 is an example of a map with different soil classifications.

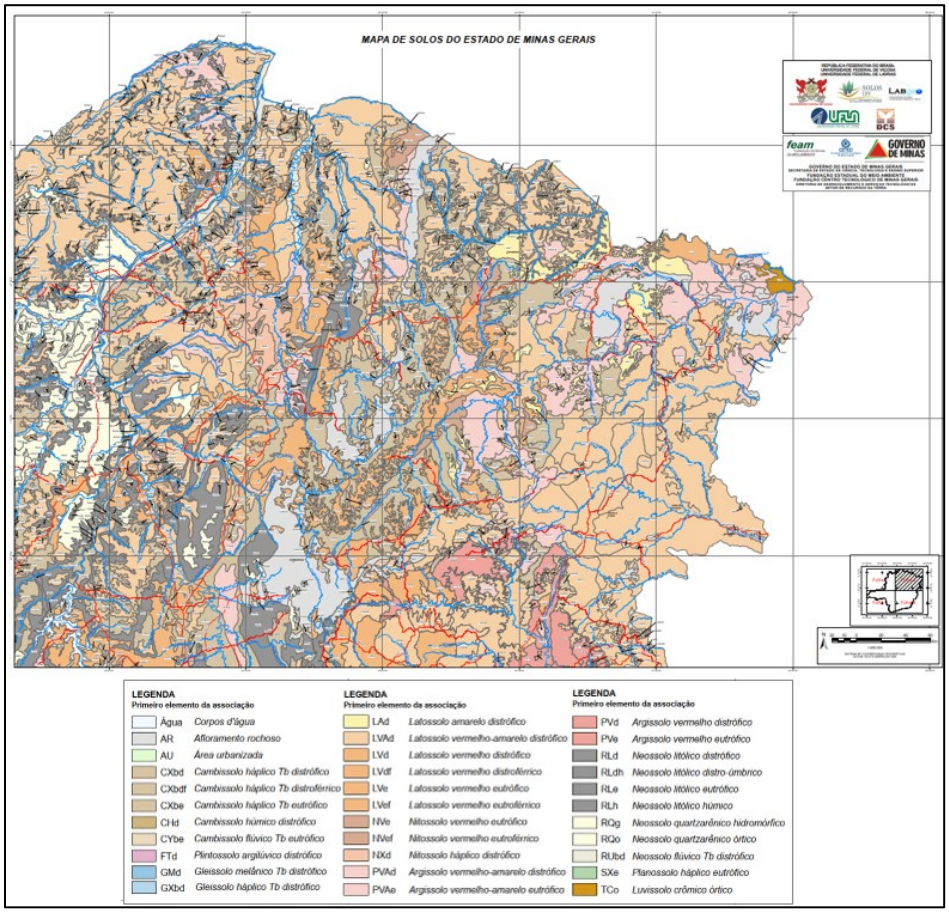

Figure 3: Soil classification of part of the state of Minas Gerais, Brazil
(Source: Universidade Federal de Viçosa; Fundação Centro Tecnológico de Minas Gerais; Universidade Federal de Lavras; Fundação Estadual do Meio Ambiente, 2010)

Calibration and hydrological modeling

As recommended by the National Mining Agency (ANM) Resolution 95 of February 7, 2022, Art. 24 § 5, *"the mining company must calibrate the data from the basins and sub-basins of his dam with data obtained from instruments with sufficient time for calibration aiming at adequate dimensioning of the spillways with real data, comprising 2 (two) hydrological cycles with significant maximum events."*

The mining company must prepare a monitoring plan to monitor and calibrate flow data to meet this requirement. There are several ways to carry out this monitoring, and it is recommended to use precision measuring instruments to measure and store data on rainfall, flow, and water levels in reservoirs for short durations (intervals of 5 minutes or less).

From the data acquired, precipitation events can be related to the study of intense rainfall for the region and, consequently, to assess the measured flows so that the adopted hydrological parameters can be calibrated. Such as:

- time of concentration;
- curve number;
- initial abstraction;
- etc.

Field information must be acquired and must be carried out together office work, such as geological mapping.

Minimum freeboard in reservoirs

The concept of freeboard is the space allocated between the maximum flood level and the crest elevation of the embankment, with the purpose of absorbing the effects of waves formed by winds or adding additional security for possible settlement of the crest.

The most used methodology for determining the required freeboard to accommodate wind-generated waves was formulated by Saville et al. (1962) by determining the fetch (extent of the surface over which the wind is present).

The U.S. Bureau of Reclamation, Design of Small Dams – USBR (1987) recommends adopting the value of 1 meter as the minimum freeboard above the maximum flood level. Resolution 95/2022, issued by the National Mining Agency – AN M, stipulates a minimum freeboard of 1 meter for dams with downstream populations. Figure 4 presents a layout of the spillway with the recommended minimum freeboard.

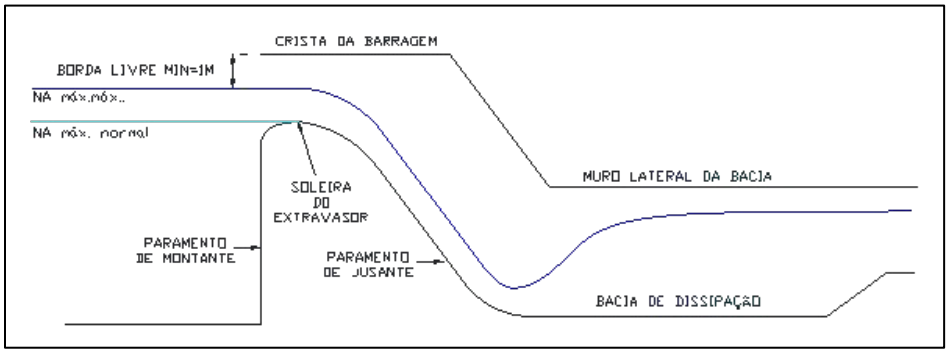

Figure 4: Layout of a spillway with minimum freeboard

Hydraulic check of the spillway system

The hydraulic verification of the overflow system must be based on a topographic survey of the structure with the presentation of plans, profiles, and sections that demonstrate the As Built geometry. Information

on all the relevant sections, such as the inlet, gallery, steps, smooth channel, stilling basin, and restitution channel must be presented.

From the characterization of the spillway, it is possible to evaluate the most appropriate methods for defining the relations between quota and discharge. Currently, it has been usual to obtain discharge curves by hydraulic modeling using established software such as HEC-RAS (Hydrologic Engineering Center – River Analysis System). For this analysis, it is important to identify all hydraulic control points along the spillway.

It is essential to develop hydraulic simulations to show the flow restriction conditions of the structures. In open-pit structures, software for one-dimensional modeling can be used to simulate the worst performance of the overflow system, such as the silting conditions of the approach channel. For structures with culverts or galleries, it is usual to present their elevation discharge curves to identify hydraulic controls and generate the most restrictive curve. Finally, for more complex structures, two-dimensional, three-dimensional, and physical model studies can be used to obtain more representative curves and understand the limits of the structure.

It is necessary to carry out the hydraulic verification of the entire spillway system for the design flow defined in the flood transit studies, with results presented through tables and graphs, as well as the waterline profile and velocities along the structure. Tables should include different sections of the structure, such as transitions, curved sections, steps, culverts, transition boxes, smooth channels, dissipation basin, and restitution channel, with variables such as maximum speed, flow depth, free edge, and Froude number, among other information.

Stilling basins and restitution channels should be checked using appropriate methodologies according to their geometry, coating, etc. As a good practice for stilling basins and restitution channels in riprap, it is recommended to present the average diameter of the blocks (D50) to withstand the design floods. Finally, stilling basins must dissipate energy efficiently without causing degradation or disturbance in the restitution channel.

Hydraulic check of the surface drainage system

The hydraulic verification of the surface drainage systems of the structures is important for managing the dam's conservation state. This verification should follow the recommendations in the Brazilian Technical Standard – NBR 13.028/2017 (ABNT, 2017) – adopting a recurrence time of 100 years for small flow devices, such as berm channels, and 500 years for large flow devices, such as peripheral channels.

To characterize the surface drainage system, it is crucial to use the cadastral topographic survey of drainage devices to identify its layout, geometries, and coatings.

Surface drainage devices usually have small drainage areas, less than one km², so it is recommended to use the rational method for calculating flows, with the premise of adopting the intensity of the design rainfall with a duration equal to the time of concentration of the catchment.

The results should include all drainage devices, and may be in tabular format, with information such as geometry, dimensions, coating, time of concentration, maximum requested flow, maximum allowable flow, maximum velocities and depth, and freeboards at its various points.

It is noteworthy that there are dams with special drainage structures, such as belt channels, whose function is to reduce the contribution of tributary flows to the reservoir. Therefore, they are usually dimensioned for the return time equivalent to that adopted in the reservoir flooding analysis. It is important to carry out reservoir flooding studies, disregarding the presence of these channels, since they may present operational failures/obstructions throughout the useful life of the dam.

Conclusion

Considering the current scenario of climate change to which tailings dams are subjected, in which increasing and frequent extreme weather events are possible, the evaluation of the hydrological and hydraulic safety of tailings containment structures requires frequent checks to evaluate aspects such as freeboards of dams/reservoirs, capacity of hydraulic structures (overflow and surface drainage systems), as well as adequate restitution of flows before discharge to the receiving water body.

The frequent assessment of the structure's hydrological and hydraulic safety will allow for the timely introduction of corrective measures, ensuring the safety of the facilities and affected communities and increasing the resilience of the structures in the face of extreme weather events.

TAILINGS AND
MINE WASTE 2024

Agnico Eagle LaRonde Filtered Tailings Project, Concept to Commissioning

Ajit Baruah, Metso Canada Inc., Canada
Paul de la Duarantaye, Metso Canada Inc., Canada

Abstract

Agnico Eagle Mine (AEM) Limited is a senior Canadian gold mining company, producing precious metals from operations in Canada, Australia, Finland, and Mexico. In 2018, to make their operations more sustainable at LaRonde concentrator in Quebec, Canada, AEM decided to review its tailings management system with alternate tailing storage methods including thickened, paste and filtered tailings. As the existing tailings storage facility was reaching its capacity limit, it was imperative for AEM to move ahead with an alternate tailings storage system in order to keep the operation going. After review and a detailed study of various options of dry stacked filtered tailings, a system was evaluated as the best feasible option to enhance the tailing storage facility's (TSF's) life and to transition towards a more sustainable solution for tailings management.

This paper presents the storyline of the AEM filtered tailings project, from concept to successful commissioning stage. The tailings filter plant was designed for a rated capacity of 10,000 tpd of tailings generated from both the LaRonde and the LZ5 operations, with different mineralogical characteristics. The project began with laboratory testing through an independent testing agency, followed by confirmatory filtration testwork by Metso, the original equipment manufacturer (OEM) eventually selected as the preferred supplier for the filtration technology. The filtration plant was commissioned in October 2022 with AEM's special attention to integrating state of the art control systems to ensure maximum operational efficiency. The filter plant has been running satisfactorily for the last nine months, meeting the required performance parameters.

Introduction

In 2019 a bidding process was started and RFQs were issued to reputable equipment suppliers for dewatering equipment including thickener, pressure filters, and other auxiliaries for the proposed filter plant to handle 10,000 tonnes per day of tailings with a cake moisture target of 16%. Patterson and Cooke, the third-party consulting company involved in the early phase of the project, was responsible for the collection of various samples and for completing the review process with multiple dewatering equipment suppliers.

Individual original equipment manufacturers (OEMs) conducted confirmatory testwork in support of offering dewatering solutions, including thickeners and filters. After carefully reviewing the test results and being offered solutions by individual OEMs for filtration systems including thickening and filtration, Metso was selected as the successful bidder. The selection was made primarily based on the following criteria.

- Ability to meet the targeted cake moisture and capacity.
- Flexibility of equipment operation for feed with multiple characteristics.
- Optimized quantity of filters considering the significant impact on the overall filtration building size and cost.
- Maintenance requirements and operating costs.
- Expandability features for future increases in capacity.
- Ability to integrate AEM's preferred control system (Mine 4.0) with the OEM supplied equipment control.
- Proven references with AEM and other operators for similar operations.

Filtration testwork

In October 2019, Metso conducted dewatering testwork for thickening and filtration to review and optimize the equipment selection and to provide necessary the process guarantee. As the tailings to be fed to the filtration plant would be reporting from two different concentrators, namely LaRonde and LZ5, with significantly different characteristics, testwork was conducted with various blend ratios, as listed below.

Table 1: Material properties for the filtration testwork

Blend ratio	SG	P80	% Solid
LaRonde/LZ5		(µm)	(%w/w)
75/25	1.688	74	60.0%
50/50	1.697	56	60.0%
0/100	1.648	30	58.5%

Figure 1: Labox 100 test unit

A Metso proprietary pressure filtration test equipment, Labox100, with a 0.02m^2 filtration area, was used to conduct pressure filtration tests for various blends of samples. Some findings from the pressure filtration testwork are listed below.

Table 2: Summary of filtration testwork results

Blend	Unit	Sample 1		Sample 2		Sample 3	
(Laronde/LZ5)		75/25		50/50		0/100	
Feed % Solid	%w/w	60.2	60.2	61.1	61.1	58.3	58.3
Feed Pressure	Bar	7	7	7	7	7	7
Pres. Pressure	Bar	12	12	12	12	12	12
Chamber depth	mm	45	45	45	45	45	45
Cycle time	min	8.25	8.25	8.75	8.25	10.5	8.5
Cake moisture	%w/w	12.99	12.84	13.87	14.52	17.2	16.8
Filtration rate	KgDS/m^2/hr	278.4	254.0	245.1	261.1	191.7	232

The following conclusions were reached after the completion of the filtration test work.

- Cake thickness of ~+40 mm cake thickness was achieved using a 45 mm chamber.
- 12 bar membrane squeezing pressure was required for effective membrane pressing.
- The impact of air drying was significant on the final cake moisture content, and could easily reduce the cake moisture by 6–7%.
- The LZ5 material was the most difficult material for filtration, and the final cake moisture achieved was ~17%.

Figure 2: Cake with and without air drying (Sample 1: 75/25 blend)

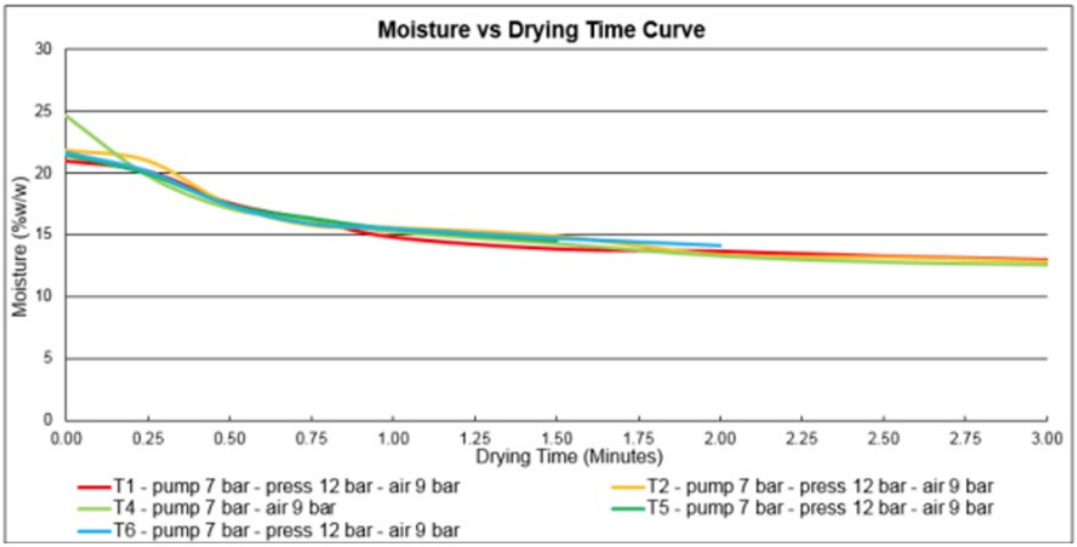

Figure 3: Sample 1: 75/25 Blend – effect of drying time on moisture

Filter sizing

After a detailed review of the filtration testwork runs and a careful review of the individual parameters, the production plant filter units were sized for the below mentioned process conditions.

Table 3: Process data

Design capacity	444 tph
Solid SG	3.06
Feed % solid	58.3% (%w/w)
Slurry density	1,645 g/l
pH	10.7
P80	56 µm
Cake moisture target 16.0%	

Table 4: Filter sizing parameters

Filling and filtration	3.0 min @ 7 bar
Pressing	0.5 min @12 bar
Cake air drying	1.5 min. @ 9 bar
Technical Time	4.5 min
Total cycle time	**8.5 min**
Estimated cake thickness for sizing	39 mm
Estimated solid fraction in cake	51% % vol/vol
Filtration rate for sizing	214 kg/m^2/hr
Calculated filtration area requirement	831 m^2

Selected filter

Metso Larox FFP3512 62/74 M45 3 units

Table 5: Technical specifications of each filter unit

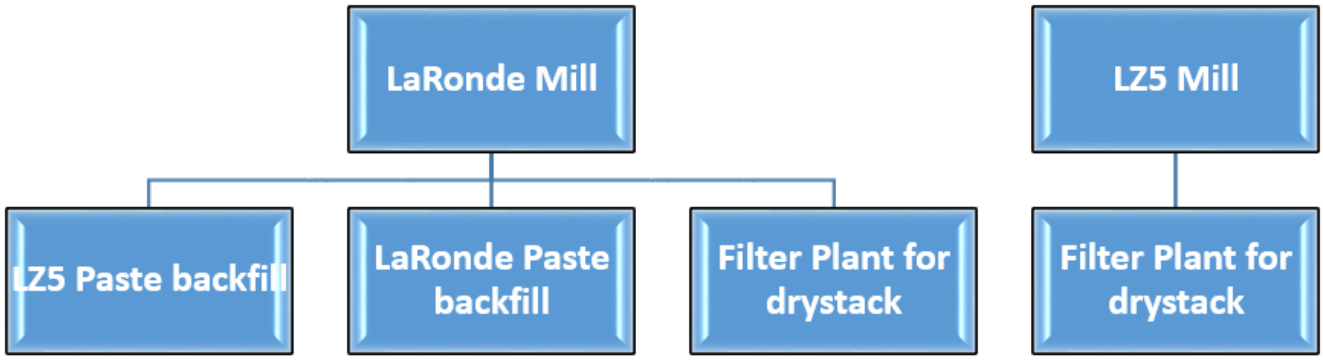
Filtration area per filter with 62 chambers	831 m^2
Filtration area per filter with expansion 74 chambers	992 m^2
Chamber thickness	45 mm
Total chamber volume with 62 chambers	16.7 m^3
Total chamber volume with 74 chambers	20.0 m^3
Total installed power per filter(only)	96 kW
Filter Plate size	3.5 m x 2.5 m

Project execution

Three units for Mesto FFP3512 62/74 M45 filters were selected for the final plant configuration based on various considerations for operating methodology, as well as different feed scenarios. A 36 m diameter High-Rate tailings thickener was installed alongside the filtration building to feed the filters at a desired solid concentration, as established by the testwork for optimum performance. The building layout was decided upon in light of the various maintenance requirements that would be critical with multiple units of large pressure filter units.

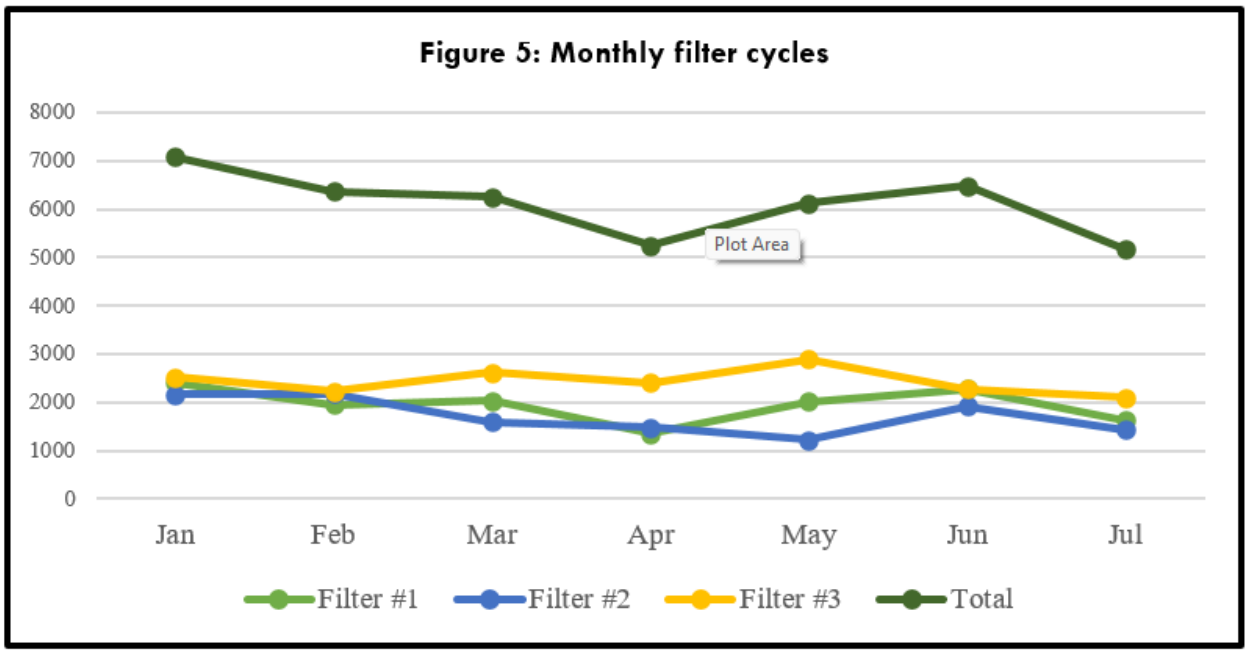
After careful consideration of the layout based on the selected filters and other associated equipment, engineering work started in January 2019. Cold commissioning began in June 2022 and full-scale production started in December 2022.

Figure 4: Metso 36 m high-rate tailings thickener and 3xFFP3512 62/74 M45 filter

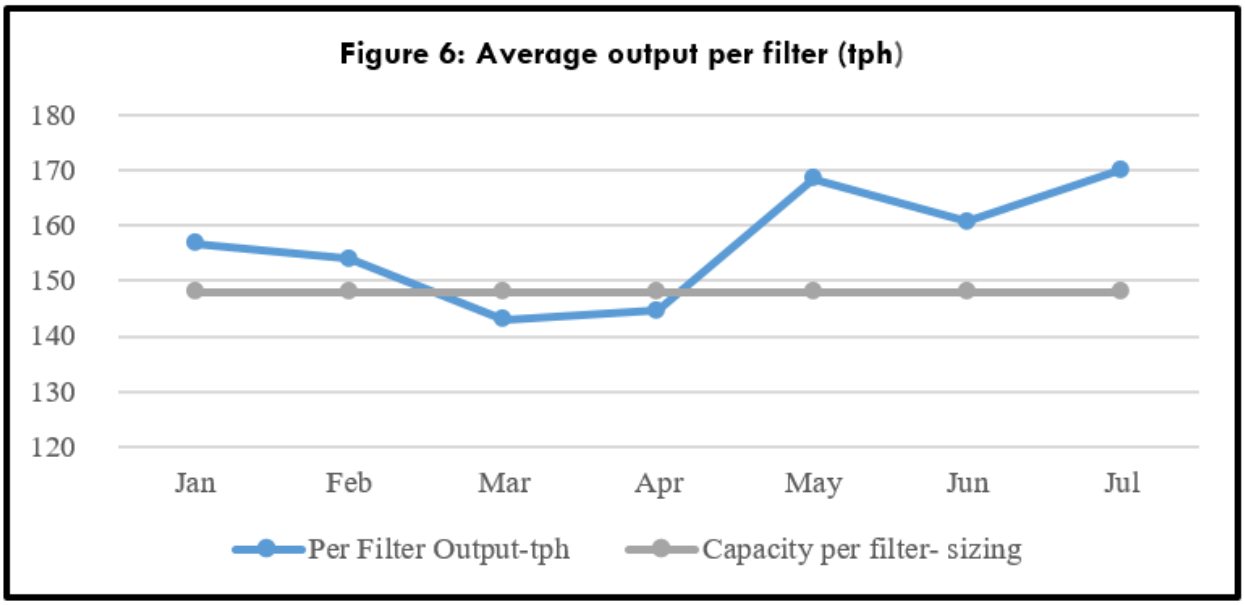


High level project milestones

High level project milestones are shown below.



Filter plant operation



The filter plant was commissioned in August 2022, and full-scale production started on December 2022. It was designed for 444 tph nominal throughput rate; however, depending on the demand of the paste backfill for underground operation, feed to the filter plant averaged at 202 tph for the period of January to July 2023.

To ensure maximum availability of the three filters, a unique operational methodology was implemented to operate only two filters at a time and evenly distribute the operating hours for the individual filters. Figure 5 indicates the total cycles operated with the individual filters on a monthly basis.

The throughput rates from each individual filter were consistent over the seven months of the reported period, consistently meeting or exceeding the design numbers, with some level of variability based on feed characteristics. Some of the operating data have been presented in the following figures.

The cycle times of the individual filters were consistent, ranging between 8.5 to 10 minutes versus the sizing basis of 8.5 minutes. However, cake moisture content was consistent. The change in cycle time was attributed to target moisture content and manual intervention to change the cycle time, depending on

whether LZ5 mill was operating or not. Since August 2023, the filter plant has been fed with a lower ratio of tailings from the LZ5 mill (as the LZ5 mill is not operating) and cycles time were in the range of 7 to 8 minutes during this period.

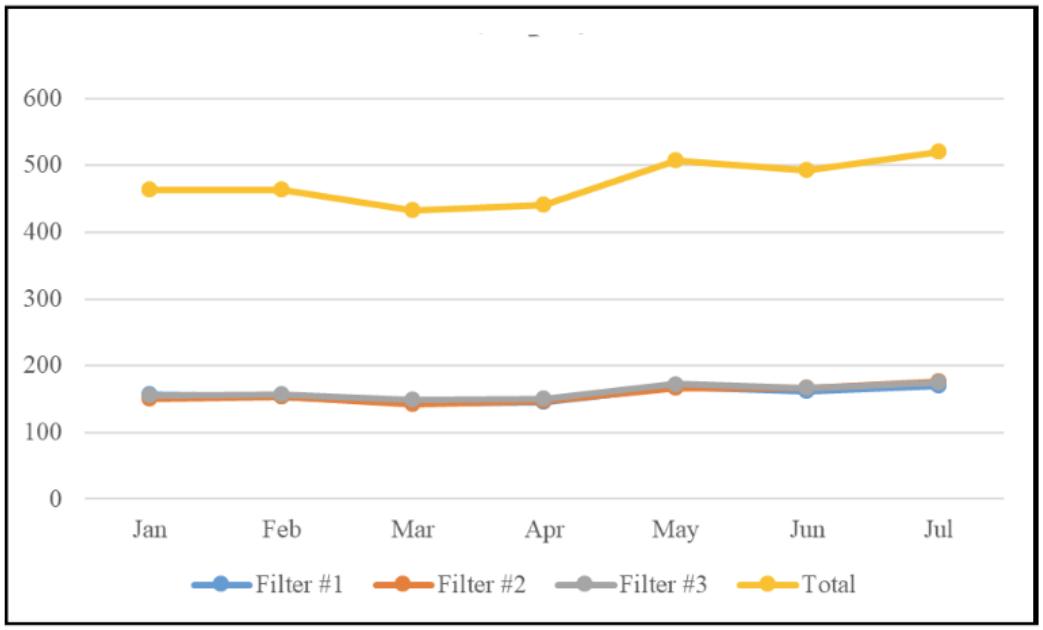


Figure 7: Individual filter production rate (tph)

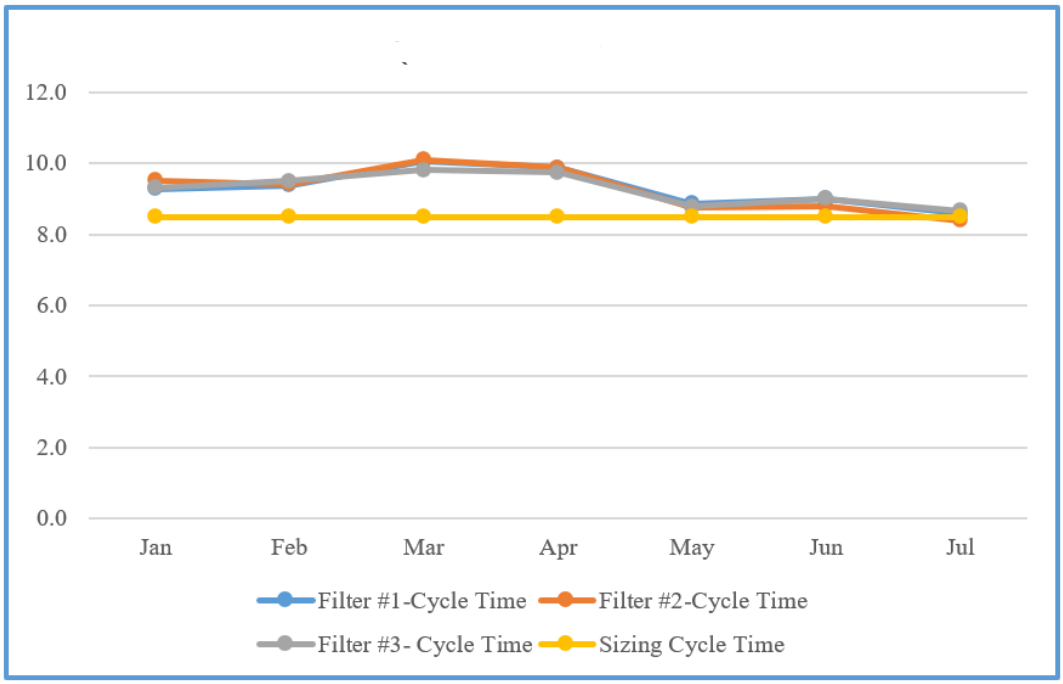

Figure 8: Cycle time

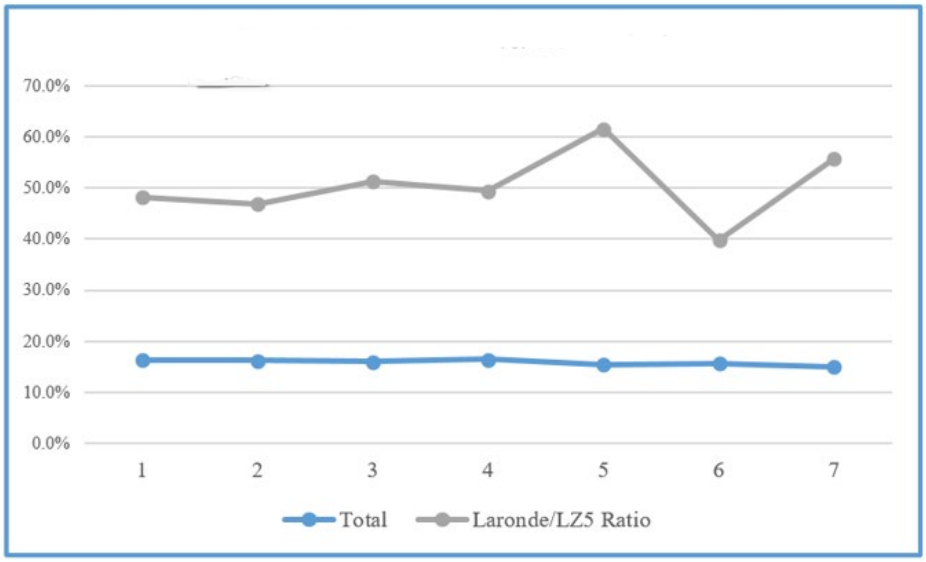

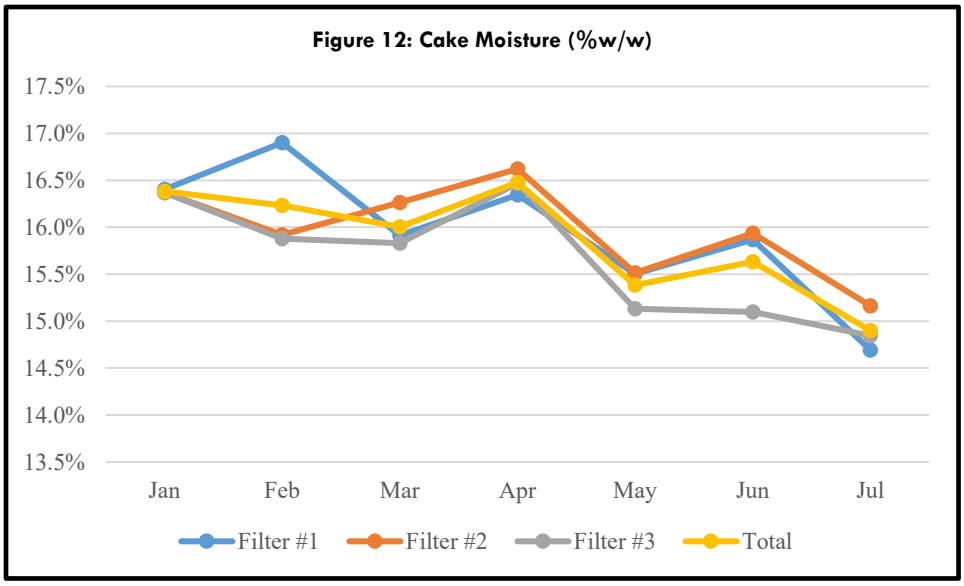

Figure 9: Cake moisture vs. ore blend ratio

Figure 10: Filtered tailings cake from discharge conveyor

Figure 11: Filtered tailings stockpile

Consumables

Cloth life is currently 4,300 cycles and no diaphragms or feed shoes have been replaced. The filter cloth being used currently is made with Polyamide material, a monofilament fabric with an air permeability specification of 140 l/dm^2/min @200Pa.

Conclusion

The LaRonde filtered tailings project has been operating since December 2022. The filter plant is consistently meeting the targeted process performance parameters. The success of this project has been attributed to the following:

- Significant work was done in the early phase of the project with an extensive amount of laboratory-scale test work to mitigate any process risks due to possible changes in ore characteristics.
- Emphasis was given to the proper selection of dewatering technologies and to developing a building design that would ensure seamless maintenance practices and the highest level of safety standards for its operators and maintenance crews.
- Existing Laronde concentrator personnel were transferred during the commissioning stage, in order to develop a clear understanding and knowledge of filter plant equipment and operations prior to start-up.

This project has been considered as a step forward to meet Agnico Eagle Mine's long-term sustainability targets.

The Closure of the Germano Pit Tailings Storage Facility

Mauricio Pinheiro, Stantec, USA
Richard Dawson, Stantec, Canada

Anelisa Vasconcelos, Samarco, Brazil

Abstract

Germano Pit (GP) is a decharacterized tailings storage facility located in an iron ore mined-out pit, about 25 km north of Mariana, Minas Gerais, Brazil. Operations started in 2000 and stopped in 2015 following the Fundão dam failure. Long-term plans to reestablish operations at GP were discontinued once the facility was reclassified as an upstream tailings structure by the regulator, and therefore became subject to decharacterization as per the regulatory requirements that came into effect in 2019. "Decharacterization" is a term coined by the Brazilian mining dam regulator to describe the process in which a facility is safely removed from operation and remediated to eliminate catastrophic failure and improve environmental performance. Decharacterization is thus the first step towards closure of upstream tailings facilities under the new regulations. Construction activities associated with the decharacterization of GP started in 2019 and were completed in June 2023. These activities involved construction of a reinforcement wasterock buttress and underdrains; regrading of the reservoir to eliminate ponding; and construction of a surface water management system to convey runoff flow away from the structure. As of January 2024, the State regulatory body endorsed the decharacterization of GP, the first upstream tailings facility to be decharacterized in Brazil. This paper shares some of the key aspects of the project, including Stantec's involvement as designer of record, engagement with technical auditors and other review bodies, and impacts of an evolving regulatory environment.

Introduction

The failures of Fundão and B1 tailings storage facilities (TSFs) changed the regulatory scene in Brazil as it

pertains to the management of TSFs. On February 15, 2019, immediately after the Brumadinho failure, the National Mining Association (ANM) instated Resolution No. 4/2019, prohibiting the use of the upstream construction method of tailings dams, and enforcing the decharacterization of upstream constructed tailings dams (and dams of unknown construction method) in Brazil (ANM, 2019a). Concurrently, in the state of Minas Gerais, the environmental regulatory entities Secretaria de Estado de Meio Ambiente e Desenvolvimento Sustentável (SEMAD) and Fundação Estadual do Meio Ambiente (FEAM) passed Joint Resolution No. 2784 on March 21, 2019 (SEMAD/FEAM, 2019), requiring mining dam owners in the state to prepare plans for the decharacterization of their upstream tailings dams.

The term "decharacterized mining dam," first defined by Ordinance No. 70.389/2017 issued on May 17, 2017 (DNPM, 2017), was further elaborated with Resolution No. 4 as being a structure that does not receive tailings and/or sediments from mining activities; a structure that does not have the characteristics or does not function as a dam according to its intended design. To provide more clarity to the definition, the following activities were described in Resolution No. 4 as part of the decharacterization process:

- Cessation of active tailings deposition operations and decommissioning of associated infrastructure (e.g., slurry pipelines, conveyors).
- Implementation of measures to minimize or eliminate runoff and groundwater flows towards the reservoir.
- Implementation of measures to ensure the long-term physical and chemical stability of the structure.
- Monitoring as required to substantiate the effectiveness of the design measures.

Resolution ANM No. 13/2019, issued on August 13, 2019, replaced Resolution No. 4 and instituted new target dates for the decharacterization of upstream tailings dams, but did not effect changes to the definition or interpretation of a decharacterized structure (ANM, 2019b). A few years later, ANM issued Resolution No. 95/2022 on February 7, 2022 (and Resolution No. 130/2023 on February 27, 2023), to consolidate several national regulations pertaining to the safety of mining dams into a single updated document (ANM, 2022, 2023). The definition of a decharacterized structure was maintained, except for establishing a minimum monitoring period of two years post-construction of the decharacterization design.

These regulatory changes affected 74 TSFs in the country (IBRAM, 2024). Germano Pit (GP), a TSF operated by Samarco Mineração S.A. (Samarco), a joint venture between Vale S.A. and BHP Billiton, is one of them. Formerly regarded as a drained stack, the facility was reclassified by the regulator in 2019 as an upstream tailings dam – and as such, subject to the new regulations and to the decharacterization process. GP is located at the Germano Mine, 140 km south of Belo Horizonte, Minas Gerais, Brazil. The facility is contained within the mined-out Germano Pit. Figure 1 shows a situational map of the facility, which is

situated just upstream of the former Fundão and Germano TSFs. The structure is about 50 m high and stores about 14 Mm^3 of sand tailings derived from iron ore mining and processing operations.

This case study paper describes key aspects of the decharacterization project of GP, Stantec's involvement as designers, the impacts of an evolving regulatory environment, and our engagement with technical auditors and review bodies.

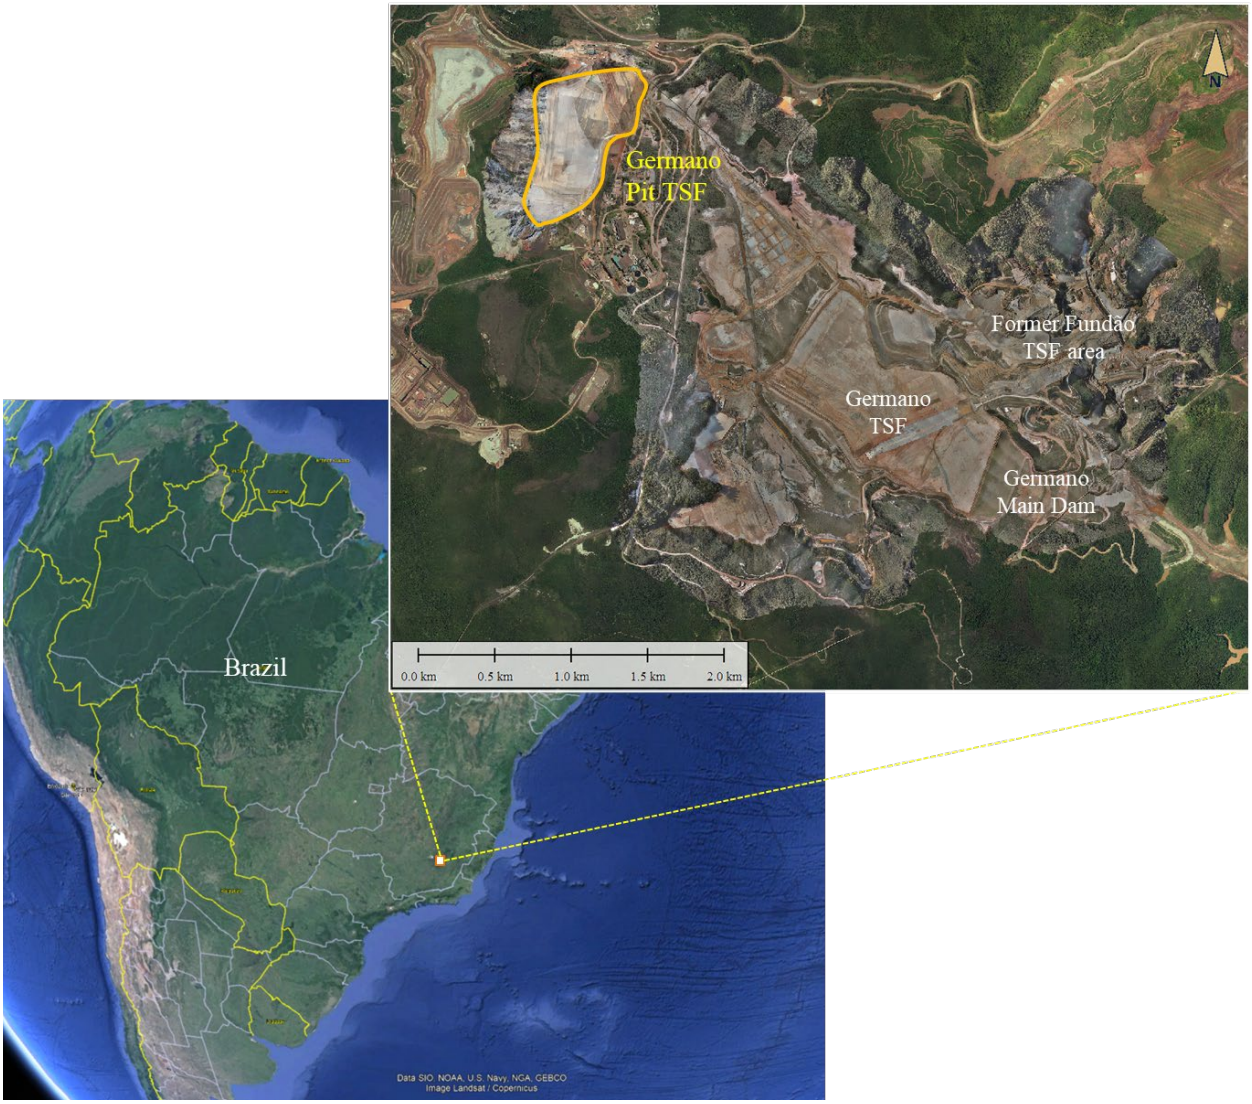

Figure 1: Situational map of the Germano Pit TSF

Germano Pit: history and site conditions

Iron ore was mined at Germano pit from late 1970s to the 1990s. After that, the pit was repurposed as a tailings storage facility, receiving underflow feed. Tailings operations started in 2000 and were suddenly halted in November 2015 in the aftermath of the Fundão dam failure.

The Germano Pit tailings is a silty-sand / sandy-silt material, with average fines (particle diameter less than 75 μm) content of about 52%, and clay percent less than 1%. The tailings mineralogy comprises mostly silica (70–75% SiO2) and iron (17–22% Fe) (Pereira, 2005). Crystalline minerals of quartzites, silicates, iron and aluminum oxides are also present. Very low (trace) levels of other metals (i.e., Sb, As, Ba, Co, Cu, Pb, Ni, Ag, V, and Zn) are present in the tailings. The silica has angular to sub-rounded grains. The tailings were deposited hydraulically from spigots. Beach development during operations resulted in a sand-like tailings structure throughout most of the facility and a slightly segregated clay-like tailings at the back of the facility, where the supernatant pond was maintained.

The site is located in a tropical climate, with well-defined rainy and dry seasons. The rainy season typically occurs from October to March, and the dry season occurs from April to September. The average annual rainfall at the site is 1,554 mm (Stantec, 2022). The area also experiences significant levels of evapotranspiration, with an annual average value of 840 mm (Stantec, 2022). The catchment area of the facility is about 140 ha.

Groundwater flows towards the south and east of the facility, mostly through aquifer Itabirite Formation.

The mine is located on a relatively low seismic zone with no significant ($M_w > 3$) regional earthquakes recorded. A peak ground acceleration (PGA) of 0.168g and peak ground velocity (PGV) of 6.3 m/s were estimated from a site-specific probabilistic seismic hazard assessment (PSHA) for an annual exceedance probability of 10,000 years (Stantec, 2022).

Decharacterization design

With the failure of B1/Brumadinho dam in 2019, and the inception of new mining dam regulations, ANM reinterpreted GP as an upstream tailings dam. A Term of Commitment was then signed in 2019 between the mine owner and various government federal and state bodies to decharacterize Germano Pit within three years, i.e., by late 2022.

A conceptual plan for the decharacterization of GP was immediately developed. The plan was advanced based on the new federal and state regulations and existing international guidelines, like those published by the Canadian Dam Association (CDA, 2014, 2019). The CDA guidelines recognize closure as a progressive multi-phased process extending over several years. Three stages are distinguished in the guidelines: (a) Transition – during this stage the tailings structure is no longer in operation, and activities are undertaken to prepare for closure care stages; (b) Closure / Active Care – when the closure elements are monitored for performance and a substantial maintenance component is set in place; (c) Closure / Passive Care – following cessation of active mining activities on site, when the structure has attained steady-state conditions and the monitoring history demonstrates no further intervention is required by the owner or other

parties. Although the term “decharacterization” is new to the international mining industry, it essentially defines a stage in the closure process similar to Active Care as defined by CDA.

Decharacterization objectives were then defined for the project, in alignment with Resolution No. 13/2019 and existing CDA guidelines. However, with the advent of the Global Industry Standard on Tailings Management (GISTM) (GTR, 2020) and ANM Resolution No. 95/2022, the objectives were updated but maintained their initial core elements, as follows:

- Objective #1: Eliminate “credible” high consequence failure mechanisms or render them non-credible. The Brazilian practice is to classify mining dams according to the associated failure consequence. Failure of a “high” consequence structure would result in significant loss of life, large environmental damages, and/or large reparation costs (similar to Extreme consequence as defined by CDA). An important decharacterization objective for GP is to eliminate or mitigate credible high consequence failure modes, especially those associated with liquefaction or other mechanisms that would lead to a breach and flow of tailings.
- Objective #2: Manage surface water to minimize ponding and erosion. Excessive ponding from heavy rainfall events is a hazard that could lead to overtopping and uncontrolled erosion. This objective attempt to eliminate permanent ponding and minimize temporary stormwater storage on the tailings deposit by designing a water management system that collects surface flows and diverts them downstream, away from the TSF, via positive flow gradients. The surface water management system at GP must also minimize erosion for flows over the structure.
- Objective #3: Manage long-term seepage and drainage performance. GP reservoir is a recharge area. The decharacterization design must consider how to collect these seepage flows and convey them downstream and away from the structure. Understanding the long-term steady state condition in the structure is key to evaluating and mitigating high consequence failure modes related to Objective #1.
- Objective #4: Identify Active Care and Passive Care stage monitoring and maintenance requirements. The types of monitoring (e.g., visual inspections, measurements, parameters, etc.) and maintenance (e.g., erosion control, revegetation, channel repairs) will be selected according to the resource requirements at each stage.
- Objective #5: Accommodate design compatible with future land use objectives, which involved repurposing the facility to store filtered tailings.

Key design elements

With the decharacterization objectives outlined, the following key design elements were proposed and implemented for GP:

- A reinforcing engineered buttress at the toe of the facility, sized for a minimum post-liquefaction factor of safety of 1.2; considering the existing underdrainage system would clog / degrade over time and reduce its effective hydraulic conductivity, and assuming residual strength (post-liquefaction undrained strength ratio) for the saturated tailings below the long-term water table. Figure 2 presents plan and cross-section views of the buttress, comprising a plateau area and benches. The extended plateau area was required to provide support for the future conveyor belt lines (shown in green in the figure).
- Extension of the existing underdrainage system. The new system comprises: (a) a 1 m thick sand blanket under the footprint of the buttress and (b) a rockfill drain network. This underdrainage system collects seepage flows from the existing drainage system and conveys them to a culvert outlet that crosses an internal access road and the state highway MG-129, as shown in Figure 3. The system will require long-term monitoring and periodic maintenance to ensure that seepage and drainage are not interrupted.
- A surface water management system, consisting of bench channels, left and right abutment secondary channels, and a Main Drainage Channel, located in the right abutment (see Figure 2). Sized for the probable maximum precipitation (PMP) event, with updated considerations on climate change, the Main Drainage Channel is the primary conveyance structure for the GP watershed. It combines open channels, stepped channels, culverts, and dissipation basin, as shown in Figure 2. With an approximate length of 462 m and a total elevation difference of 42 m, this structure begins at the GP crest, where it receives runoff from the tailings deposit and pitwall, and discharges downstream through a pair of culverts passing underneath the highway MG-129. Secondary channels tie-in to the Main Drainage Channel at various locations along the structure.
- Re-grading of the reservoir towards the in-pit perimeter channel, to eliminate permanent ponding of stormwater runoff on the deposit.
- An instrumentation, monitoring, and maintenance plan, to assess performance and conformity with basis of design, particularly over the next two years of Closure / Active Care as specified by Resolution No. 95, and to provide early warning of defects or impending threat to stability.

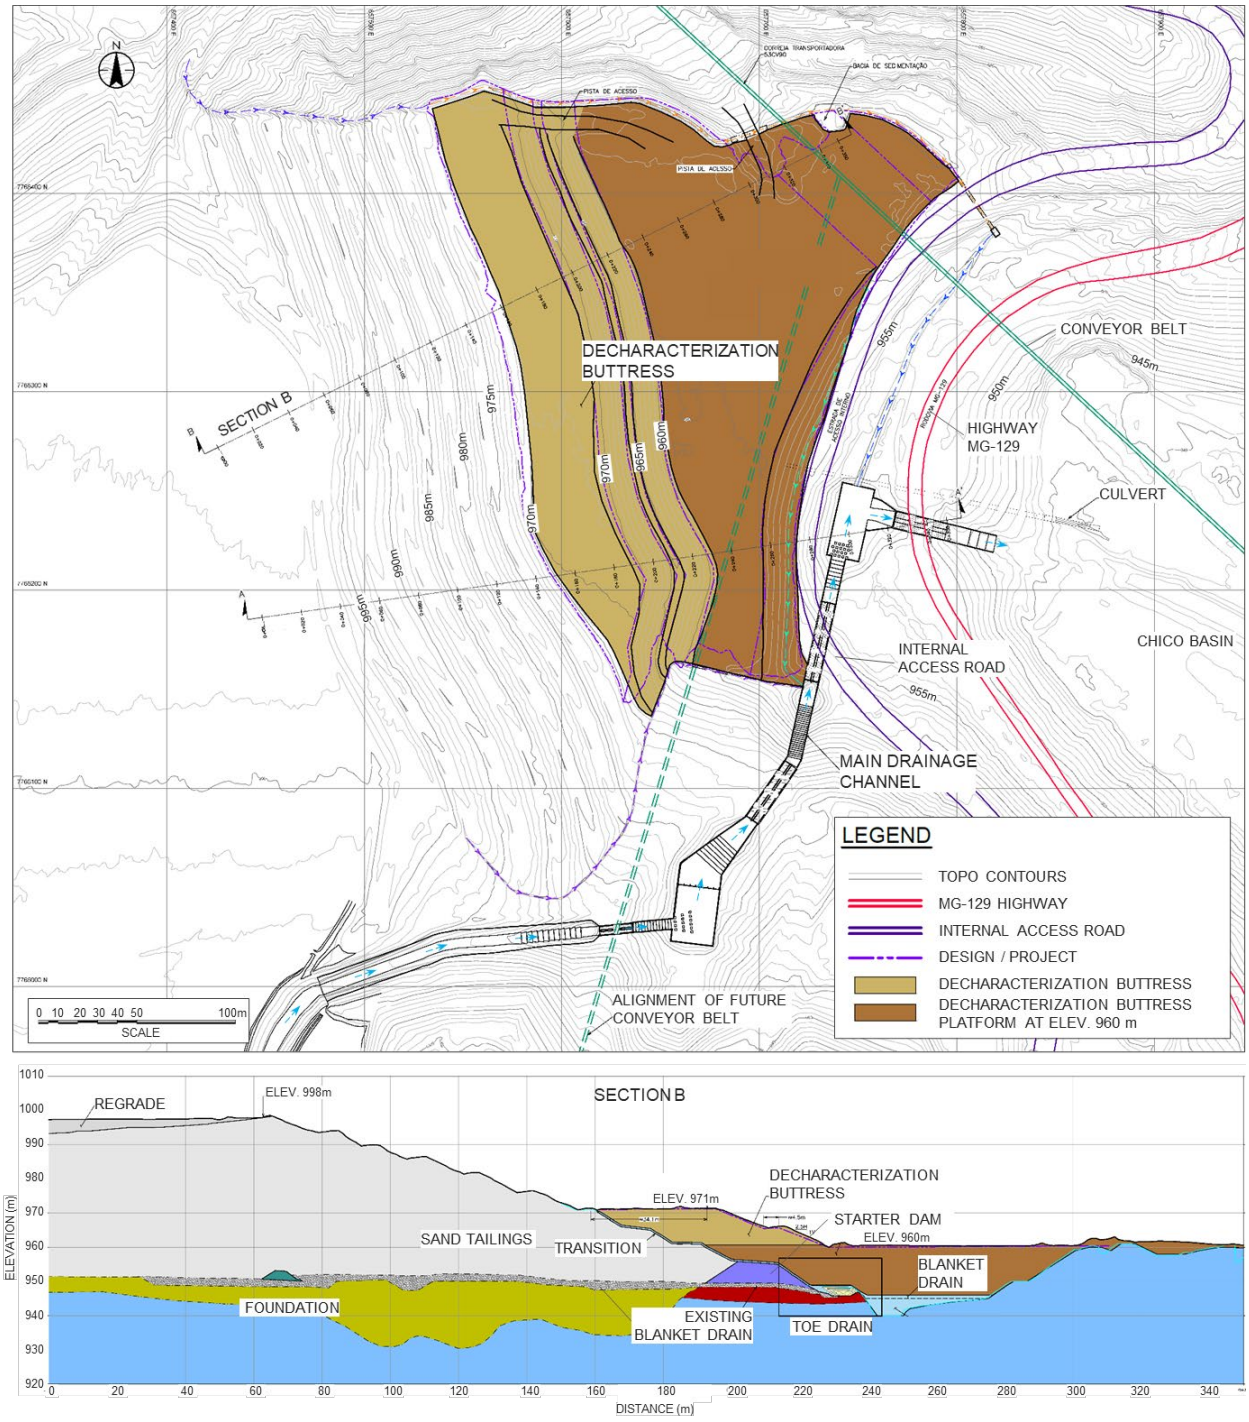

Figure 2: Decharacterization buttress and main drainage channel

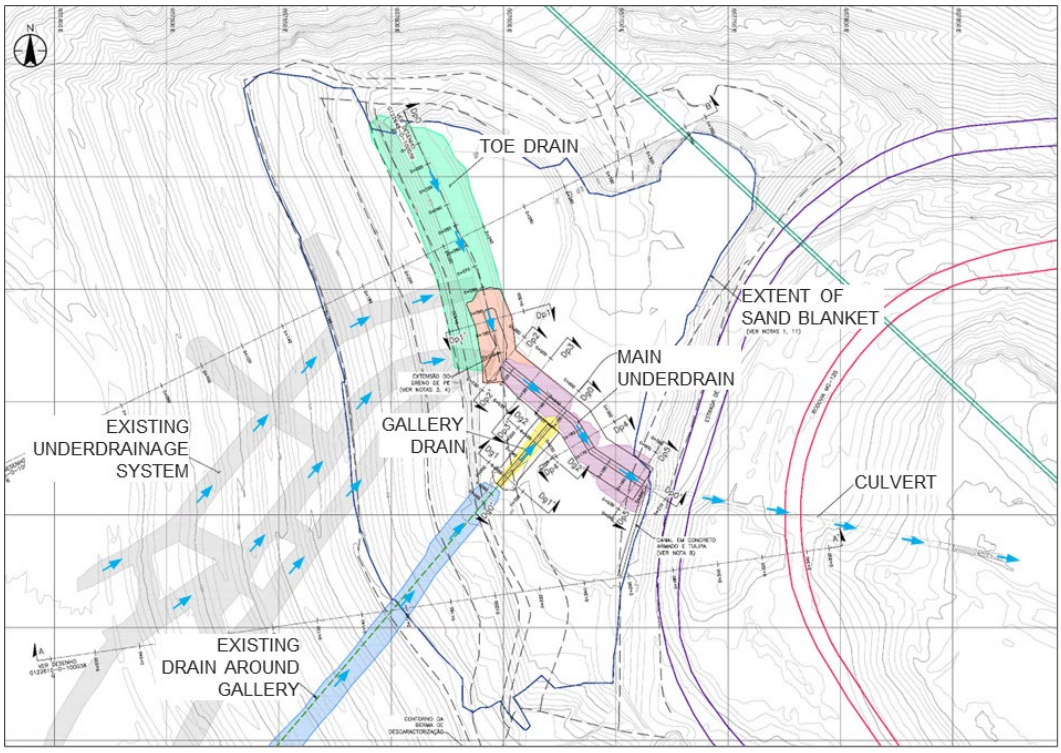

Figure 3: Connection between existing and new underdrainage system

Construction

Construction activities associated with the decharacterization of the facility started in 2020 and were safely completed by mid-2023. These activities included:

- Removal of vegetation and interferences, such as a non-operational segment of a conveyor belt, buildings, and electricity poles.
- Plugging of a 460 m long bullet-shape reinforced concrete gallery, located at the right abutment, and extending from the reservoir up to the downstream toe of the facility. The gallery was used during operations to decant the supernatant pond.
- Regrading of the reservoir surface, which involved the placement and compaction of 516,000 m^3 of filtered sand tailings.
- Construction of the decharacterization buttress, which consisted of removal of unsuitable foundation material, and placement of nearly 412,000 m^3 compacted waste rock. This activity also included construction of the sand blanket drain and the new rock underdrain system.
- Construction of the Main Drainage Channel, and secondary channels. Due to schedule constraints, the secondary channels and stretches of the Main Drainage Channel were constructed with precast concrete elements.

- Construction of a twin culvert/tunnel under the state highway MG-129, as part of the main drainage channel.
- Decommissioning or raising of existing instruments and installation of new instruments.
- Revegetation of slopes and a portion of the reservoir.
- Implementation of the instrumentation and monitoring plan. This included the decommissioning of selected instruments (e.g. prisms, a malfunctioning Shape Accel Array (SAA) inclinometer, one slope inclinometer, two flowmeters, four piezometers), the raising of instruments under the footprint of the buttress, and the installation of new slope inclinometers, tiltmeters, piezometers, prisms, geophones/ accelerometers, and a flowmeter (to measure seepage flows). Most of the instruments are automated. Readings are measured remotely, continuously and in real time, and communicated to a central data management system.

In addition to these activities, the Operations, Maintenance and Surveillance (OMS) manual, Trigger Action Response Plan (TARP) and Emergency Preparedness and Response Plan (EPRP) were updated to reflect the as-built conditions of the structure. Figure 4 shows a drone photo of GP post-decharacterization works.

Figure 4: Germano Pit post-decharacterization construction (Source: Samarco)

As per Article 8 of Resolution No. 13, the decharacterization of Germano Pit had to be completed by December 15, 2022. However, the COVID-19 outbreak, contractor performance, weather constraints (long raining season), heterogeneous wasterock sources, and rise in phreatic levels during reservoir regrade work impacted project timeline. A revised Term of Commitment between Ministério Público de Minas Gerais (MPMG), Ministério Público Federal (MPF), SEMAD, and FEAM, with the intervention of ANM, was then prepared and signed in 2022, extending the target date for the decharacterization of the structure to October 2023.

Auditing, review engagement and regulatory context

In 2019, with the enactment of ANM Resolution No. 4 (and then No. 13) and local state regulations, MPMG retained an external expert consultant to provide independent technical auditing of several decharacterization projects in the State, including Germano Pit. As a government institution responsible for defending the rights of citizens and interests of society, MPMG's role includes minimizing the risks associated with catastrophic failure of upstream construction TSFs. The auditing scope for GP included areas of geotechnical engineering, dam safety, surface water management, hydrogeology, environmental engineering, instrumentation/monitoring, and construction quality.

During construction, the auditors conducted monthly site visits to inspect the construction, document site conditions, and identify nonconformities/anomalies that needed to be remediated. Reported nonconformities were logged by Samarco, and a responsible person and target completion date were assigned to each nonconformity.

The site visit was followed by a one or two-day technical session, in which Stantec, other consultants and the client's engineering and operations groups presented various aspects of their work, provided updates about field activities and response/trends of the monitoring instruments. These were often fruitful and collaborative sessions in which the state auditors not only challenged the design basis and methodology of assessment but also provided recommendations to minimize risks and improve the resilience and robustness of the design. On one occasion, following the presentation of a Computational Fluid Dynamics (CFD) assessment to support the detailed design of the Main Drainage Channel, the auditors raised concerns about the selection of user-defined hydraulic parameters and their potential impact on flow depths and assessment of freeboard allowance along the channel under PMF condition. They recommended building a physical model of the channel to calibrate the input parameters and benchmark the CFD model for various stormwater return periods. Samarco honored the recommendation and partnered with Fundação Centro Tecnológico de Hidráulica (FCTH) of the University of Sao Paulo (USP) to construct a 1:10 scale model of the channel and run the hydraulic tests (Figure 5). The work spurred the development of a doctorate and

two Master of Science research projects. The results of the reduced scale model led to optimizations to the original design that were implemented during construction.

In addition to the technical auditor team, an Independent Tailings/Technical Review Board (ITRB) provided a similar review scope, although with a less “boots on ground” involvement and a more “big picture” / senior perspective than the auditing team. Initially, the ITRB sessions were held quarterly; however, by the end of the construction phase, meetings were held twice a year. The sessions comprised a site visit and technical meetings with consultants and client’s engineering and operations groups, followed by a wrap-up session with the Accountable Executive.

The GP project also had other levels of external reviews provided by an independent consultant team representing Samarco, and the other two independent consulting firms, each representing the two main shareholders: Vale and BHP.

The multi-tiered review process at GP was an important part of the process to restore stakeholder confidence following the Fundão and Brumadinho disasters. These reviews needed to be carefully integrated into the project design and construction planning process to minimize delays and optimize the value-added benefit they provided. This was a unique and necessary aspect of the project which can be expected on other tailings projects in Brazil to improve public perception and prevent future catastrophic failures.

Figure 5: Constructed physical model at the FCTH Hydraulics Laboratory Facility

Conclusion

The decharacterization of Germano Pit TSF spanned several years – a period that included the implementation of strict national regulations for upstream-constructed TSFs and the development of global standards for the safe management of tailings facilities, towards the goal of zero harm. The design and construction of the decharacterization works for GP were closely examined and evaluated by teams of technical expert auditors, the ITRB, and other independent reviewers representing Samarco and its shareholders. Concerns raised and recommendations proposed during the multi-tiered review process were carefully integrated into the design and construction to minimize risks, to improve the robustness and resilience of the design and its as-built elements, and to restore stakeholder confidence. In June 2023, Samarco concluded the construction of the decharacterization works of the facility. After assessments by ANM, the local regulators and the external state auditor, the decharacterization of Germano Pit was endorsed in January 2024, making it the first upstream tailings facility to complete the "decharacterization" process in Brazil. Other decharacterization projects completed prior to GP involved either partial or complete removal of the tailings deposit (e.g., Gonçalves et al., 2023). In June 2024, the Brazilian Mining Institute (IBRAM) announced that 22 out of 74 TSFs that fell under the regulations had been decharacterized in the country (IBRAM, 2024). The national objective is to complete 90% of the decharacterization projects over the next three years.

Acknowledgements

The authors acknowledge the successful planning and execution of the Germano Pit decharacterization project by its various contributors – Samarco's engineering and operations groups (especially Jonathas Pinto, former Samarco), contractors, QC/QA teams, technical auditors, reviewers, and Stantec's design team and field personnel.

A Safe Approach to Assess the Trafficability of Tailings Beaches for Operation and Closure Construction Activities

Abstract

Infrastructure construction on tailings beaches is necessary for multiple reasons, including tailings deposition and pond closure activities. The main challenges for infrastructure construction on a tailings beach are the proximity to the pond's edge and the presence of a potentially liquefiable tailings beach within the construction area. Construction activities on a tailings beach could trigger liquefaction, and assessing this potential is a key factor in managing risk. Liquefaction failures could occur rapidly and do not manifest any early signs or warnings, limiting the ability to react promptly to safeguard personnel, infrastructure, and equipment. Therefore, assessing the trafficability of construction equipment and developing a safe operating procedure prior to infrastructure construction is critical to tailings operation and managing risk during construction.

This paper will discuss case studies involving the construction of tailings infrastructure to facilitate the safe deposition of tailings and the construction of infrastructure to conduct a field trial for the closure of a tailings pond. The approach adopted in these case studies has been successfully implemented in several other tailings ponds in Northern Alberta, Canada. The proposed approach can also be used as a general guideline for tailings facilities other than oilsands to manage the risk of infrastructure construction on the tailings beaches.

Introduction

Infrastructure construction on tailings beaches is essential for berm/corridor construction for tailings deposition, closure work, and operational support activities such as barge launch and maintenance. Energy Safety Canada (2021) recommends conducting a trafficability assessment, a process that necessitates the

approval and expertise of a geotechnical engineer who plays a key role in assessing the risk and developing a safe work plan when ground conditions are unknown in tailings facilities. Therefore, assessing the trafficability of a tailings deposit, such as a tailings beach, is critical for the safe operation of the equipment, managing the risk, and reducing delays during construction.

The approach discussed in this paper for trafficability assessment can be used for infrastructure construction on tailings beaches and to manage the risk during the track packing or beach conditioning activities with different dozers. The impact of operating the equipment on the tailings beach can be assessed by performing cone penetration testing (CPT) before and after the trafficability trial (i.e., the before and after CPTs will show whether operating the equipment, such as dozers, has changed the tailings deposit state from contractive to dilative to a certain depth below the ground).

The trafficability trial must be conducted on unfrozen ground and in a ground condition comparable to, or better than, that expected during the infrastructure construction. The following steps are carried out as part of the desktop study to plan the trafficability trial:

- Understand the project needs (proposed infrastructure, access, timing of the construction, etc.) and selection of the trafficability study area.
- Conduct an aerial photographic review and assess the available geotechnical information for the specific site.
- Assess the available CPT and other relevant data for liquefaction susceptibility.
- Review available laboratory test results to understand the particle size distribution (PSD) of the tailings beach.
- Establish the trafficability lanes that cover the project area and meet the project needs.
- Finalize the equipment list for the trial based on the project needs.
- Develop the site-specific trafficability study procedures and safety measures.

Trafficability study planning and desktop study

Good trafficability is defined as the ability of construction equipment to travel on a tailings surface relatively unhindered, i.e., without excessive rutting or getting stuck in the tailings beach. The density and the undrained shear strength of the tailings deposit, liquefaction susceptibility, and the equipment's ground-bearing pressure govern the equipment's trafficability on a tailings deposit. The soft tailings deposit typically varies between a slurry and a solid, with a shear strength from 1 kPa to 100 kPa (McKenna, 2009). If the tailings deposit predominantly consists of fine sand that is susceptible to liquefaction, the shear strength range noted above corresponds to the liquefied strength of the tailings sand beach.

A desktop study must be carried out to characterize the tailings deposit and the depositional history of the project site. Additionally, understanding the purpose of the trafficability study and the relevant background information such as details of the proposed infrastructure, construction methodology being considered, access to the site, the timing of the construction, available geotechnical testing (CPT and laboratory testing), etc. are essential to developing a site-specific trafficability study that caters to the project requirements. As part of the desktop study, satellite imagery of the pond (preferably since the beginning of the active deposition of tailings) and pond level data from different years are reviewed to identify the areas of potential soft and wet zones. As part of the desktop study, the available CPT data is also assessed for liquefaction susceptibility based on the latest criteria, such as the Robertson's (2022) method. In the absence of CPT information, a CPT investigation using an amphibious CPT rig is recommended prior to the trafficability study. The following information is also gathered as part of the desktop study:

- The client-specific guidelines for working close to a water body and the province or territory's occupational health and safety regulations.
- Beaching locations within the trafficability study area and the duration of beaching.
- Type of tailings beach, i.e., coarse sand, fluid fine tailings, or treated tailings.
- Existing field and laboratory testing data for the tailings beach.
- Normal operating pond level, the highest pond level in recent years, and the expected pond level during the field trial and actual construction stage.

Based on the above information and the project requirements, trafficability lanes for the trial area are selected to assess the performance of the tailings beach under the equipment loading. As part of the trafficability study at the oil sands tailings facility, no personnel or equipment are allowed within 30 m from the edge of the pond (measured from the point closest to the pond). If personnel or equipment need to enter within the 30 m zone close to the pond, more rigorous site-specific guidelines/safety measures must be developed. Figure 1 shows the typical trafficability trial lanes developed for a berm/corridor construction for the tailings deposition at an oil sands tailings pond. As part of the trafficability trial, test pits are also excavated with a hand shovel or with a smaller excavator (based on the trafficability study findings to access the test pit location) to observe the subsurface conditions, describe the soil/tailings deposition, and collect samples for laboratory testing such as sieve analysis and hydrometer testing. Figure 1 shows the four test pit locations within the proposed corridor for tailings deposition.

Equipment for the trafficability study and the infrastructure construction

The construction equipment used for the trafficability study should be comparable to the equipment required for the infrastructure construction at the site. Additional equipment might have to be added to the

trafficability study to provide flexibility for the execution team during the infrastructure construction stage. All trafficability studies must start with an amphibious vehicle, such as an Argo.

Different bulldozers, such as low ground-bearing pressure (LGP) bulldozers, regular bulldozers, and articulated trucks (wiggle wagons) with and without the payload, are typically used in all field trials. Depending on the project requirements, special construction equipment such as pipe loaders and side booms may also be considered for the field trial.

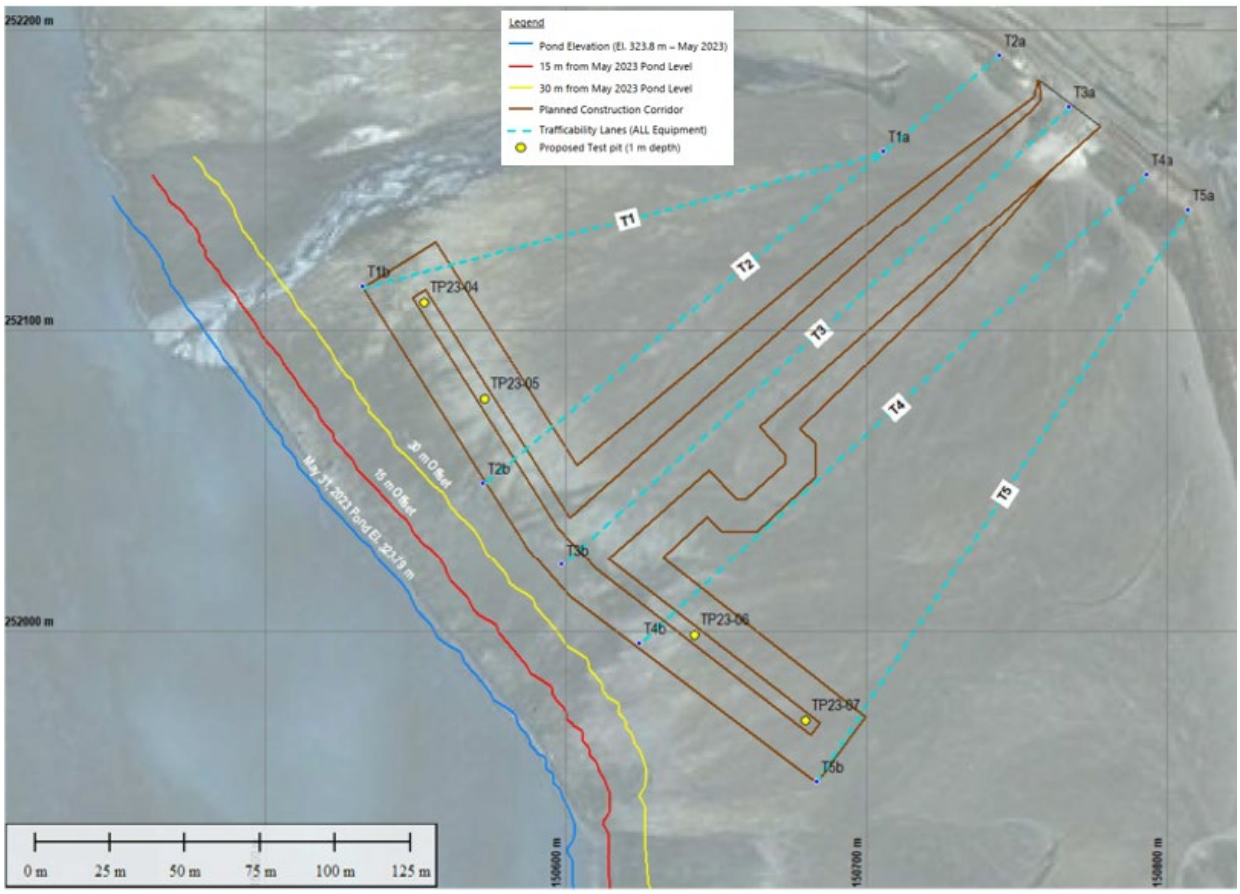

Figure 1: Project site with pond offsets and trafficability lanes based on the desktop study

Additionally, a large bulldozer, such as a CAT D10 or equivalent with a long cable sling, is required for the trafficability trial to retrieve (with winching/towing) any equipment that gets mired during the trial. This large bulldozer must be perched on a competent ground close to the trafficability study area, and it is not expected to travel along the trafficability lanes.

The weight of the equipment and the ground-bearing pressures are assessed as part of the desktop study to develop the details of the field trial. The typical equipment used in the oil sands tailings beaches for various infrastructure construction is summarized in Figure 2 with the relevant information.

The required construction equipment for the trafficability study should be readily available at the site at the time of the trial, as the sequence of the equipment is a key factor in the field trial. The sequencing requirements for the equipment are further discussed in the general guidelines section below.

Figure 2: Equipment typically used for trafficability study on an oil sands tailings beach

General guidelines for the trafficability study

The general guidelines discussed in this section have been successfully followed in several trafficability studies in the oil sands industry. However, additional guidelines and safety measures might have to be considered for other tailings storage facilities based on the findings of the desktop study for the specific site. The general guidelines and safety measures adopted for the trafficability studies at various tailings sand ponds at an oil sands facility are summarized below:

- As part of the trafficability study, personnel and equipment should not be allowed to travel within 30 m (100 ft) from the edge of the pond (measured from the point closest to the pond).
- The surveyors must use an amphibious vehicle, such as an Argo, to install the survey stakes for the 30 m offset limit from the pond edge and the trafficability lanes prior to the field trial.
- The trafficability study should not be carried out if fog, smoke, wind, ice, or snow obscure the pond edge, 30 m offset limit stakes, and the trafficability lanes.

- All equipment must travel along the competent ground (such as on the dyke crest) up to the trafficability lane locations.
- A larger bulldozer should be on standby with a long cable sling on the competent ground to retrieve any equipment in the event it gets mired during the trial (an amphibious vehicle such as an Argo can be used to transport the operator of the mired equipment, and the operator of the equipment must be trained in self-rescue).
- During the trial, all equipment should travel at a low speed (at the oil sands tailings beaches, trafficability studies are conducted with equipment traveling at approximately 5 km/hr) along the trafficability lanes.
- All equipment should travel within 5 m of the specified trafficability lanes during the field trial.
- The traverse of the sequentially heavier equipment along a trafficability lane should be within 2 m of the nearest path of the previously trafficked lighter equipment.
- All equipment operators must avoid sharp turns, including the operator of the Argo.
- The amphibious vehicle (such as an Argo) must be used as the first equipment for all the trafficability lanes, and the trial along a particular lane is continued by sequentially sending equipment with increasingly higher ground-bearing pressure.
- The empty articulated truck must travel along the lanes before sending the loaded articulated truck (with payload) along the same trafficability lane.
- All equipment should travel straight down the trafficability lanes toward the 30 m limit from the pond edge and then travel straight back until reaching competent ground within the beach. All equipment should avoid turning or reversing near the end of the trafficability lane that is close to the pond edge or near a location of poor trafficability previously identified along a trafficability lane. The loaded articulated trucks must be reversed down the beach along the trafficability lanes (with a competent person traveling on the Argo in radio communication with the operator of the truck all the time) to allow the operator to dump the load and drive forward to the competent ground if the loaded truck becomes mired during the trial.
- Equipment traveling parallel to the pond is exposed to a higher risk, which must be avoided at the site.
- Heavier equipment should not travel/approach the location where lighter equipment had poor trafficability or became mired, and should not go past the zone where lighter equipment had issues. The location where the lighter equipment had poor trafficability or got mired should be staked in the field to indicate the limit for the heavier equipment.

- The equipment operator must be prepared to reverse out (loaded trucks will travel in a reverse direction towards the pond, so they will have to drive forward) of any soft areas. The competent person traveling on the Argo parallel to the equipment will act as the spotter and must communicate with the operator if they identify any potential soft or problematic areas along the trafficability lanes.
- In saturated tailings sand, it is common to have water coming to the surface in the form of sand boils (see Figure 3) during the trafficability trial. This indicates the densification of the beach due to the equipment loading. To benefit from the densification, the area should be left undisturbed to allow pore pressure dissipation. In such events, the trafficability trial can be moved to the next trafficability lane until the sand boils are settled in the previous lane. Once the sand boils are settled/reduced, the remainder of the equipment can be allowed to travel along the areas that manifested sand boils.

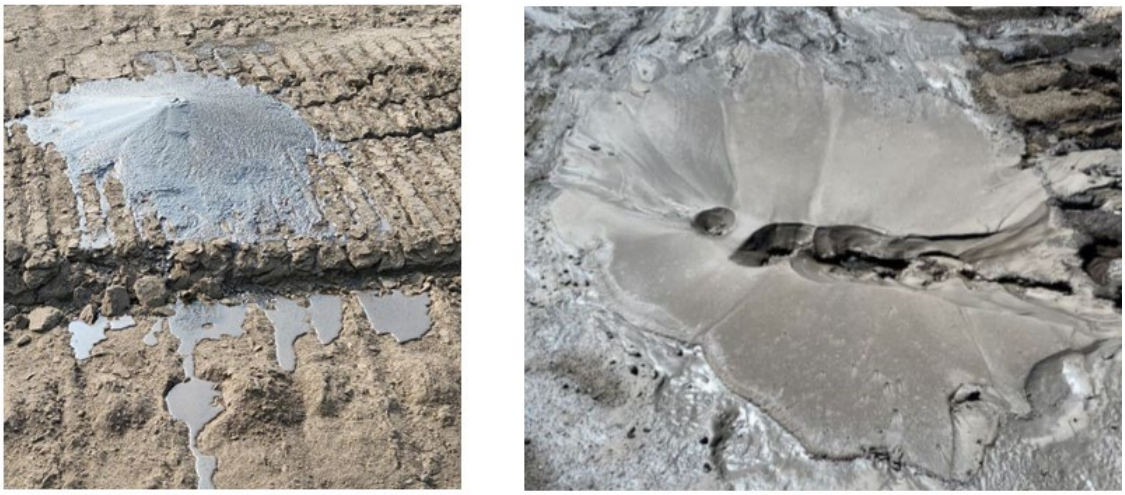

Figure 3: Sand boils observed during the trafficability study

In addition to the above guidelines, it is critical to have competent geotechnical staff at the site and a qualified geotechnical engineer (with experience conducting trafficability studies) who understands the project objectives and operational risks plan and oversees the trafficability study.

CPT testing and test pits

If the desktop study indicates a lack of geotechnical data at the site, CPT testing with field vane shear testing, along with dissipation testing, is typically carried out before, or as part of the field trial. The selected CPT test holes can be done before and after the trafficability trials to understand the densification and pore pressure conditions of the tailings beach due to the equipment loading as part of the trafficability trial. The CPT investigation on the tailings beach must be carried out using an amphibious rig.

The field staff overseeing the trafficability trial can perform the test pitting at the site, make observations of the test pit (the soil profile, depth to the water table, and the performance of the test pit slopes), and collect samples from the site for laboratory testing. The test pits can be left open until the completion of the trafficability trial to perform a follow-up observation of the test pit side slopes performance and the amount of water accumulated within the test pits. At the end of the field trial, the test pits must be backfilled with the material excavated at the site.

Field trafficability study and execution phase

The client representative, competent geotechnical staff, and experienced equipment operators must meet at the site to review the safety procedures for working close to a water body, verify the survey stake locations, and confirm that the site conditions meet the general guidelines provided above for the trafficability study. Additionally, the competent geotechnical staff overseeing the trafficability study is responsible for the following tasks:

- Recording the field activities and the weather conditions during the days of the field trial.
- Recording information for each piece of equipment used in the field trial, including photographs capturing the equipment brand, model, unit number, tire size, and any other relevant information.
- Measuring the ground contact area for each piece of equipment.
    - For the equipment with tracks, measure the width of the track and the portion of the length that is in contact with the ground.
    - For the equipment with tires, measure the width of the tires and the tire length that is in contact with the ground. If the equipment has dual tires, measure the effective contact area outside the two tires.
- Travel in an amphibious vehicle parallel to the equipment performing the trafficability trial, document the observations, and communicate with the equipment operator when signs of poor trafficability are recognized, or when it is necessary to stop the trial.
- Record the location (with a handheld GPS) where each type of equipment started the trial and had poor trafficability conditions or got mired during the trials. Place a survey stake where poor trafficability conditions were observed, and where the trafficability trial for a particular piece of equipment along a trafficability lane was terminated.
- Ensure that heavier equipment along the same trafficability lanes does not pass beyond the termination location for the lighter equipment.
- Capture photographic documentation of sand boils, ground rolling, cracking, and seepage locations.

- Measure the rut depth for each piece of equipment at various locations along the trafficability lanes.
- Communicate with the experienced geotechnical engineer frequently (when practical) regarding the observations, findings, and the progress of the field trial, in order to assess the risk continuously.

Poor trafficability conditions are indicated by deep ruts, excessive roll (ground surface manifesting a wave motion) representing high pore pressures in the soil below the surficial crest, excessive cracks, and excessive seepage water expressed at the surface along the trafficability lanes. If poor trafficability conditions are observed at the site, the trial must be paused, and the site condition must be reassessed by the field staff, client representative, and the geotechnical engineer, based on the safety requirements. Prematurely finishing a trial will limit the construction equipment's access and may result in the construction of the infrastructure being impractical.

Delaying the termination of the trial might result in safety issues, such as equipment getting stuck and potentially sinking by triggering liquefaction within a larger area. Therefore, it is critical to have an experienced field geotechnical staff overseeing and coordinating the field trial in consultation with a geotechnical engineer, as trafficability trials involve significant engineering judgment. Performing a thorough desktop study, following the trafficability study approach discussed in this paper in conjunction with the site-specific conditions, and having an experienced geotechnical staff to conduct the field trial is paramount, not only for the safety of the field trial but also to assess the feasibility of the project/infrastructure construction.

After the completion of the trafficability trial, field observations, information from the test pits, and the start and end points of different equipment are reviewed along with the information from the desktop study and the project requirements. Based on the findings, the project area may need to be relocated or reduced to manage the risk during the infrastructure construction. The findings and recommendations for the permissible limits of construction equipment access on the tailings beach for construction activities are developed, and the recommendations are typically summarized in a drawing. The drawings summarizing the recommendations for the two recent trafficability studies at an oil sands tailings facility are provided as part of the case studies below.

Trafficability study case studies

Case study 1: construction of a corridor to support the tailings operations

The tailings sand beach at this site consists of treated tailings, and the trafficability trial was conducted to develop a strategy for a berm/corridor construction to support the tailings deposition. Four test pits were also excavated with a hand shovel at selected locations to perform visual characterization/observations of

the tailings beach. Figure 1 shows the proposed infrastructure, trafficability lanes, and the test pit locations for this trafficability study.

A desktop study was carried out for this site, which included reviewing aerial photos, existing CPT data, and laboratory test results. The approach for the trafficability study provided in this paper was adopted in the field trial for this site. Sand boils (see Figure 3) and ground rolling (see Figure 4) were observed in some areas of the beach during the trial. The trafficability trial was completed successfully, and the recommendations provided to the client for equipment access for the corridor construction are shown in Figure 5.

Figure 4: Ground rolling observed close to the end of a trafficability lane

Figure 5 shows a color-coded map for the construction equipment safe access limits; the green hatched area represents the area where all equipment up to a 40-ton loaded truck can be permitted during the construction; the yellow hatched area is limited to a 30-ton loaded truck and smaller equipment tested during the field trial; and the red hatched area was limited to Argos and bulldozers comparable to a John Deere 850WLT model or smaller bulldozers.

The termination points for each type of equipment along the trafficability lanes are also shown in Figure 5 (for example, the T3-300D(E) location marked on the figure indicates the furthest point the 30-ton empty truck travelled along Trafficability Lane 3). The recommendations were reviewed with the client's construction and execution teams, and these recommendations were successfully implemented at the site during the construction.

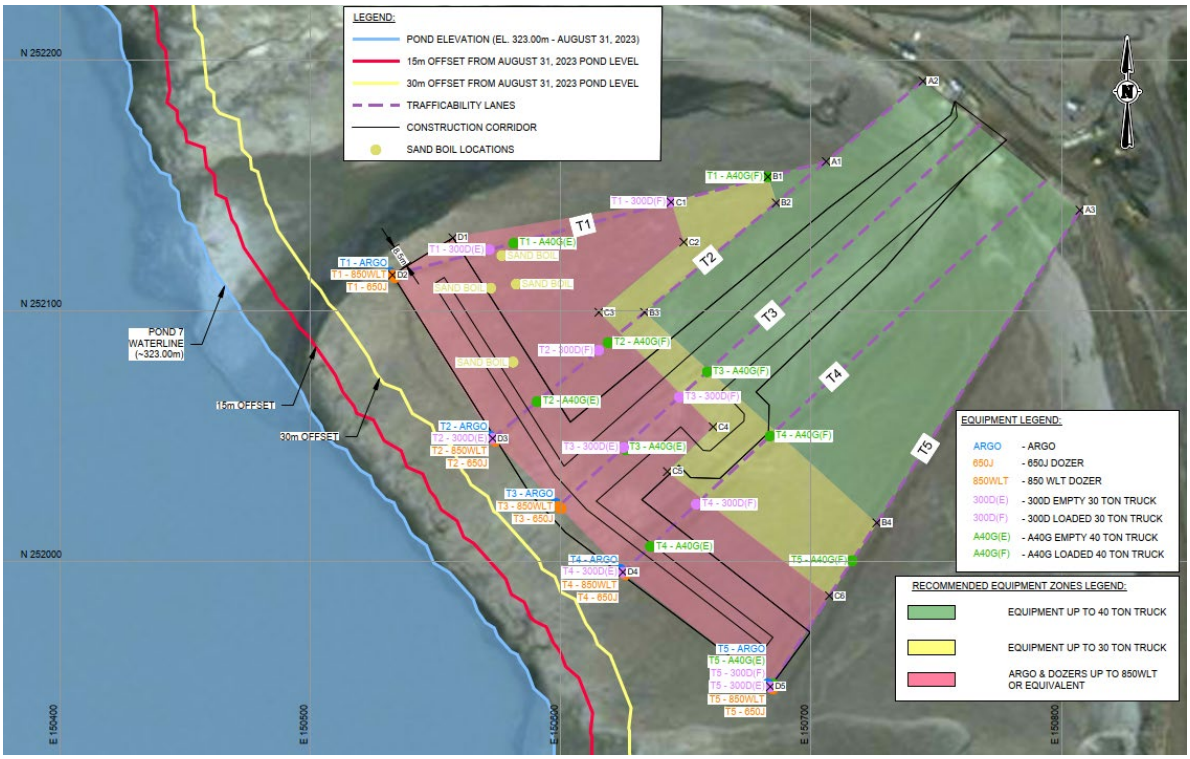

Figure 5: Trafficability study recommendations for the spur construction

Case study 2: infrastructure construction for closure trial at an oil sands tailings pond

The tailings sand beach at this site consists of composite tailings, and the trafficability study was conducted to develop an infrastructure construction plan on the tailings sand beach to perform a closure trial for the tailings pond. Ten test pits were excavated as part of the field trial at selected locations, to perform visual descriptions and observations of the tailings beach and to collect samples for laboratory testing to characterize the composite tailings beach.

Figure 6: Sand boils and seepage along the trafficability lanes in Case Study 2

A desktop study was carried out for this site, which included reviewing aerial photographs, existing CPT data, and laboratory test results. The construction on the tailings sand beach consisted of a stockpile, a solid handling area, a mixing hopper, pipelines, and other associated infrastructure. Sand boils, excessive seepage, and soft ground conditions were observed close to the competent ground along Trafficability Lanes 1 and 2 (see Figure 6).

During the trafficability trial, the loaded truck got mired close to the starting point of Trafficability Lane 1 due to the presence of soft ground conditions underneath the surficial crust (see Figure 7). Encountering sand boils, excessive seepage, and soft ground conditions was not uncommon on tailings sand beaches, and similar observations were also observed at different oil sands tailings sand beaches, as summarized in Martens et al. (2008).

Figure 7: Loaded truck mired close to the starting point of Trafficability Lane 1

Figure 8 (on the next page) shows the trafficability lanes, initially planned access ramp location, infrastructure locations, revised ramp location based on the trafficability study findings, and recommendations for equipment access limits. Due to the soft ground conditions and the poor performance observed in the northern part of the trial area (Trafficability Lanes 1 and 2), the initially planned access ramp location was deemed unsuitable for the construction equipment and the operation of the proposed infrastructure for the closure trial.

During the trial, the client and the geotechnical engineering consultant team assessed alternative locations for the access ramp, and the proposed infrastructure was shifted to the south, based on the revised access ramp location. The collaborative effort and the initial understanding of the site based on the desktop study were critical to implementing the design change without creating major downtime for the fieldwork during the trial. In addition to the typical construction equipment (see Figure 2), a side boom was also required for the construction of the infrastructure at the site. A trafficability trial was conducted with a side boom, and a spin test with the counterweight was also conducted as part of the field trial to simulate the construction.

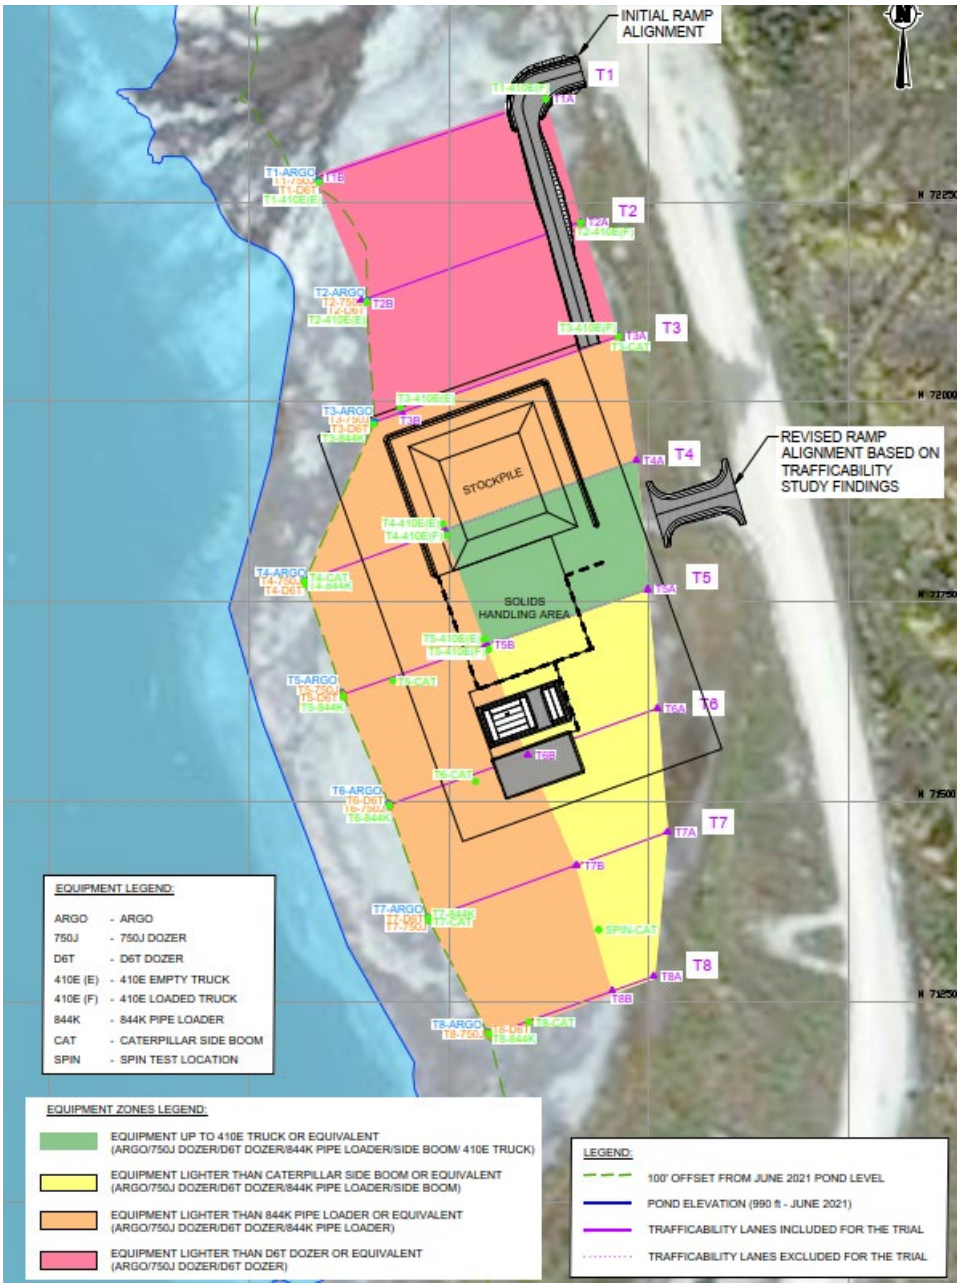

Figure 8: Trafficability study recommendation for the closure trial infrastructure construction

Figure 8 shows a color-coded map for the construction equipment safe access limits based on the desktop study and the findings from the field trafficability assessment. As shown in Figure 8, the general area close to Trafficability Lanes 1 and 2 is limited to only small bulldozers or Argo access; hence, the proposed infrastructure was shifted southward to align with the revised access ramp location. The recommendations were reviewed with the client's construction and execution teams, and the infrastructure construction was successfully completed at the site without any safety issues or delays.

Conclusion

This paper provides a safe approach for conducting a trafficability study and developing safe access limits for construction equipment on tailings beaches. The proposed approach has been successfully used in various oil sands tailings beaches to reduce the risk and uncertainty during field trials and infrastructure construction.

Abstract

Reclamation of old and sometimes abandoned mine sites can pose significant environmental challenges, due to the pre-oxidized (weathered) nature of tailings and the long-term occurrence of acid mine drainage. The abandoned mine site Aldermac, a legacy of metal mining during the 1930s in the Abitibi-Témiscamingue region, Quebec, Canada, was one of the most contaminated mine sites in Quebec prior to its reclamation. The multimillion-dollar reclamation project built in 2011 has subsequently improved site conditions and reduced the environmental impacts. The southern sector was reclaimed using a landfill cell with a high-density polyethylene (HDPE) geomembrane. The selected reclamation method of the northern part of the site consisted of a monolayer cover combined with the elevated water table technique. The elevated water table, positioned above the tailings, was designed to maintain the reactive tailings saturated, thus reducing direct oxidation of sulfides. A monolayer cover composed of coarse-grained (sand and gravel, also known as an evaporation barrier cover) was placed on the reactive tailings to minimize the evaporation while promoting infiltration. In this study, four monitoring stations were installed near observation wells to assess the performance of the cover. Each station was equipped with suction and volumetric water content probes, while pressure sensors were installed in observation wells to continuously monitor water table variations. Field observations indicated that the water table was maintained above the tailings during the monitoring period. This case study demonstrates the capacity of a monolayer cover of coarse-grained materials to effectively reduce evaporation fluxes by enhancing the site water balance. Presented results provide valuable insights for the development of new strategies to enhance climate resilience in reclamation methods using coarse cover.

Introduction

Abandoned mines represent a legacy of safety and environmental concerns across Canada, with around 10,000 abandoned sites across the country (Mackasey, 2000). Abandoned mine sites typically present a complex set of environmental challenges, which are largely caused by prior inadequate mine wastes management. Common issues encountered at abandoned mine sites include a variety of conditions, including spills of tailings in the environment (Maqsoud et al., 2016), dam failures (Ranđelović et al., 2020), the presence of unknown and heterogeneous mine wastes (Cornelissen et al., 2019), wind erosion and transportation of contaminants (Rodríguez et al., 2009; Corriveau et al., 2011), modification of landscape (Mhlongo and Amponsah-Dacosta, 2016), accumulation of contaminants (Navarro et al., 2008), and extensive generation of acid mine drainage (AMD) (Seal II et al., 2008).

Tailings that are produced at the concentrator to extract the metals of interest can contain sulfide minerals, which can generate AMD in contact with oxygen and water (Blowes et al., 2014). AMD is characterized by high concentrations of sulfates, metals, and metalloids, and low pH (Jambor et al., 2005). In abandoned mine sites, tailings have typically been exposed for decades without any method of mitigation, and in some cases the low pH (2 to 4 standard units) and the presence of ferric iron (Fe^{3+}) can further contribute to the persistence of AMD (RoyChowdhury et al., 2015). The low pH can increase significantly the mobility of metals such as Fe, Cd, Ni, Zn, and Pb in the interstitial water and the final influent (Blowes et al., 2014). Typically, secondary minerals are accumulated (Jönsson et al., 2006; Favas et al., 2016) and in some cases can generate cemented layers or hardpan (Hakkou et al., 2008; Quispe et al., 2013), which cause high heterogeneity of the hydrogeological properties (McGregor and Blowes, 2002; Elghali et al., 2019). Therefore, reclamation of abandoned mine sites requires complex fieldwork to select the appropriate methods of reclamation, such as building dams, reprofiling slopes, excavating tailings that have been spilled into the environment, and characterizing the mine waste and the underlying geology (Kubit et al., 2015).

Under humid climate conditions, the exclusion of oxygen is considered the most efficient method of AMD mitigation (Bussière and Guittony, 2021). The low oxygen diffusion rate in water (10,000 times lower than in air) inhibits the direct oxidation reactions leading to AMD (Aubertin et al., 2016). Among the available techniques, the elevated water table technique (EWT), combined with the monolayer cover, consist of raising the water table to half of the air entry value (AEV) of the reactive tailings (Pabst, 2021) and adding a coarse layer on the top to control the water balance (Dagenais et al., 2006; Ouangrawa et al, 2010). The cover reduces evaporation, tailings erosion and favors infiltration. In cases of highly pre-oxidized tailings, the water table can be raised up to the surface of the tailings (Pabst et al., 2018) or in the cover (Maqsoud, 2017).

In this paper, the reclamation work performed on the abandoned Aldermac site is presented. The study specifically concentrates on the northern part of the site, where the selected method of reclamation was the

EWT combined with a monolayer cover of sand and gravel. The water table was raised into the cover because of prior extensive oxidation (Maqsoud, 2017; Maqsoud et al., 2022). The sector of this site has been monitored since 2011 by the Ministry of Natural Resources and Forest of Quebec (MNRF) and the Mineral Technology Research and Service Unit (URSTM). Instrumentation stations were installed for continuous monitoring from 2020 to 2022 for this research project. This case study demonstrates the efficiency of a monolayer cover made of coarse-grained materials as an evaporation barrier to enhance the site water balance. The effectiveness of the method was also evaluated in response to extremely dry climate conditions recorded in summer 2021.

Methodology

Site description

Aldermac mine site is located 15 km west of Rouyn-Noranda, in Abitibi-Temiscamingue, Quebec. The mine site was operated for copper and zinc mining from 1931 to 1943. During this period, approximately 1.3 million tonnes of tailings were generated and deposited on approximately 50 hectares and exposed to atmospheric conditions (SNC Lavalin, 2007). The tailings spilled over a surrounding area of 26 hectares along 10 km of Creek 1 and the Arnoux River, following the failure of a dam in 1942 due to the limited means of confining. These tailings contained a significant concentration of sulfide minerals, ranging from 20% to 30% of pyrite and pyrrhotite, and were generating AMD (e.g., pH ranging from 2.3 to 5). On-site observations revealed the presence of a 5 cm to 30 cm thick hardpan, characterized as goethite, jarosite, natrojarosite and gypsum (Bédard, 2000). Heavy metal concentrations (such as iron, copper, and zinc) exceeded provincial legislative criteria, affecting water quality in adjacent receiving environments including the Arnoux River and Lake Arnoux (Mocq and Hare, 2018).

The planning for the reclamation began in 2005 and the reclamation construction was completed between 2008 and 2010. The site was divided into three sectors: the Southern sector with higher elevation, the Intermediate sector, and the Northern sector in a valley. The Southern sector was reclaimed using a landfill cell with the tailings deposited on the surface of a high-density polyethylene (HDPE) geomembrane. The tailings of the Intermediate sector and the spill area were excavated and transported to the North sector.

The selected method for the North sector was the elevated water table (EWT) combined with a monolayer cover. The constitutive material of the monolayer cover was sand and gravel, extracted from a borrow pit directly on the site. The target thickness of the cover was 1 m. The fieldwork included the construction of three dams (F, G, and H in Figure 1) and the enhancement of dam E to maintain the water table positions close to the surface of the tailings. The Northern sector was divided into two sections to optimize the placement of tailings excavated from the spill by a central dam (dam G). Terrace 1 was 3 m higher than the final elevation of Terrace 2. Four spillways were built on dam G to control overflow from

the accumulation areas and the water table position of Terrace 2. After the placement of the cover during winter 2011, differential displacements were observed, and the site was reprofiled by adding additional cover material (except for 5 hectares in Terrace 2 where a swamp formed).

Figure 1: Northern part of the Aldermac site reclaimed using the elevated water table technique combined with a monolayer cover of sand and gravel (aerial photo from Google Earth).
Observation wells T1 to T6 and Station 1 to 4 are shown with blue circles and green squares, respectively

A total of twelve piezometers and observation wells were installed in the Northern area of Aldermac following the reclamation to monitor the groundwater and surface water quality. Six observation wells, labeled T1 to T6, were installed in the cover close to the interface of the tailings to monitor the water table position. The performance of the reclamation method has been evaluated through multiple water level monitoring and water sampling campaigns since 2011 (Maqsoud et al., 2013; Maqsoud, 2017; Maqsoud et al., 2022), and the site continues to be monitored by the Ministry of Natural Resources and Forest of Quebec (MNRF).

Climate conditions at the Aldermac site

The Aldermac site is in a humid climate, and the yearly water balance is positive. The annual climate was estimated using the Daymet method on a 1 km grid (Thornton et al., 2020). The total precipitation, which included snow and liquid precipitation, was on average 910 mm from 1994 to 2023 (Table 1). The minimum annual total precipitation estimated during the monitoring period (2020 to 2022) was 770 mm (2021), which was also the minimum annual total precipitation for the period 1994 to 2023. The maximum total precipitation was 1,030 mm (2022), which was the second-highest total annual precipitation since 1994.

The climate is temperate and cold during the winter. The average temperature for the period 1994 to 2023 was 2.4°C.

Table 1: Annual climate data over the last 30 years (1994 to 2023)

	Total precipitation annually (mm)	Temperature (°C)
Minimum	770 (2021)	-43.1(1994)
Maximum	1,050 (2008)	35.9 (2005)
Average (1994 to 2023)	910	2.4

Monitoring program in the Northern area

The aims of the monitoring program were the evaluation of the cover performance to maintain the water table above the tailings. During the fall of 2020, four instrumented stations (S1 to S4) were installed, close to the observation wells T3 to T6 to characterize the hydrological behavior of the covers. Trenches were excavated to install pore-water pressure probes (Watermark ±1 kPa) and volumetric water content probes (GS3 ±0.03 m^3/m^3) at depths of 30 cm, 60 cm, and 90 cm under the surface of the cover. At Station S1, the probes were installed at 20 cm, 45 cm, and 75 cm due to high water table position. A total of four pressure sensors were placed in the observation well T3 to T6 to continuously monitor the water table level (Figure1). Cover material and tailings were also collected for characterization. The atmospheric conditions data were collected at the meteorological station Rouyn Noranda 15 km from the mine site and compared to the dataset from Daymet (Table 1). The potential evapotranspiration was calculated with Penman-Monteith model using PyDaymet from HyRiver (Chegini et al., 2021).

Material in-situ properties

Tailings were sampled under the cover and their particle size distributions (PSD) were obtained using laser diffraction analysis (Malvern Mastersizer). The PSD of the cover samples was determined according to ASTM D6913 (2021) (Figure 2a). The water retention curves were obtained with the MK model (Aubertin et al., 2003) for both materials (Figure 2b). The in-situ porosity of the cover was determined using a nuclear densimeter, and varied from 0.22 to 0.30 on the site. A significant contrast between the water retention curve (WRC) of the cover and the WRC of the tailings suggested an effective capillary break. The low air entry value (AEV) of the cover can prevent capillary rise, thereby limiting evaporation (Ouangrawa et al., 2010).

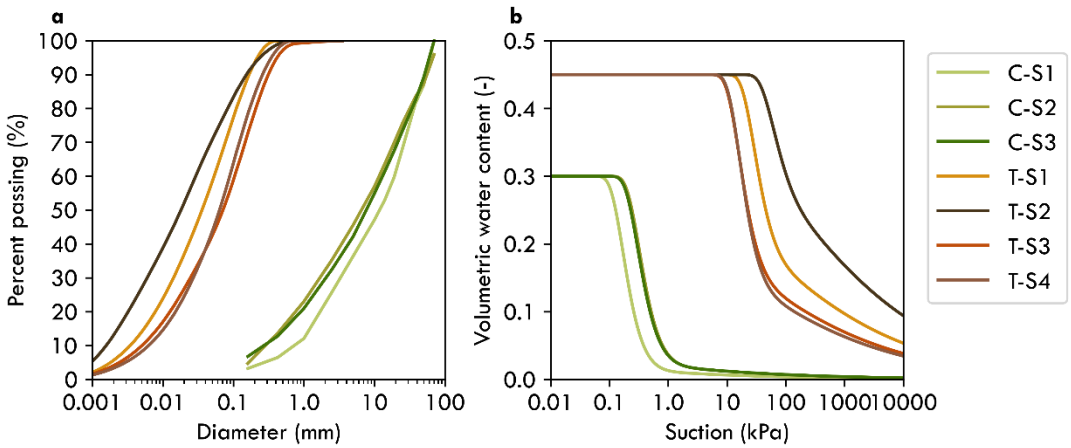

Figure 2: (a) Particle size distribution and (b) water retention curves of the tailings (T) at the stations S1 to S4 and cover material (C) at the stations S1 to S3

Results and discussion

Water table position by manual measurements (2011 to 2023)

The water table position was measured manually over the period 2011 to 2023, initially by URSTM from 2011 to 2015 (Maqsoud et al., 2022), subsequently by the MNRF from 2015 to the present and during this research project from 2020 to 2022. The water table elevation in Terrace 1 was approximately 3 m greater than the water table elevation in Terrace 2. T1 is located downstream of the energy dissipation basin, and T2 is located downstream of the Intermediate Sector basin, separated by dam H. The water table remained close to the surface of the cover as those basins controlled the water table position. In Terrace 2, near T4, a swamp formed because of vertical displacement of the cover and tailings during the early years of the reclamation works (see section Site description above) (Figures 3e and f).

The position of the water table in Terrace 1 was monitored using manual measurements in observation wells T1 to T3 (Figure 3a, b, and c). For T1 and T2, the water table level remained close to the surface and occasionally exceeded the surface level of the cover. Water table elevation in the observation well T3 (Figure 3c) was lower than T1 and T2 (e.g., 0.25 m to 0.45 m; Figures b and c) because of the proximity to dam G, which is built with four spillways to control the water table position in Terrace 2. Fluctuations of +/-0.7 m were observed in observation well T3.

Terrace 2 water level was monitored using observation wells T4, T5, and T6 (Figures 3d, e, and f). The water table elevation in T4 was close to the surface or above the surface during the entire observation period (Figure 3d). Significant fluctuations of the water table position in T5 and T6 (up to 0.9 m) were also observed.

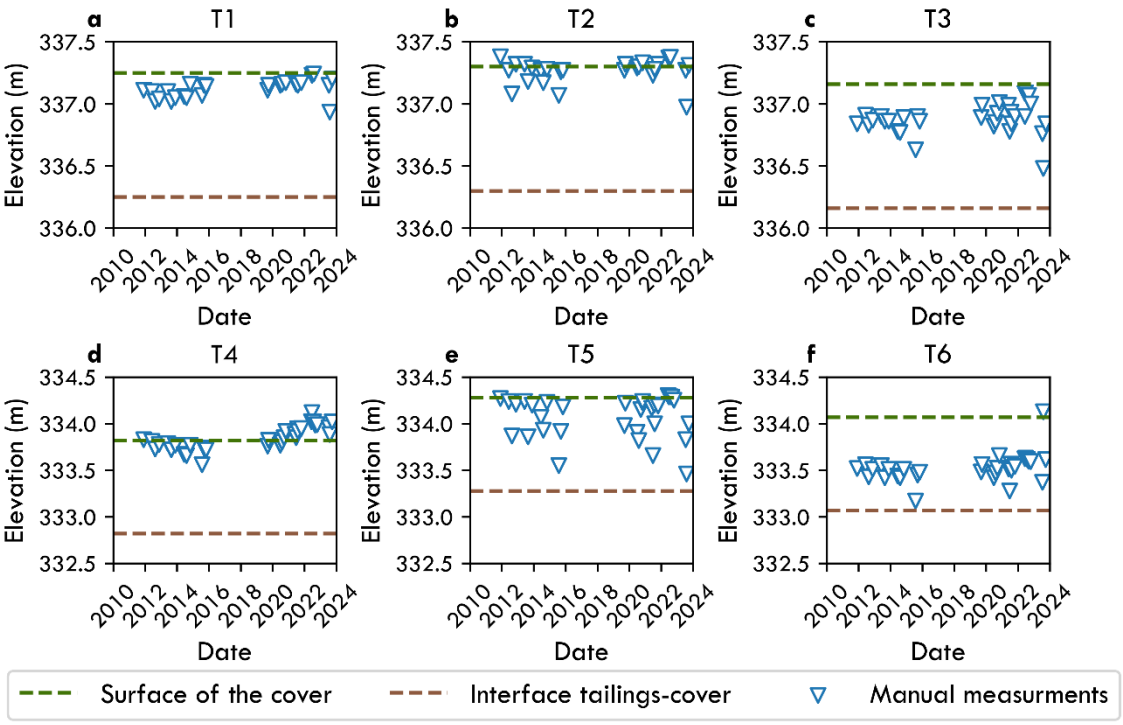

Figure 3: Water table elevation (m) obtained by manual measurements of the observation wells for the monitoring period (2011 to 2023). The dashed brown line presents the tailings interface approximated by Maqsoud et al. (2022) during the installation of the observation wells, and the green dashed line presents the estimated cover surface elevation

The performance of the reclamation method was previously analyzed by Maqsoud et al. (2022) for the 2011 to 2015 monitored period. The manual measurements of the water table level in all observation wells (T1 to T6) suggested that, during this period, the water table was maintained above the tailings, within the cover, which could suggest that direct oxidation of the tailings was efficiently controlled (Maqsoud, 2017; Maqsoud et al., 2022). These findings were correlated with a decrease in electrical conductivity and dissolved elements in the groundwater (Maqsoud et al., 2022), as well as improvement of water quality downstream in the Lake Arnoux just one year after the reclamation of Aldermac mine site (Mocq and Hare, 2018). The manual measurements campaigns conducted between 2016 and 2023 by the MNRF and the authors suggested that the water table has remained above the tailings, and within the cover since its reclamation. This indicated that the tailings remained saturated (Figure 2b) and the reclamation was deemed efficient.

Continuous monitoring of the water table (2020 – 2022)

The water table elevations were measured continuously in the observation wells T3, T4, T5, and T6 from 2020 to 2022. The year 2021 was the driest recorded in the past 30 years (total annual precipitation

770 mm), while 2022 had above-average yearly precipitations (1,030 mm). A significant difference in the water table elevation was observed between 2021 and 2022. For example, near station 1 during the summer of 2021, the water table in T3 ranged from 336.6 m to 337.1 m with significant variations of 0.5 m. In contrast, during the summer of 2022, the water table remained close to the surface of the cover at 337.2 m, with significantly smaller amplitudes of maximum 0.2 m (Figure 4a). The same trend was observed in observation well T5 near Station 2, although greater amplitudes were recorded in 2021 (e.g., 0.9 m; Fig 4b).

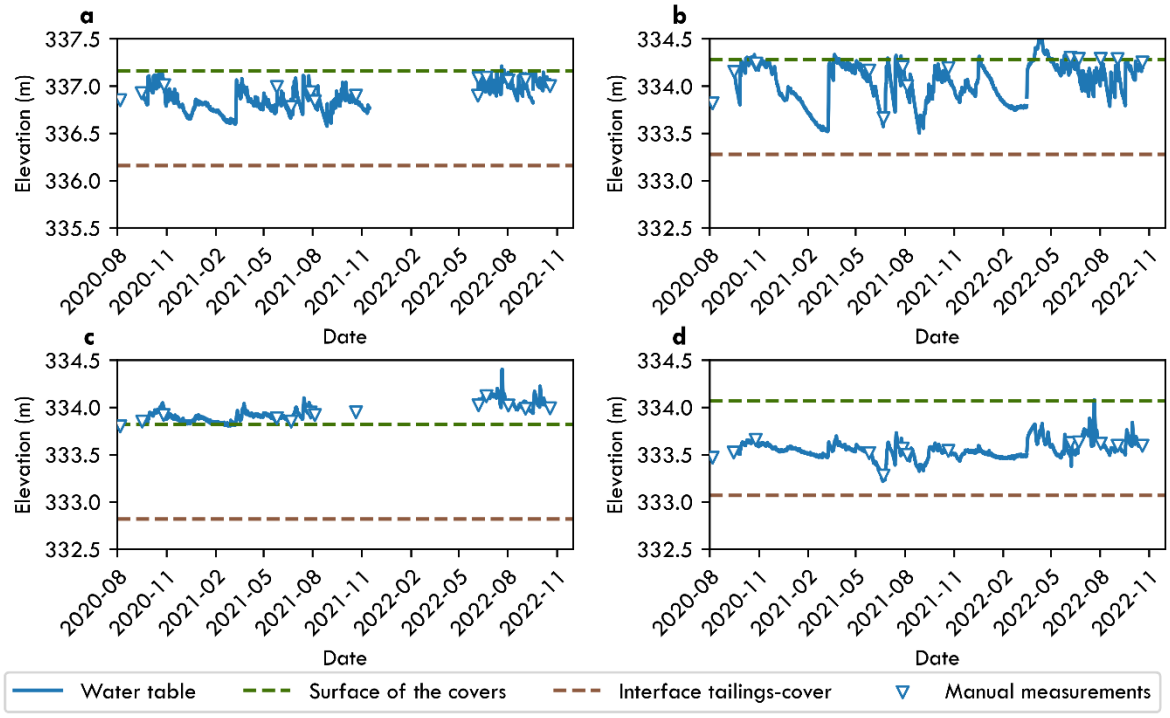

Figure 4: Continuous water table elevation in observation well at Terrace 1 a) T3 (Station 1), and at Terrace 2 b) T5 (Station 2) c) T4 (Station 3) and d) T6 (Station 4).
The gaps of measurement of the water table in a) and c) are due to equipment failures

The water table was continuously above the cover in the observation wells T4 (Figure 4c). The water table elevation in the observation well T6, which is located near the final effluent, remained above the interface of the tailings for the monitoring period, although the water table significantly decreased during the summer of 2021 (Figure 4d). The monitored period revealed that the water table elevation was intrinsically sensitive to the climatic conditions, as a great increase of the water table elevation was observed on-site.

Dry years (2021)

From spring to the fall of 2021, two months, May and August, were characterized by a potential water deficit period where precipitation fell below the potential evapotranspiration (PET) (Table 2). August was particularly dry, with total precipitation of 47 mm, an estimation of 93 mm of PET, and a maximum of 15

consecutive days without precipitation. During this period, the water table in the observation wells decreased by 0.6 m in T5 in Station 2, 0.4 m in T3 in Station 1 and 0.3 m in T6 (Figure 5). The water level remained above the cover in T4, near station 3, so the results are not presented here.

Table 2: Precipitations and PET comparison from May to September

	Rainfall (mm)	Estimated potential evapotranspiration (mm)	Maximum number of consecutive days without precipitation	Date
May	61	75	5	26 to 30
June	116	85	4	14 to 17
July	136	90	6	7 to 12
August	47	93	15	13 to 27
September	119	53	3	1 to 3, 18 to 20, 28-30

Generally, the water table at Stations 1, 2, and 4 were sensitive to periods of precipitation and evaporation (Figure 5). For example, the water table level at Station 2 (T5) and at Station 1 (T3) rose by approximately 0.7 m and 0.6 m, respectively, after an intense rainfall of 50 mm on July 15th. The water table at Station 4 (T6) was at the lowest elevation of the North sector, with a depth of 0.4 m to 0.5 m from the surface of the cover, and exhibited smoother increases in response to periods of rainfall and evaporation.

The volumetric water content in the probes at the bottom of the cover remained at saturation in all Stations 1, 2, and 4 (red line; Figure 5), as the water table level remained above the probes throughout the period. In Station 1 and Station 2, the water table was generally above the middle probes, positioned at depths of 0.45 m and 0.6 m respectively, with occasional measurements at greater depth corresponding to a decrease in the volumetric water content (orange line; Figure 5). In Station 4, the water table fluctuated between depths of 0.4 m to 0.8 m, resulting in periods of saturation and periods where volumetric water content decreased as observed in the middle probes. Finally, the volumetric water content of surface probes (purple) was near saturation when the water table was increasing after rainfall, and remained at residual volumetric water content when the water table was deeper than the probes.

Therefore, during a particularly dry year, the water table remained above the interface between the tailings and the cover, which indicates that the cover effectively maintained saturation in the tailings by preventing evaporation, thereby minimizing the direct oxidation of the tailings. However, the results showed that the water table is sensitive to an extensive period of evaporation and drainage as the water table decreased between 0.3 m to 0.9 m during a period without any rainfall, or with low rainfall. The low AEV of the cover maintained a capillary break, and therefore no capillary rise to the surface, which did reduce the evaporation.

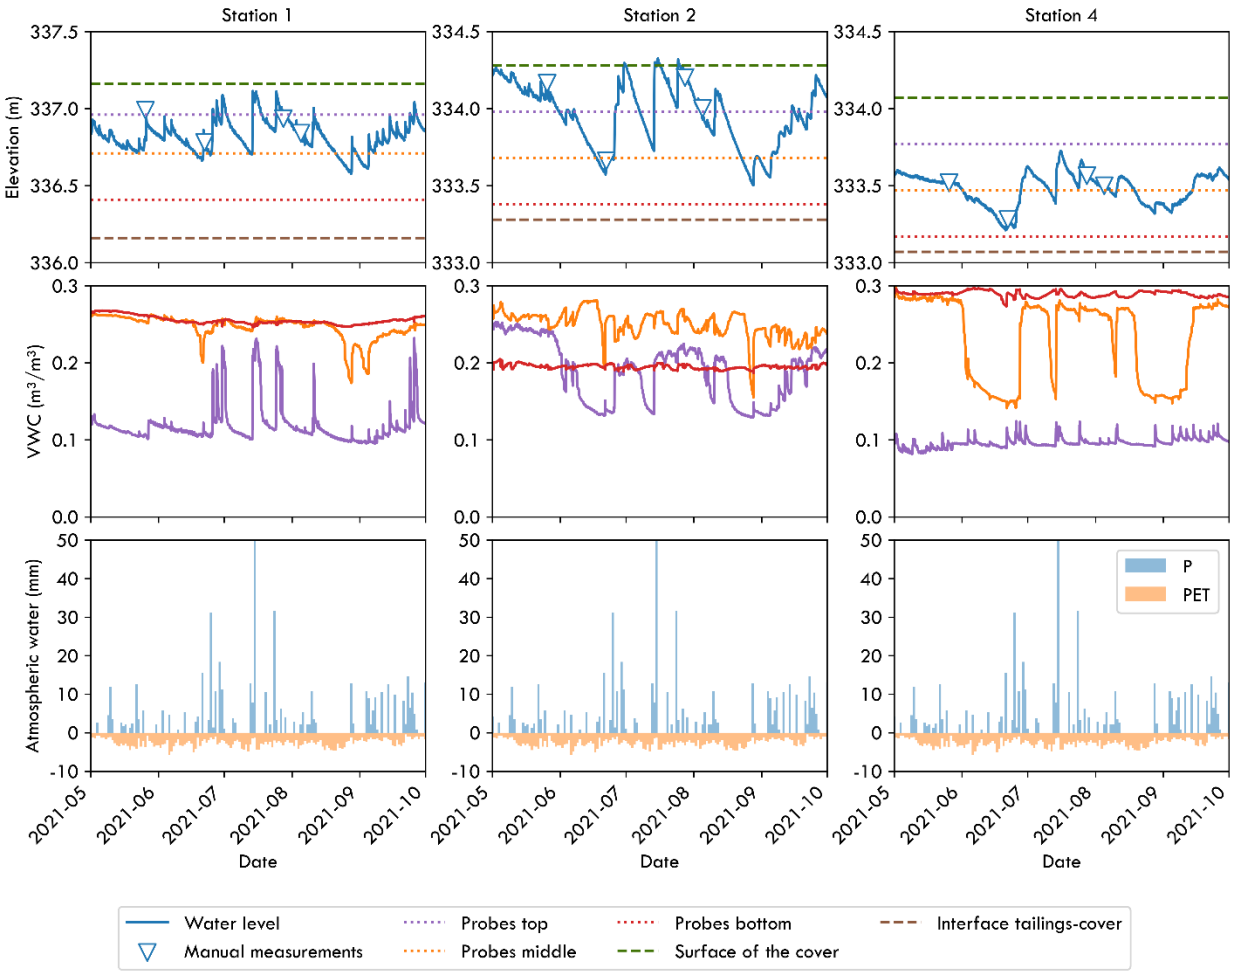

Figure 5 : Evolution of the water table elevation (m), volumetric water content regarding the atmospheric water balance of precipitation (p) and potential evapotranspiration (PET) of Station 1, 2 and 4

Conclusion

The water table at the Aldermac site was raised in the cover to control AMD generation of the pre-oxidized tailings. The water table level was maintained above the tailings from 2011 to 2023, as shown by the manual measurements campaign. Continuous measurements of the water table level and the volumetric water content were performed at four stations for 2020 to 2022, providing insights into the amplitude of the water table fluctuations. Specifically, an analysis of the water table and the volumetric water content during the driest recorded year (770 mm of total precipitations) since 1994 indicated that the water table remained above the tailings, which suggests the importance of the coarse-grained layer to prevent excessive evaporation. However, during the intense period of drought in August 2021, the water table decreased by 0.4 m to 0.7 m in the Stations 1, 2 and 4, which indicated the sensitivity of the water table regarding the period of water deficits. Future work involves modeling climatic scenarios to assess the performance of the cover during periods of intense droughts.

Geotechnical Failure of a Waste Rock and Heap Leach Facility at the Bellavista Gold Project

Terry Braun, SRK Consulting, USA

Abstract

On October 24, 2007, a slow-moving landslide damaged an active waste rock stockpile and a "downstream" gold heap leach facility. The deep-seated landslide under the waste rock stockpile and heap leach facility involved approximately 35,000 cubic meters of material. The combined failure resulted in permanent shutdown of the open mine after two years of operations. The contributing factors to the failure included insufficient investment in geotechnical characterization of the foundation below the waste rock stockpile, disputed interpretations of the complex geomorphology and geologic conditions underlying the site, limited emphasis on the engineering design of the waste rock stockpile, surface water and groundwater management challenges associated within a high rainfall environment, and ineffective technical communications within the owner and external project teams.

This paper evaluates the applicability of the observational method relied upon during the design-build process for the waste rock and heap leach facilities at the Bellavista Gold Mine. The paper also explores various governance aspects and engineering design and oversight failures that contributed to the geotechnical failure.

Introduction

The Bellavista Gold Mine, located near Miramar, Costa Rica, started operations in 2005 as a 4,500 ore tonnes per day open pit gold operation, heap leach facility (HLF), and waste rock stockpile. Table 1 presents the project milestones leading to and following the geotechnical failure. Figure 1 presents the general layout of the facilities. The October 2007 deep-seated landslide damaged the HLF and process plant after two years of commercial operations. Figure 1 also shows the approximate extent of the deep-seated failure area. Rapid movement of the landslide stopped by the end of November 2007. No lives were lost and Glencairn Gold (Glencairn) reported no release of cyanide into the environment. Glencairn and successor entities continued geotechnical monitoring of the post-failure landscape for several years. Monitoring included water quality sampling upgradient, on-site and downgradient in the watershed, in coordination with the responsible governmental authorities.

Table 1: Bellavista project milestones

Date	Milestone
June 29, 2005	Glencairn announces first gold pour and plans to ramp-up the open pit and heap leach operation to a design rate of 60,000 ounces of gold per year.
Mid-2006	Glencairn commissioned design of "uphill" expansion of the HLF.
2006 Annual Financial Report	Cumulative total of 1.67 million tonnes (3 million cubic meters) of heap leach ore under active leach. Approximately 2.9 million tonnes (5.2 million cubic meters) of waste rock in the stockpile
Q1 2007 Report	Quarterly gold sales of 10,475 ounces, contributing to the life of mine gold sales of 53,055 ounces and revenue of US31.8 million.
July 27, 2007	Glencairn announces suspension of mine operations due to concerns over recent ground movements. 33% decrease in market capitalization of Glencairn (TSX:GGG).
August 14, 2007	Glencairn confirms rinsing the HLF as a precautionary measure to reduce cyanide in the HLF and announces the start of an extensive ground monitoring program.
September 13, 2007	Glencairn announces that a deep-seated ground creep had occurred between the processing plant and the HLF.
October 24, 2007	Glencairn reports an overnight landslide, resulting from ground movement and continuing heavy rains, which caused significant damage to the structure of the gold recovery plant.
December 2010	Central Sun Mining (successor to Glencairn) filed a conceptual study to re-start mining operations with new off-site infrastructure and flotation-type metallurgical process technology.

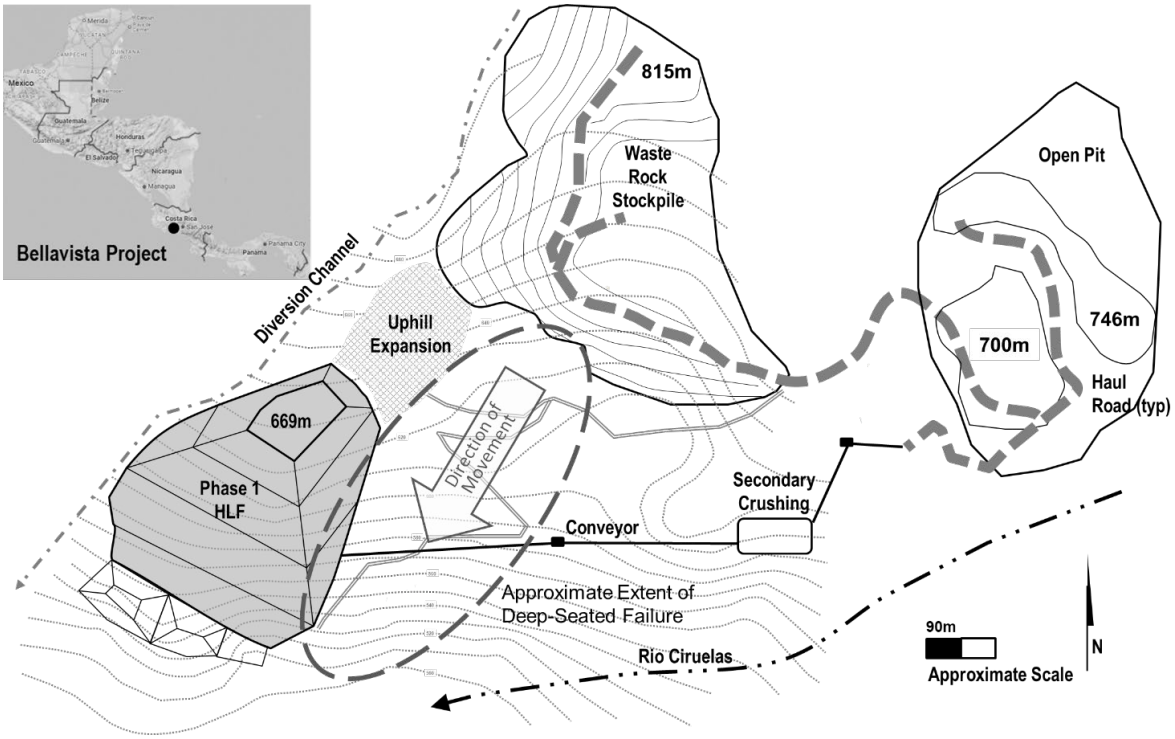

Figure 1: Site location and general layout

Within a few years after the failure, successor entities to Glencairn brought a lawsuit that named multiple design firms involved in the Prefeasibility and Feasibility Studies for the Project and the detailed design of the HLF. All claims were settled by November 2017.

Financial perspective

Glencairn acquired the Bellavista project on October 31, 2002, through issuance of 750,000 common shares (valued at CAD 240,000) and CAD 140,000 in cash. On October 17, 2003, Glencairn acquired the El Limon mine, an existing 1,000 tonnes per day underground gold mine in Nicaragua. Glencairn funded both acquisitions and subsequent capital investments through a series of equity financings in late 2003 and 2004.

Equity finance is common in the junior mining sector. It allows mining companies with limited cash resources and limited ability to service debt to finance project acquisition or development through the issuance of new equity shares. This method of finance dilutes the equity ownership of existing shareholders with the strategy that the associated acquisition or development activities increase total equity value at a higher rate than the dilution incurred, generating net shareholder value. Successful junior mining companies typically focus on the advance and/or delivery of development projects, which often includes the requirement to raise significant funds. During the project development and delivery phase, junior mining companies manage primary technical, financial, and schedule risks through the efficient use of capital. Projects that require unforeseen capital investment or experience production delays are part of the risk profile of investors in the junior mining sector. Delays or cost overruns commonly trigger additional equity raises, which dilute shareholders at a faster rate than the associated value-add activities, and can result in net value destruction for shareholders.

In 2003, Glencairn planned to build the Bellavista mine while operating the newly acquired El Limon mine. This business strategy offered equity investors a degree of confidence with potential financial returns from an operating gold mine and the near-term delivery of the Bellavista project that would match, and then exceed, the annual gold production from El Limon.

Project development

The Bellavista gold deposit is in the Tilarán-Montes del Aguacate gold belt, a 100 km long by 30 km wide region in the western part of the San José Quadrangle. The mine site is approximately 70 kilometers northwest of San Jose and 3 kilometers northeast of the town of Miramar, a district of the Montes de Oro canton in Costa Rica. Mining activity started pre-World War I with a 100 tonnes per day stamp mill and cyanide vat leaching process. Artisanal mining took place through the 1950s. Junior Canadian companies started work on the property in the 1970s (PAH, 2002).

Ownership history

Wheaton River Minerals (Wheaton) advanced the project to the feasibility level in April 1999, held, and then sold the project to Glencairn in 2002. Glencairn commissioned a National Instrument 43-101 Technical Report for the project in December 2002 (PAH, 2002). Glencairn obtained the financing to fund the project in 2003 and started construction in early 2004. In November 2007, Glencairn became Central Sun Mining, which was purchased by B2Gold in April 2009.

Physical setting

The topography surrounding the mine site varies from less than 100 meters above sea level to over 1,000 meters in the northern part of the mine property. The average elevation of the mine site is 750 meters. The Ciruelas River lies near the southern boundary of the property and is the primary drainage for the sub-basin that contains the mine site. The region is seismically active. The University of Costa Rica estimated the maximum credible earthquake as Richter magnitude 7.0 on the Barranca fault, which is at a distance of 11 km from the site.

Geology

The Costa Rican Gold Belt includes the Montes de Oro District, which hosts the Bellavista epithermal gold-silver deposit. PAH (2002) described three lithologic units in the project area. The underlying Tilarán Group forms the bedrock over approximately 80% of the project area. The Liz Fault is the most dominant structural feature at Bellavista and is pre-Monteverde Formation (Alan et al., 1992).

The Monteverde Formation unconformably overlies the rocks of the Tilarán Group and consists of interbedded andesitic lava flows, pyroclastic rocks, ignimbrites, and lahars. The volcanic sediments were deposited in paleo-topographic lows on an undulating bedrock surface composed of the weathered rocks of the Tilarán Group. The Monteverde Formation outcrops mainly in the north and north-western part of the project area.

Figure 2 shows the exposed lahar contact at the site. PAH (2002) described the base of the Monteverde Formation as a lahar unit consisting of large round and subangular blocks of varying igneous composition deposited on an irregular surface of Aguacate rocks (Alan et al., 1992). This basal sequence is up to 80 meters thick in the Bellavista project area.

Geomorphology

The dominant topography in the project area exhibits flat-undulated and flat-concave slopes followed by rough or very rough and steep hills. PAH (2002) reported a thick weathered horizon of bedrock due to tropical weathering and high annual rainfall. Site data indicate that the bedrock surface is weathered to

depths of between 10 and 40 meters depending on location. As a result, non-weathered outcrops of bedrock are mainly confined to locations within steeply incised drainages.

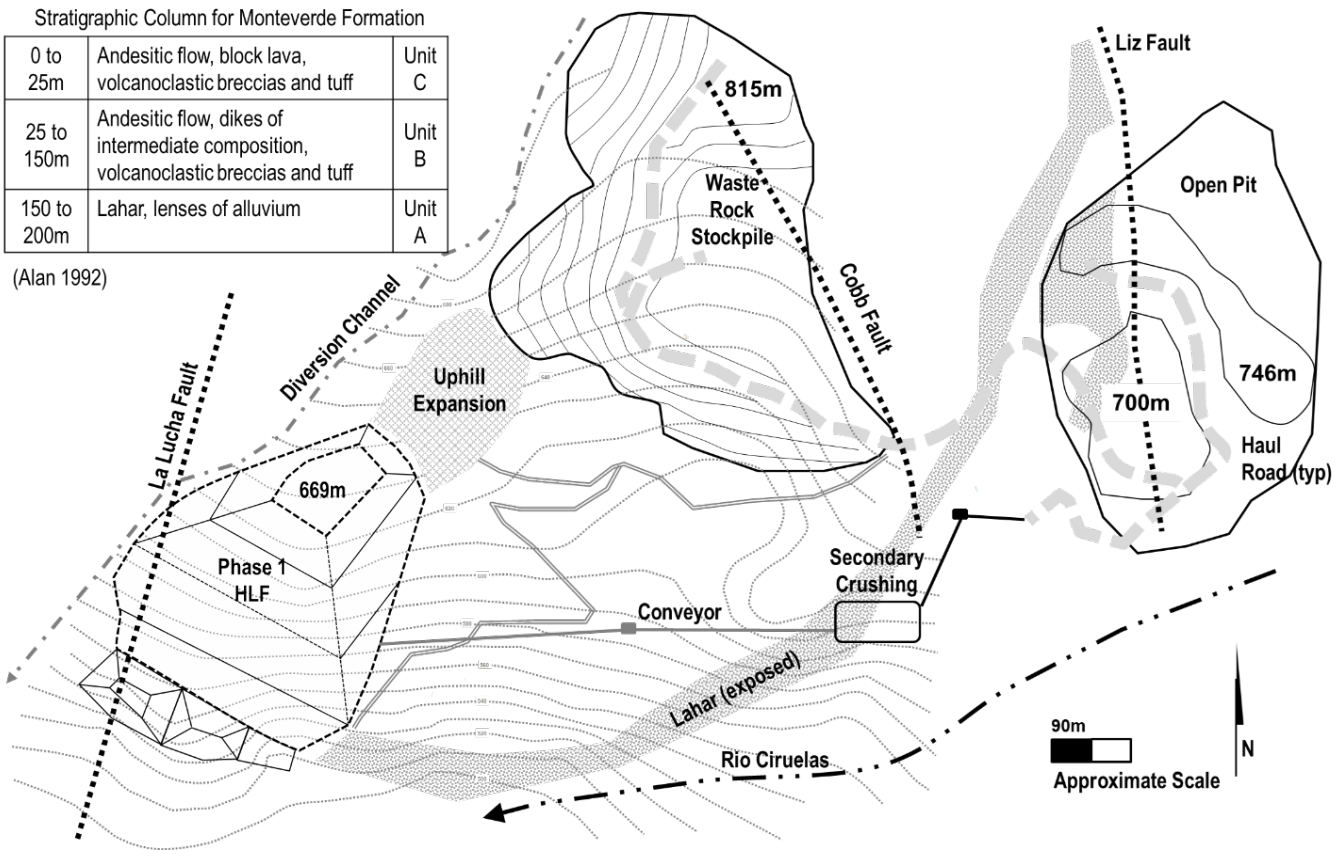

Figure 2: Site geology and structure

Pre-design site work included the review of aerial photography of the waste rock stockpile site. This geomorphological interpretation of the terraced topography suggested a large landslide. Geologic mapping, combined with drilling and geophysical data, indicate the Monteverde Formation consists of inter-layered pyroclastic tuffs, lahars, and breccias. Under this geomorphological interpretation, the terraced topography was due to rapid and deep weathering of the bedrock surface coincident with recent faulting. These contrasting interpretations led to uncertainty in the conceptual geotechnical model.

Hydrogeology

Within the project area, the Monteverde Formation contains groundwater within fractured lava flows and brecciated areas. This formation includes an intermittent clay matrix that contributes to the isolation of saturated zones. The twelve springs in the vicinity of the waste rock stockpile and HLF occur near the Monteverde-Tilaran contact. Outflow from the Monteverde Formation feeds two perennial springs (Montezuma 1 and 2) east of the HLF and south of the Waste Rock Stockpile.

Heap leach facility and waste rock stockpile

The Feasibility Study (1999) presented the Phase 1 HLF detailed engineering design and a future, conceptual phase as a lateral, eastward expansion of the Phase 1 HLF. The presence of the Montezuma Springs within the proposed second phase footprint removed this concept from further consideration. The Phase 1 Detailed Engineering design included approximately 3.2 million tonnes of ore (5.76 million cubic meters), stacked in 21 lifts to a top heap elevation of 680 meters.

The Feasibility Study for the waste rock stockpile contemplated an ultimate storage capacity of approximately 14.9 million tonnes. The average strip ratio for the first 2.5 years of operations was 1.75 (Wheaton, 1999); therefore, the required waste rock stockpile capacity associated with the Phase 1 HLF was approximately 5.6 million tonnes (10.08 million cubic meters). The Feasibility Study included a conceptual layout of the waste rock stockpile. There was no detailed engineering design of the waste rock stockpile.

The project went on hiatus between 2000 and 2002 until Wheaton sold the project to Glencairn, who re-started project development in mid-2003. Waste rock stripping activities and Phase 1 HLF construction commenced in late 2003. The mine operations team scheduled and placed waste rock in accordance with the mine plan developed by the owner's team.

Glencairn announced completion of the Phase 1 HLF in late 2005 and, in 2006, commissioned detailed engineering for an uphill expansion of the HLF (avoiding the footprint of the proposed Phase 2 HLF). Construction of the uphill expansion started in early 2007. Braun (2022) provided a more detailed timeline which highlighted the challenges of maintaining an integrated knowledge base with transitions in project ownership and multiple external engineering firms.

HLF design

For the Bellavista project, an external Engineer of Record (EOR) oversaw construction of the Phase 1 HLF and design of the uphill expansion. The design firm of the EOR provided field construction quality assurance (CQA) during Phase 1 HLF construction. The design firm de-mobilized their field CQA staff following construction of the complete Phase 1 HLF lined footprint and surrounding engineering controls. Field staff for the design firm returned to the site for the uphill expansion project.

The design firm for the Phase 1 HLF and uphill expansion provided a HLF Operations Manual. This document provided guidance related to loading of the pad, construction sequence for pad development and stacking through the life of mine. The manual included survey monitoring requirements, piezometer monitoring and normal operating ranges for monitoring results. Glencairn's contract miner, under the supervision of the operations team, placed ore on the Phase 1 HLF. Glencairn's operations team collected and reported operational monitoring data.

Waste rock stockpile design

The design of waste rock stockpile started with the volumetric requirements, the geochemical characterization of the material and the site layout defined in the 1999 Feasibility Study. The owner's team assumed responsibility for site preparation, scheduling and placement of waste rock. The owner requested technical support from the HLF engineers of record and the pit slope design consultant during operations and construction of the waste rock stockpile. Unlike the Phase 1 HLF or uphill HLF expansion, the waste rock stockpile did not have a designated engineer of record.

Pit slope design

While the pit slope design consultant and owner's team anticipated, encountered and ultimately mitigated the geotechnical challenges posed by the lahar contact in the northwest open pit, this experience did not translate into a better understanding of the conceptual geotechnical model for the waste rock stockpile and HLF. When viewed as a lesson learned, this missed opportunity was a failure to integrate the site knowledge base.

Conceptual geotechnical model

Hawley and Cunning (2017) describe the conceptual geotechnical model during the initial site selection as a combination of site geology, geochemistry, hydrogeology and hydrology. As the project moves from conceptual to prefeasibility to feasibility level, the geotechnical model progresses from conceptual to preliminary to advanced. At the preliminary feasibility study level for site selection, site characterization work supports preliminary stability analyses and site selection while the feasibility study level defines stability criteria for the advanced stability analysis and supports the final site selection. The detailed design is an optimization process, including year by year stability assessments as the facility is built. Hawley and Cunning (2017) note that much of the necessary data are collected at stages throughout the process and site selection inevitably becomes an iterative process.

The Feasibility Study and Environmental Impact Study for the Bellavista project incorporated site characterization work through 2000. The study team developed a conceptual geotechnical model and conducted 2-D stability analyses of sections through the waste rock dump and through the heap leach facility. Over the course of the PFS and FS, the 2-D stability analyses included variable water tables in the underlying Monteverde Formation.

During the Phase 1 HLF design, the design team used site sampling and test work to assign strength parameters to the upper Monteverde Formation. The owner and design team debated the presence of potential deep-seated failure surfaces (within the Monteverde Formation and/or within the weathered interface zone of the upper portion of the Tilarán Formation) shown in Figure 3. The limited vertical and

horizontal extent of geotechnical investigation led to uncertainties in geologic interpretation of the interface between the Monteverde and Tilarán Formations as well as uncertainties regarding the strength parameters for the two units and the weathered interface zone.

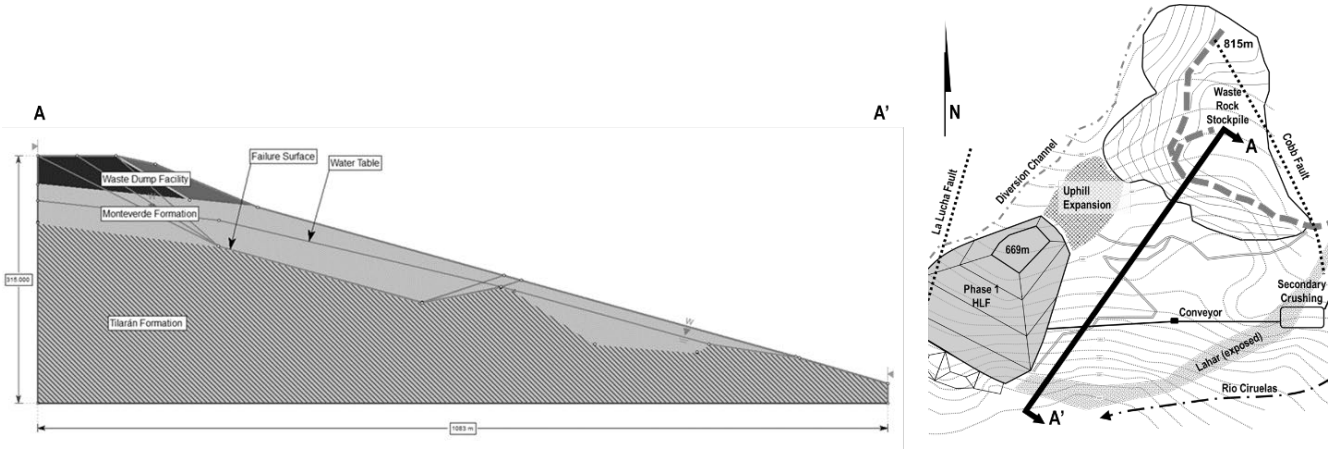

Figure 3: Conceptual geotechnical model

At the time, the design firm, owner and third-party engineer postulated that the Observational Method approach, when combined with potential modification of the HLF design and specification of monitoring systems, would allow the waste rock dump and HLF to be built, operated and closed safely despite the uncertainties in the foundation characterization at the time of project development. This sequence of decisions also assumed a slow-moving deep-seated failure could be mitigated with adequate monitoring and sufficient notice to implement a contingency plan.

Observational method and mine waste facility design

Chapter 41 of the Tailings Management Handbook (TMH) (Morrison, 2022) states the "application of the observational method is a carefully orchestrated **proactive** process" that requires "continued engagement and consistent attention." These authors reiterate this method "allows the mining community to move closer to monitoring the "critical issues" and allows proactive responses to monitoring results". When applied to tailings facilities, the proactive process requires the geotechnical engineer to transform a potentially complex foundation stratigraphy into a simplified site model and consider site-specific design criteria, including the change in load of the facility over time and the potential interaction with adjacent facilities.

Peck's (1969) framework for the observational method includes the assessment of the most probable conditions and the **most unfavorable conceivable deviations** from these conditions. This assessment leads to selection, in advance, of a course of action or modification of design for "every foreseeable significant deviation" of the observational findings from those predicted. Morrison (2022) also references four key

requirements by Powderham (1996) for successful application of the observational method, including the requirements that design alterations are possible during construction and that monitoring can identify trends in "separate key construction-induced events from background to secondary effects."

Original implementation

The three-year delay between completion of the detailed engineering design for the Phase 1 HLF and the re-start of detailed planning and mobilization in late 2003 was long enough for meaningful turnover within the technical and operational teams, including the handover from Wheaton to Glencairn in late 2002. Where there was continuity in the technical team, the ability to build and maintain the integrated knowledge base was limited. Braun (2022) notes the geotechnical model of the open pit was sensitive to the geologic contact of the Tilarán and Monteverde Formations. The incumbent geotechnical consultant factored this observation into the design of the north walls of the open pit from the start of pit operations.

HLF and waste rock stockpile construction commenced around the same time as the open pit. The owner construction team retained a contract miner for open pit and waste rock operations and site surface water infrastructure. The new HLF design firm provided field construction quality assurance.

The as-built field monitoring program included conventional survey prisms on and adjacent to the HLF, water level measurements in piezometers installed at the base of the HLF, water level measurements in shallow groundwater monitor wells upgradient and downgradient of the facilities and daily inspections of construction activities. Field crews surveyed the prisms on a manual basis. Field technicians monitoring groundwater levels in monitoring wells upgradient and downgradient of the HLF and waste rock stockpile. Construction started in the dry season and carried into the wet season. Field quality control measures at the HLF included subgrade inspection and conventional destructive and non-destructive testing of the liner material. Contractors cleared organic matter and installed drains at the bottom of the waste rock stockpile prior to placement of waste rock.

Surface water management relied on temporary and permanent diversion channels and ponds to facilitate construction activities. Figure 4 presents the conceptual surface water management system. Daily field reports during the wet season emphasized the day-to-day challenge of surface water management to maintain effective working platform for liner installation and equipment access. Given the heterogeneity of the Monteverde Formation, surface water precipitation at a given location would either recharge or runoff rapidly. Construction related surface water management likely increased recharge into the Monteverde Formation relative to pre-mining conditions. This excess recharge would have increased the saturation of the lahar contact with the Tilarán Formation.

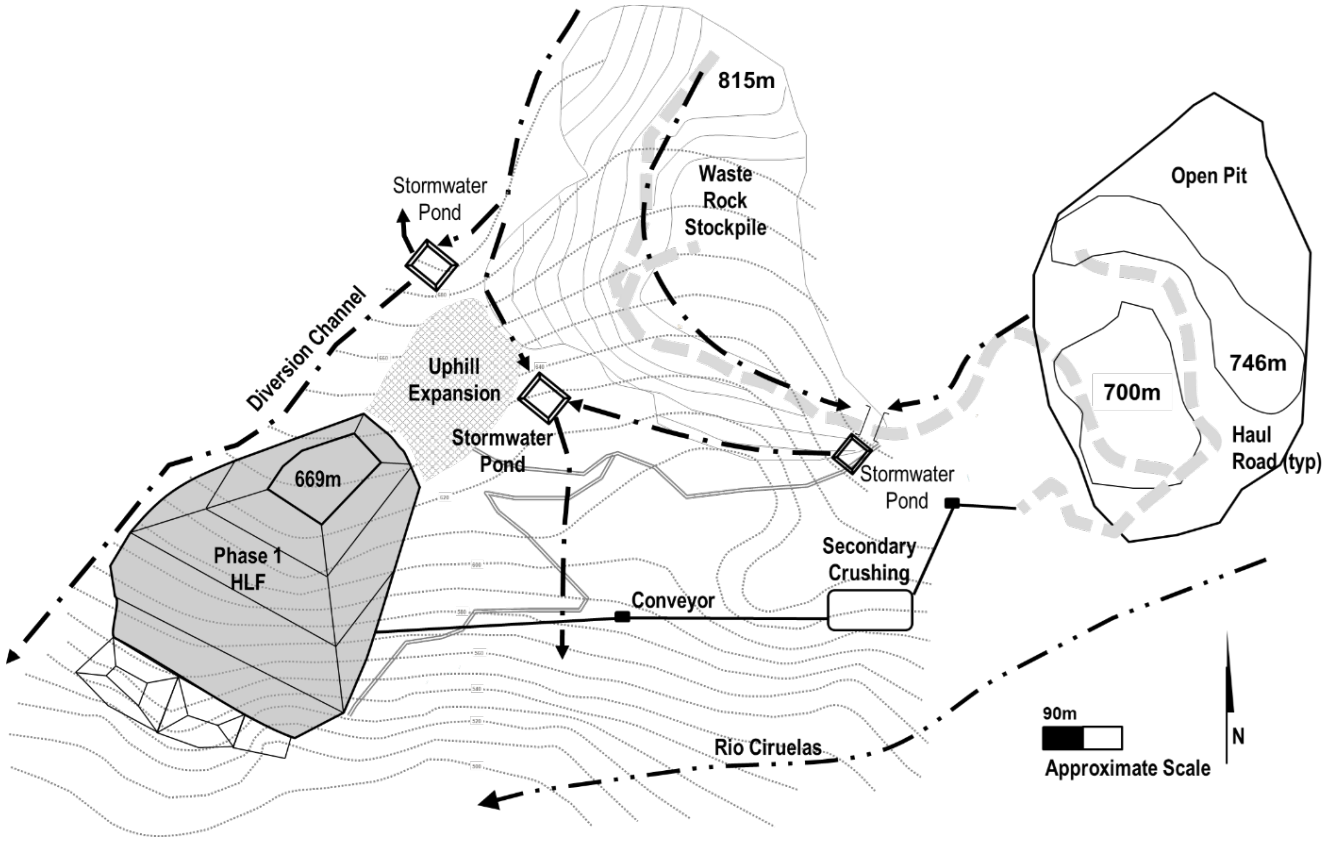

Figure 4: Conceptual surface water management system

Remedial measures

Given the deep-seated nature of the landslide, the report of initial ground movement between the processing plant and HLF, and the size of the waste rock stockpile above the landslide zone, the author assessed three types of remedial measures to mitigate the risk of the deep-seated failure:

- **Water Control:** improve hydraulic control of the saturated zone within the Monteverde Formation, including upgraded surface water controls to reduce enhance recharge in disturbed areas and use of shallow dewatering wells
- **Waste Rock Stockpile Unload:** reduce the waste rock mass in the credible failure zone
- **Engineered Buttress:** design and build a structural buttress near the toe of the credible failure zone

Table 2 summarizes each scenario for this screening level assessment. The precursor monitoring period starts once the monitoring plan detects the potential failure condition. The design-construct period is the estimated duration to design and implement the contingency measure.

Table 2: Remedial measures for potential mitigation of deep-seated failure

Scenario – goal	Description	Pre-cursor monitoring period	Design-construct period
Water Control: improve hydraulic control of the saturated zone within the Monteverde Formation	Upgrade surface water controls to reduce enhance recharge in disturbed areas	Timing subject to integration with construction planning and production scheduling	3 to 6 months with construction in December and March (dry season) Operations and post-closure
	Install shallow dewatering wells	3 to 6 months of site characterization and public consultation related to protection of Montezuma I and II springs	6 months to complete installation and surface works Operations and potentially post-closure
Waste Rock Stockpile Unload: reduce the weight of waste rock stored in the credible failure zone	Consider in-pit disposal with potential reduction of mine life	6 months to assess viable alternatives; additional 12 to 24 months to amend operating license	3 months for mine plan revisions
Engineered Buttress: increase the resistance to ground movement near the approximate toe of the credible failure zone	Subsurface structure anchored in bedrock or engineered embankment to restrict ground movement	6 to 12 months for site characterization and analysis 12 to 24 months to amend operating license	9 to 12 months

Improved hydraulic control of the saturated zone within the Monteverde Formation would offer the fastest implementation and short-term benefit in terms of managing the upper water table at or below pre-mining levels. Shallow dewatering wells below the waste rock stockpile could pose a potential risk to the perennial flows at the Montezuma I and II springs and, potentially, an indefinite obligation to operate and maintain.

Waste rock stockpile unloading would require an alternative storage location for relocated material and for future waste rock materials. Haul distances could increase. A new location would likely require a siting study, site characterization, application to amend existing permits, and mine plan revisions. If in-pit disposal is considered, the mine life could be curtailed if mine scheduling could not accommodate the required storage volume.

The engineered buttress would carry the most significant upfront capital. The precursor period would involve geotechnical characterization of the foundation conditions in the vicinity of the exposed lahar surface. This effort would include re-use of inert waste rock materials, where possible, and development of borrow materials for the buttress fill. Following development of the engineering design, construction of the buttress would require an application to amend existing permits.

This simplified assessment of remedial measures includes a wider possible range of design alterations to potentially mitigate the risk of a deep-seated failure. These design alterations carry additional initial cost

for site characterization and design work. In addition, the time required for permitting and construction would likely curtail or stop mine operations. Once mine operations re-started, the mineral reserve statement for the project would be impaired. The additional cost, the potential for curtailment or suspension of mine operations and likely reduction of mineral reserves are material business risks for a junior mining company working toward profitability.

Governance

The *Guide to the Management of Tailings Facilities* (MAC, 2021) and the Global International Standard for Tailings Management (GISTM, 2020) re-opened and updated the governance associated with design, operations and closure of tailings facilities. In terms of governance, these guidelines identify the importance of accountability in the owner's management team, of a designated design professional, and of a facility-specific Operation, Maintenance and Surveillance Manual. GISTM emphasizes the role of an integrated life-of-asset knowledge base to inform and guide the owner and design professionals during personnel transitions or asset transition from operations to closure. These tailings-related governance items are relevant to HLF and waste rock stockpile design.

Conclusion

The external design firms and the successive ownership's technical team offered substantive project experience relevant to the Bellavista project. The coordination and continuity challenges during project development and construction contributed to underlying technical uncertainties in the conceptual geotechnical model and in the interpretation of the monitoring program, including the relevant operational learnings from pit slope instability. Early recognition of this uncertainty and conceptual development of a wider range of critical controls was a missed opportunity. Further, the engineering design process for the waste rock stockpile lacked continuity of responsible oversight.

The author suggests the original monitoring plan for the HLF could have provided sufficient warning for the owner to conduct emergency HLF rinsing and to assess more substantial remedial measures. These remedial measures would require additional initial cost for site characterization and design work and permitting/construction timelines that would likely curtail or stop mine operations. Once mine operations re-started, the mineral reserve statement for the project would be restated and likely be impaired.

Equity markets react negatively to material disclosures such as suspended operations and/or reduction of mineable reserves. These are material business risks for a junior mining company and many companies in this situation successfully disclose, adopt, and implement a recovery plan. In July 2007, the only viable remedial plan for the Bellavista property was an accelerated permanent shutdown. If the project team had identified timely and viable alternative remedial measures for the worst-case deep-seated failure scenario,

the owner could have stopped production, implemented the remedial measures and followed a staged return to production. In retrospect, Glencairn, as a junior mining company, needed to prioritize mitigation of some operational risks over others during development and operations at the Bellavista property. As a result, the risk of the deep-seated geotechnical failure scenario near the HLF and Waste Rock stockpile was understated in the project risk register.

Abstract

Tailings hydraulically disposed are prone to gravity separation processes throughout reservoir occupation, which brings high complexity to the disposal model in terms of predictability of occupancy and operational quality control. Initial design conditions based on laboratory tests may present limitations in response reliability over years of operation, given the large number of variables impacting the behavior of tailings in disposal, such as: ore characteristics; comminution process stability; discharge flow rate; solids content in slurry; and specific weight of minerals. The vast array of variables can impact the robustness and quality of the Tailings Disposal Plan, aimed at maximizing volumetric occupancy.

Salobo Mine implemented the PDCA (Plan, Do, Check, Act) methodology, to systematize data acquisition methods, modeling, and operational management (Control + Key Performance Indicators – KPIs) of copper tailings disposal at the Mirim Tailings Dam. The Mirim Dam currently has 110 Mm^3 of accumulated tailings and will, at the end of its useful life, store 758 Mm^3 after the extraction of approximately 1 billion tons of copper. It is expected to become the largest tailings dam in Brazil.

Topobathymetric data acquisition is routinely conducted to assess the evolution of tailings disposal. Aerial surveys are conducted using a DJI Phantom 4 RTK drone and bathymetry with a Syqwest Bathy-500HD equipment. The resulting data is processed using Deswik.CAD software, specialized in compliance evaluation to volume disposal plans.

The employed methodology applied spatial zoning in the reservoir, enabling the evaluation of operational adherence to the tailings disposal plan and feeding back parameters of the geotechnical-hydraulic disposal model. The KPIs used resemble those used in the mine planning process, such as planned and disposed volumes; planned and not disposed; unplanned and disposed; as well as indexes that assess

the adherence and geometric/volumetric compliance to the tailings disposal plan. Such tools enable short- and medium-term plan adjustments to reduce the impact on optimal (planned) reservoir occupancy and minimize future needs for mechanized tailings management or robust pumping systems.

Real data on tailings behavior in disposal, such as angles of repose and dry consolidated density, were recalibrated with data from the reservoir itself, enhancing the geometric predictability of tailings occupancy.

Introduction

Worldwide production of tailings increases with every decade. Mining operations in the late 1800s and early 1900s produced only about 1–100 t/d (metric tons per day), while modern mining operations can produce 1 million t/d (Morrison and Lammers, 2020). It is estimated that every 30 years, the maximum height of hydraulically filled tailing reservoirs doubles and that in the same period, the volume of tailings and water processed by the mineral industry multiplies by the order of 10 times (Robertson, 2011). The challenges of tailings management in large reservoirs increase constantly in order to meet global industry standards (GISTM) and guarantee the governance and management of tailings in a safer manner (International Council on Mining and Metals, 2020).

Most conventional tailings store facilities (TSFs) are designed, constructed, and operated considering staged development based on the mine plan, particularly the schedule for ore production and waste rock removal and processing for facility construction. Staged development is intended to match TSF capacity with tailings generation to satisfy operational requirements and incremental tailings dam raises or lateral expansion (Snow, 2020).

The Mirim TSF began operations in 2012 and since then, raising have been and will be carried out to achieve the project geometry, in order to meet a storage volume of 758Mm³ of tailings (current mineral reserve at the Salobo mine). In 2024 the volume occupied by tailings is approximately 124Mm³.

The development of tailings facilities depends, necessarily, of the production volume and behavior of tailings during disposal. Aiming to maximize reservoir occupancy, tailings disposal plans are developed to support operational and financial decisions (water management, geotechnical, hydraulic and environmental risks) of short, medium and long-term scenarios, while being adherent to national and internation standards as well as local legislation. This process results in cycling the discharge points, causing each sector to have periods of active and inactive discharge. (Mussé, 2020). Subaerial and subaqueous beach slopes are usually determined by laboratory tests where they are performed to determine those (and other) parameters (physical, chemical, rheology, etc.). Sometimes, flume tests are used to get an indication of deposition slopes; however, they are used more to show, for example, the degree of segregation of the tailings from the spigot discharge based on a range of solids contents. Most typical examples of uncertainties include tailings beach slopes (and their changes along the surface and the time), size and location of supernatant

pond (for slurry tailings), and tailings geotechnical/rheological properties. The deposited tailings will acquire some slope and density, depending on the characteristics and discharge flow energy. The range of variability (as well as the complexity of the topography configuration) can demand comprehensive sensitivity analyses.(Mussé, 2020). In order to comply with the sensitivity analysis necessary to identify any gaps between the modeling of the Mirim Dam's tailings disposal plan and the beach geometry achieved during the TSF's operation, it is proposed to use indicators of adherence and compliance with planned geometry, such as those used in the open pit mining performance indicators proposed by Câmara et al. (2014).

Nader et. al (2012) suggested that mining performance indicators are used within the mining context, with the aim of implementing control measures and consequently defining them as key result indicators (KRI), result indicators (RI), performance indicators (PI) and finally, key performance indicators (KPI), where KRI determines how activities should be carried out, RI indicates what was done, PI determines what needs to be done and, finally, the KPI that informs which parameters generate a significant increase in performance.

Mining indicators are also used to manage waste disposal in waste piles, with the same geometric indices being used to measure adherence and compliance of waste management. The evaluation of the geometry of the waste piles according to what was planned in relation to what was executed, has a desirable methodology for replication in relation to the management of tailings disposal within the perimeter of an TSF. It is understood that losses in adherence to tailings management lead to higher costs, regulatory difficulties, and reputational issues during the operation and closure process, as is becoming increasingly well understood is that closure of a TSF is "a process" rather than "an event," and that this process is no less challenging or costly than the design, construction, and operation components themselves (Andrews et al., 2020).

Study area: Mirim Tailings Dam

The Mirim Tailings Dam is part of the Salobo Project, which is located in the Tapirapé-Aquiri National Forest, in the municipality of Marabá, Pará, Brazil, as illustrated in Figure 1.

The TSF was designed to store tailings from the Salobo mine's copper ore processing, in addition to providing raw water to the three processing plants. Its main embankment is located in the narrow-enclosed valley of the Mirim creek. The morphology of the area allowed the construction of a relatively short embankment, with approximately 320 meters long and 40 meters wide at the crest. Currently the reservoir occupies an area of 9.0 km^2 and is located within a 33.0 km^2 watershed.

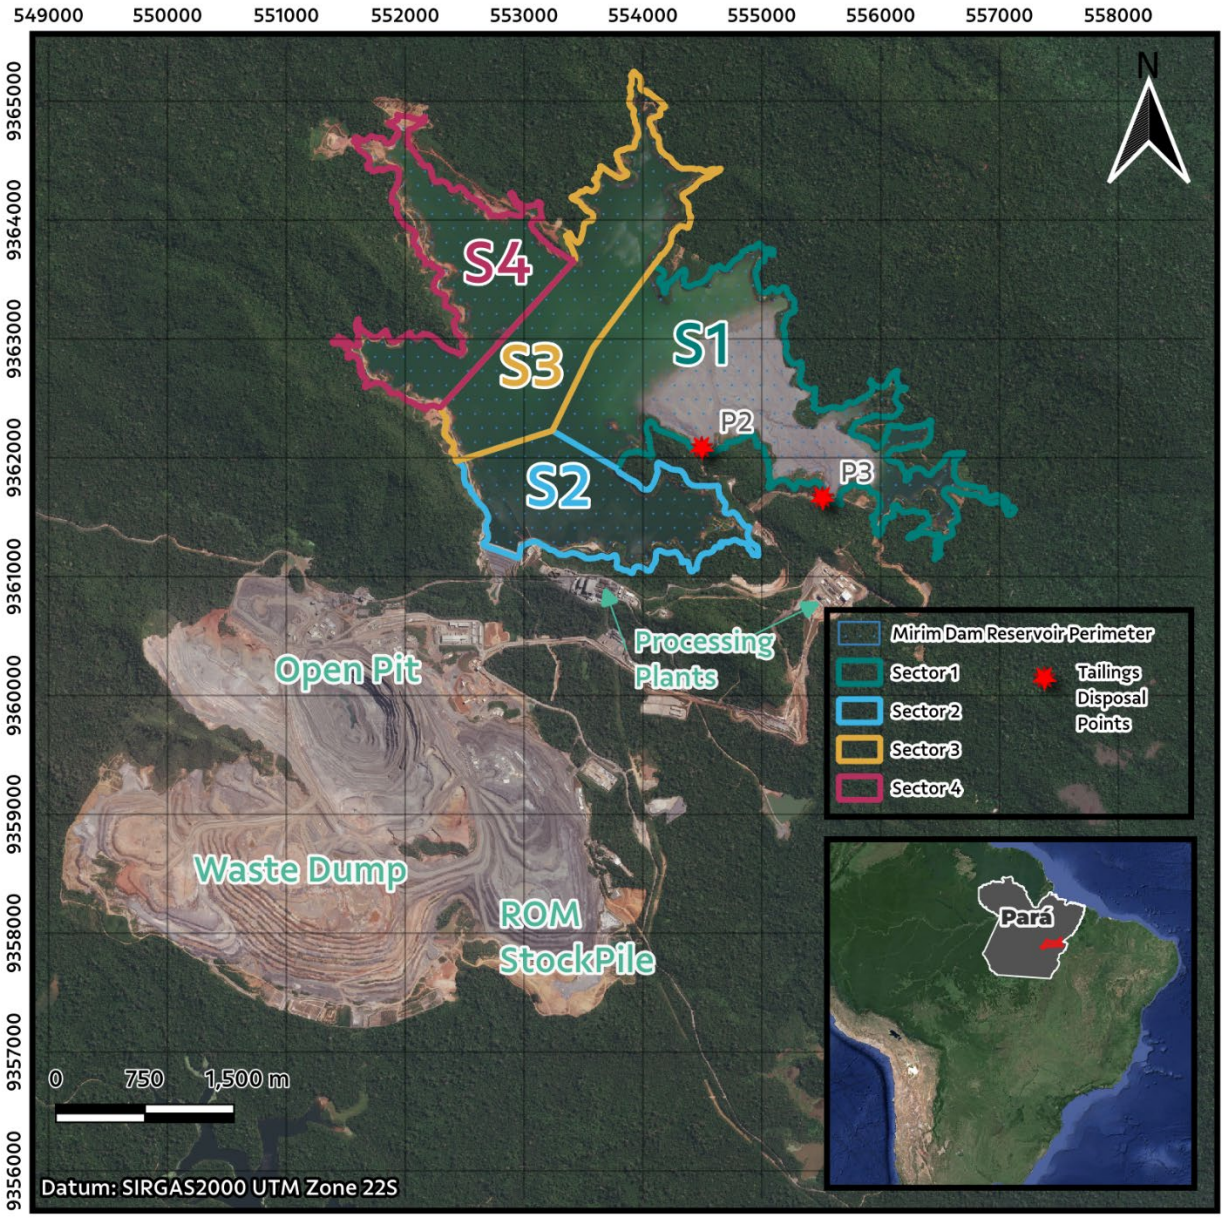

Figure 1: Site location of the Mirim Tailings Dam

The internal structure of the embankment is composed on its upstream zone of a schist rockfill, transitioning to a sieved quartzite and an impermeable clay core. The embankment downstream zone is composed of a transition filter located after the clay core. The filter comprises medium sand, fine gravel (4.8 – 9.5 mm) and coarse gravel (25 – 50 mm) in contact with the schist rockfill. The embankment is situated on a quartzite bedrock with some intrusions of mafic rocks and pegmatite veins. The mafic intrusions and pegmatite veins generated a reddish and whitish clayey soil respectively.

Tailings disposal timeline

Salobo mine has an estimated production of 36 Mt of ore per year. The tailings disposal plan plays an important role in declaring the mine's reserves and resources, as the mine has an estimated life until 2057. The disposal plan foresees the tailings discharge in the upstream part of the reservoir at an elevation close to the main embankment crest. This causes the subaerial beach slope to be around 0.5%, while the submerged tailings slope is around 2.5%. Raw water is collected for the processing plants close to the embankment, in a location with greater water depth.

The operation of Mirim TSF began in April 2012. The first discharge point was called P2 (see Figure 1). In 2017, the discharge point changed from P2 to P3, located further upstream of the TSF watershed, in order to improve the operation of the raw water pumping system. The elevation of P3 is very close to the current elevation of the spillway threshold.

According to the analysis of the topobathymetry surveyed in April 2023, the reservoir can be separated into four distinct sectors (see Figure 1). Sector 1, the main beach, contains the largest quantity of tailings. On the beach, it is possible to find slopes between 0.2 and 0.5%, and a pattern of increasing angles as it goes further downstream on the beach. Sector 2, located in the region of the main embankment, has the highest slopes, with values up to 2.7%, and the highest water column. Sectors 3 and 4 have little tailings stored and are furthest from the beach and the main embankment. In these sectors, water occupies the largest space.

Tailings management methodology

Tailings management systems

The management of tailings according to the methodology proposed by the authors aligns with the process described by the PDCA (Plan-Do-Check-Act) framework, as defined by the Mining Association of Canada (2021) for managing mining projects from conception to closure. This approach is further detailed by LePoudre and Morrison (2020):

- **Tailings disposal plan (Plan):** establish objectives, processes, and plans necessary to meet objectives (policy and commitment, planning).
- **Tailings disposal (Do):** implement processes and plans within a structured management framework (implementing the tailings management framework).
- **Geometrical analysis of tailings disposal adherence to plan (Check):** Measure and monitor all aspects of performance and analyze and report results (performance evaluation).

- **Route adjusting (Act):** Review performance, identify areas of nonconformance and opportunities for improvement. Take action to maintain and continually improve (management review for continual improvement).

The objective of this article is to establish easily reproducible metrics that provide key performance indicators, as outlined by Nader et al. (2012). These metrics enable the proper implementation of the PDCA methodology, following industry best practices.

Topobathymetric surveys

Topobathymetric surveys are carried out routinely at Mirim TSF to evaluate the evolution of tailings disposal. For the current study, surveys from June 2021 and April 2023 were used. The survey carried out in June 2021 was also used as the basis for the most recent tailings disposal plan at Mirim TSF.

The aerial survey is carried out with DJI's Phantom 4 RTK drone and bathymetric survey with SyQwest Bathy 500 equipment, GPS Trimble R12i (on the base) and GPS Trimble R10 (as rover). Data processing is carried out using Pix4Dmapper version 4.3.31 and Hypack 2020 software for noise cleaning and surface generation.

Bathymetry and aerial survey data are compiled in Deswik.CAD 2023.2 and visual maps are generated in QGIS 3.32. Solids are also generated in Deswik.CAD to calculate volumes and define performance indicators, through the geometric evaluation of solids inside or outside the originally planned surface.

Performance indicators for tailings disposal

In this study, performance indicators commonly applied to mine planning were used. Reis and Nader (2023) argue that, given the obligation to ensure the planned Run of Mine (ROM) mass values for the site, two key performance indicators are established to measure the effectiveness of the mining plan:

- The Adherence Index (AI), which determines how assertive the pre-established assumptions were, the operational maturity to follow the predetermined geometry, and hence the effectiveness of the planning in performing the geometry of the plan.
- The Compliance Index (CI), which measures the assertiveness in defining the parameters for the execution of the plan, how disciplined the operation is for the execution of the proposed geometry, the assertiveness of the block model, and the original topography for the elaboration of the plan.

In turn, the AI and CI indicators are determined by the difference between geometries. These differences between geometries generate three indicators:

- Planned Executed (PE), which determines the volume that was mined/deposited and was within the mining plan.

- Executed Not Planned (ENP), which measures the mined/deposited volume that was outside the proposed geometry.
- Planned Not Executed (PNE), which measures the volume that was within the mining/disposal plan and was not mined/deposited.

Figure 2 schematically illustrates the adoption of these criteria (PE, ENP, PNE) for tailings disposal. The identification of these parameters occurs through the comparison between planned and actual topographies over a certain time interval.

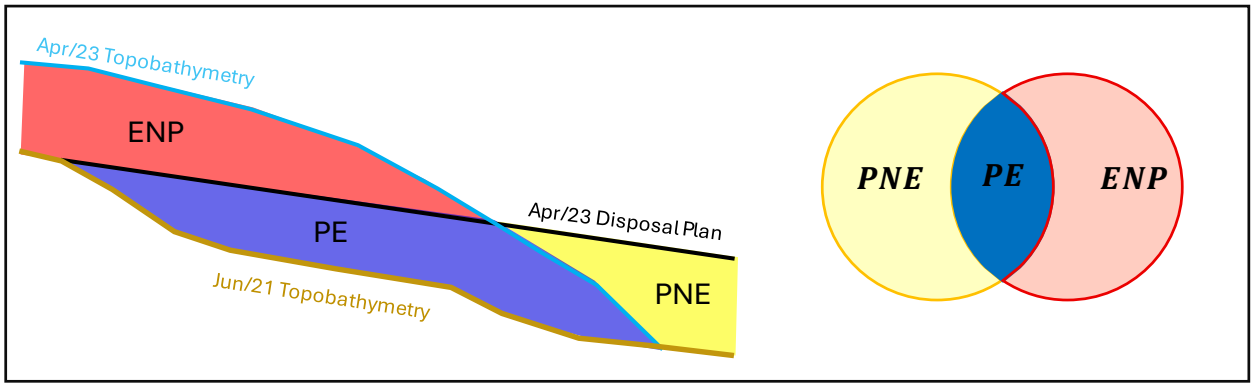

Figure 2: Schematic drawing of tailings disposal indicators used in the study

The following formulas are suggested for the calculation of the Adherence and Compliance Indexes (Costa, 2015):

$$AI = \frac{PE}{PE + ENP} \quad \text{(Equation 1)}$$

$$CI = \frac{PE}{PE + PNE} \quad \text{(Equation 2)}$$

Results and discussion

In the following sections, the results obtained in the assessment of tailings disposal between June 2021 and April 2023 will be presented, as well as indicators and indexes of disposal performance. For a better spatial understanding, the analysis was performed for the four sectors of the reservoir, defined based on the deposition patterns observed in the period (see Figure 1).

Tailings deposition assessment

Figure 3 presents the results of the topobathymetric surveys carried out in June 2021 (Figure 3-A) and April 2023 (Figure 3-B). It is also possible to compare with the surface predicted on the disposal plan for April 2023 (Figure 3-C). It is observed that most of the changes occurred within sector 1 (S1), in which elevations

increased from approximately 242 m to 250 m. The comparison between the disposal plan and topobathymetry shows that higher beach elevations were expected in the disposal plan, mainly in the most upstream portion of the basin, but they were not achieved, according to the survey. There was also an expectation of a greater tailings deposition in Sector 2, which has not happened.

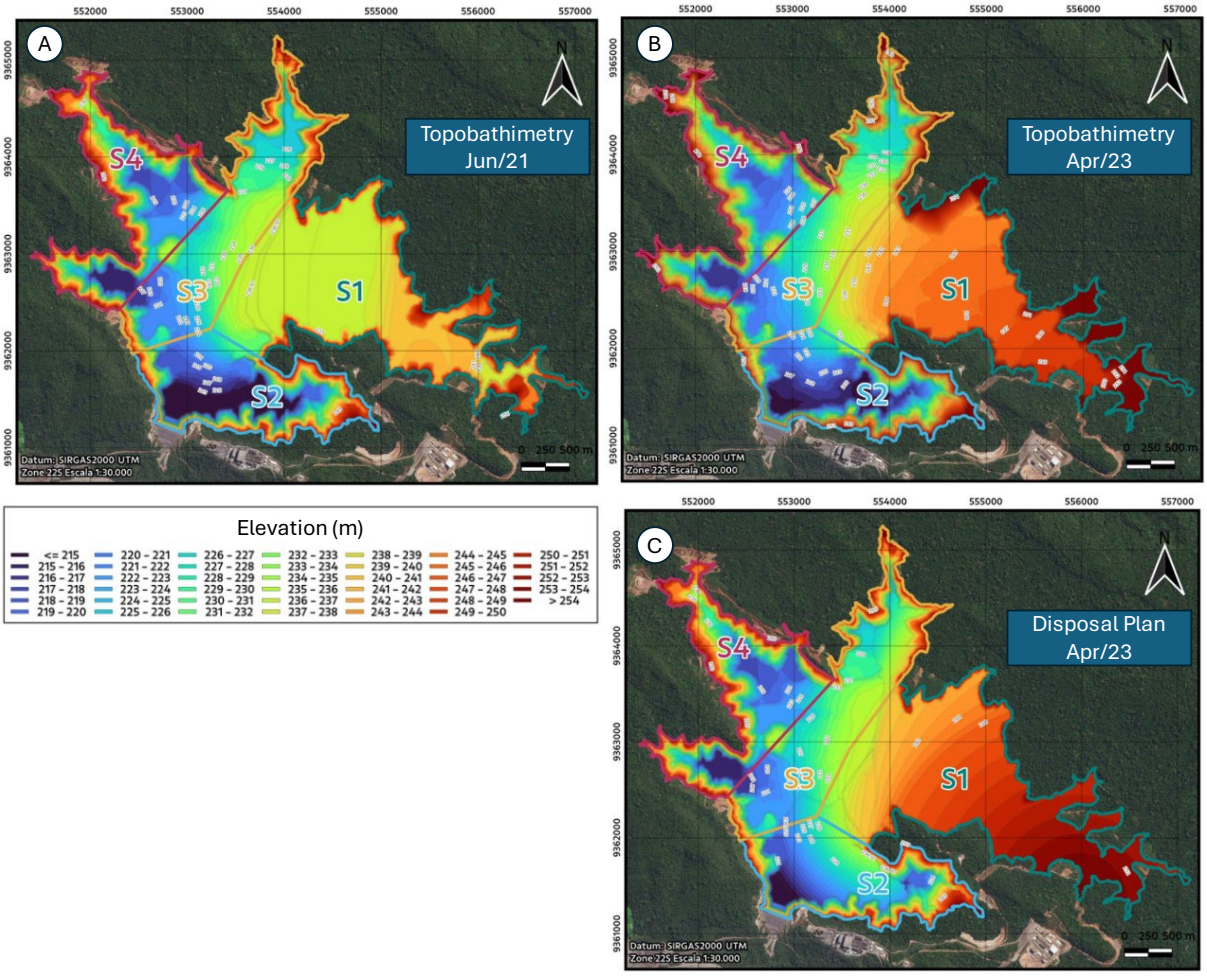

Figure 3: Topobathymetric surveys carried out in June 2021 and April 2023 and disposal plan for April 2023

Figure 4 shows a heat map with the deposition thicknesses expected by the tailings disposal plan (Figure 4-A) and measured from topobathymetric surveys (Figure 4-B). In this figure, the discrepancies between the disposal plan and the executed can be observed, as previously indicated.

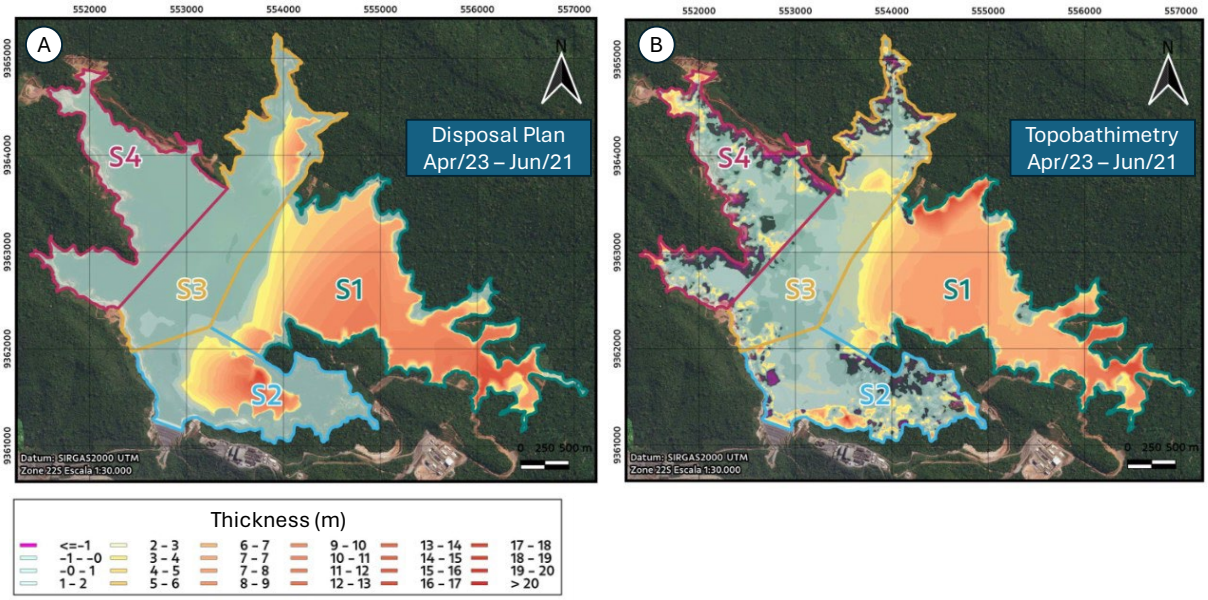

Figure 4: Thicknesses expected by the tailings disposal plan and measured from topobathymetric surveys

Performance indicators of tailings disposal

Using the geospatial assessment of the executed and planned tailings disposal, heat maps were generated for the disposal indicators of "Planned Executed" – PE (Figure 5-A), "Planned Not Executed" – PNE (Figure 5-B) and "Executed Not Planned" – ENP (Figure 5-C).

In relation to PE, it is noted that most of the disposal occurred according to the plan in Sector 1, with the deposition of 18.0 Mm^3 of tailings, followed by Sector 2 with 0.8 Mm^3 and Sector 3 with 0.4 Mm^3.

The PNE deposition was mainly concentrated in the upstream portion of Sector 1, in which a greater thickness of tailings was expected, and in the central-northern portion of Sector 2. The disposal of 4.6 and 4.7 Mm^3 of tailings in these regions were expected respectively. In Sector 3, 1.4 Mm^3 of tailings were not deposited as planned.

ENP tailings disposal occurred mainly in sectors 1 and 3. Sector 1 had tailings mainly located in the north and central-west areas, both in the downstream portion of the sector. 3.7 Mm^3 of non-planned tailings were disposed in this sector. In sector 3 there was an unplanned volume of 2.1 Mm^3 in its central portion.

The plot in Figure 5-D shows the total deposition of each sector divided into PE, ENP, and PNE indicators. Since there was no plan to received tailings in Sector 4 and it is understood that the tailings were not able to reach the area, the indicators in this sector were disregarded in subsequent calculations.

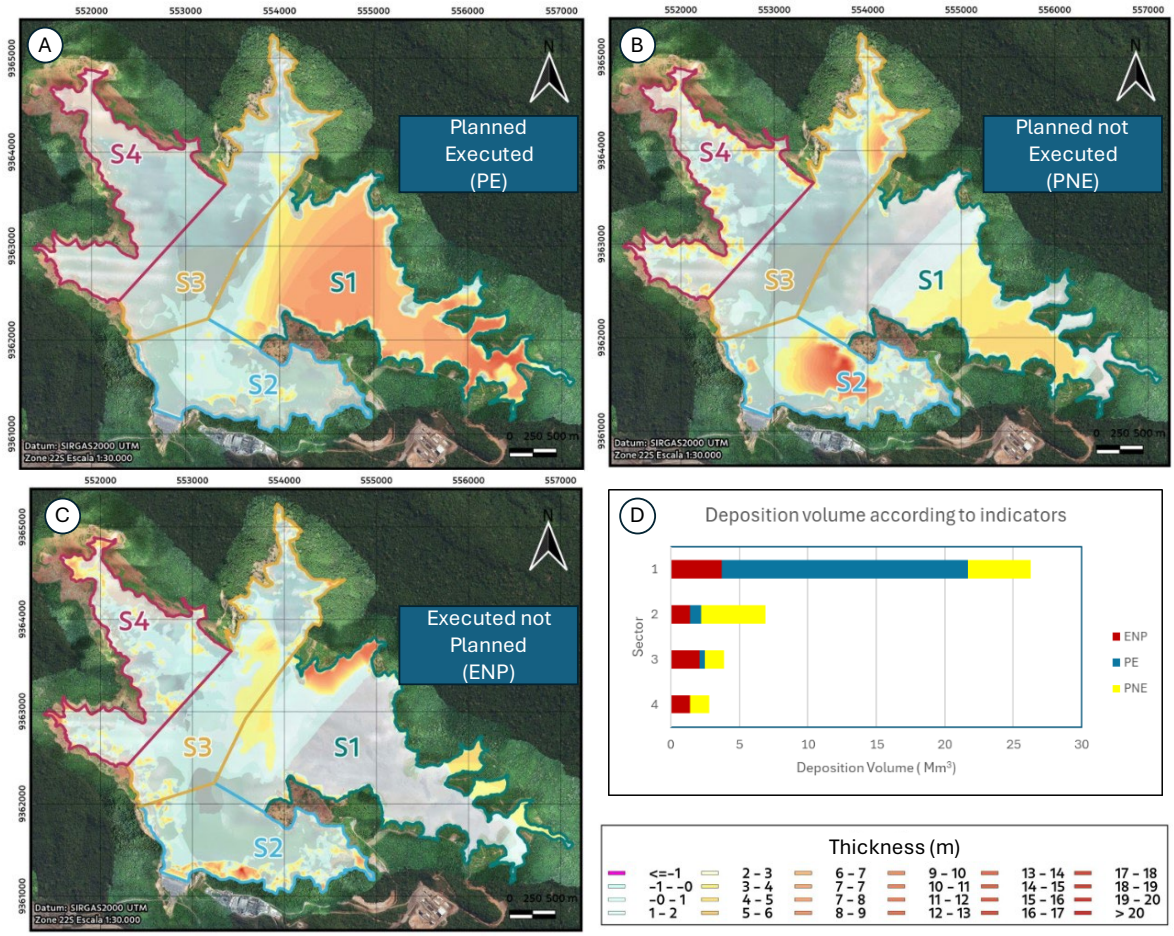

Figure 5: Performance indicators of tailings disposal

The IA and IC indices were calculated for each sector according to equations 1 and 2. The results are presented in Table 1 below.

Table 1: Key Performance Indicators for tailings management from July/2021 to April/2024

Sector	ENP (Mm³)	PE (Mm³)	PNE (Mm³)	CI	AI
1	3.7	18.0	4.6	80%	83%
2	1.4	0.8	4.7	14%	36%
3	2.1	0.4	1.4	22%	16%
4	1.4	0.001	1.4	0%	0%
Total	7.1	19.2	10.7	64%	73%

The evaluation indicated adequate adherence and compliance to the planned disposal in Sector 1, responsible for the largest deposited volume of tailings. However, Sectors 2 and 3 showed low adherence and compliance, where tailings did not reach the projected elevations specified in the disposal plan.

Conclusion

The implementation of commonly applied KPIs in mine planning has brought new perspectives to tailings management at the Mirim Tailings Dam. It allowed for evaluating the physical occupancy of the reservoir, identifying areas not occupied by tailings (individualized sectors), assessing the alignment between tailings production from the plant and measurements from topobathymetry, ensuring predictability in the tailings management plan for maximum, safe, and optimized reservoir occupancy, and developing a closure plan with minimal environmental impact.

Continued assessments based on new bathymetric data, collected semi-annually, offer an opportunity to support revisions of the tailings disposal plans, as well as the implementation of operational measures to ensure the correct geometrical conformance of end-of-life tailings surface on the reservoir.

Dam Safety Remediation Measures at the Aitik Tailings Management Facility, Northern Sweden

Romain Girard, Boliden Mineral AB, Sweden
Joseph Quinn, Klohn Crippen Berger, Canada

Abstract

At the Aitik tailings management facility (TMF), recent (2019–2023) extensive site investigations in the dams' foundations and the deposited tailings mass have highlighted the need to undertake a large program of dam safety remediation measures to improve the stability of the roughly 70 m high embankments, and to help achieve the requirements set out in the Global Industry Standard on Tailings Management (GISTM).

The techniques and management strategies used were uniquely selected to satisfy critical performance requirements, as needed to manage continuous operation and tailings deposition, and to safely execute the remediation works. They include buttressing of the existing clarification pond, construction of an extensive shear key at the toe of one of the embankments, and establishment of an exclusion zone for tailings deposition through the construction of rockfill piers across the tailings beach surface. In addition, the works involve the construction, decommissioning, or relocation of key mine infrastructure (haul roads, services, and water management features such as spillways, pump houses, and pipes).

Over the course of the 32 months duration of the project, over 45 Mt of rockfill will have been hauled to the dams and the scope, scale, timeline, and logistical complexity of the works will have impacted the entire mine site.

Summary of the Aitik tailings management facility

The Aitik TMF

The Aitik tailings management facility (TMF), located near the town of Gällivare in the arctic region of northern Sweden, receives between 40 and 45 million tonnes (Mt) of tailings annually from the enrichment plant of the largest open pit copper mine in Europe (from the main Aitik open pit and the now depleted Salmijärvi satellite pit). The mine and the TMF have been in operation since the 1960s. Tailings generated from mineral ore processing at the mine are deposited hydraulically within the Aitik TMF for storage, with approximately 1,000 Mt of tailings deposited to date. The current TMF footprint covers an area of ≈15 km^2, impounded by 10 km of continuous perimeter embankments. The main TMF impoundment is used to store

low sulfur tailings and includes Dams A-B and C-D on the east side of the facility and Dams E-F and G-H on the west side of the facility. The HS tailings impoundment, used to store the high sulfur tailings stream, is separated from the main TMF impoundment by Dam HS. The clarification pond downstream of Dam E-F is an auxiliary structure of the TMF. The embankment heights vary from ca 40 m (Dams A-B and C-D) to ca 70 m (Dams E-F and G-H) and all are currently being raised using the upstream construction method. The supernatant water is currently managed through two functioning spillways: the U2 spillway, which will soon reach its service life and be replaced by the U3 spillway, with supernatant water reporting from both spillways to the clarification pond. Figure 1 shows an overview of the Aitik Mine and its TMF.

Figure 1: Overview of the Aitik TMF prior to remediation project (June 2021)

Overview of site characterization for Dams E-F and G-H

From 2019 to 2023, site investigations were undertaken at the Aitik TMF to improve the site characterization, and over the course of the four years both the tailings and foundation were investigated using a wide array of investigation methods. While investigations occurred all around the TMF, the emphasis of the programs was on Dams E-F and G-H, as they are the highest dams and are also the dams with the highest consequence classification (Very High according to the GISTM). It is also at these dams that the investigations showed the most challenging conditions, and these dams were the focus of the subsequent stabilization remediation measures instituted, and presented in this paper.

Foundation soils

The foundation soils at Dam G-H typically comprise a series of peat and glacial deposits overlying bedrock, whereas at Dam E-F, those glacial soils are typically overlain by a layer of tailings deposited over recent years in the clarification pond. Below Dam G-H, the thickness of the glacial soils generally ranges between 4 m and 17 m, with a localized 100 m wide section where the deposit attains a thickness of 26 m. This soil unit includes the presence of loose layers located at varying depths, but generally to a maximum of around 10 m depth.

Beneath Dam E-F, the glacial soil thickness typically varies between 5 m and 18 m and includes loose layers located at varying depths. Loose layers in the glacial soils have been identified using in-situ test data from Swedish weight soundings (HfA), as well as Standard Penetration Tests (SPT) and Cone Penetration Tests (CPT).

Tailings in the clarification pond

In the clarification pond, recent deposited tailings are present, originating mostly through discharge of tailings through the U2 spillway. The thickness of these tailings varies between 1 m and 7 m and these deposits extend some 600 m to 800 m from the U2 spillway outlet into the clarification pond.

TMF tailings

The properties and condition of the deposited tailings within the TMF, whether fine grained silts to coarse grained sands, as well as whether dense or loose can generally be related to the deposition method. During early operation (1960s to late 1990s), tailings were discharged subaerially from Dam A-B and flowed towards Dams E-F and G-H where a large supernatant pond was maintained, meaning that the finer fraction and slimes settled subaqueously. During more recent operation (from the early 2000s), spigot deposition was implemented around the perimeter embankments, but with limited subaerial beach length at Dams E-F and G-H due to supernatant pond management requirements through the U2 spillway.

Typically, the subaqueously deposited tailings are fine-grained and loose, exhibiting contractive properties and potential for brittle behavior.

Stabilization measures design description

After the site characterization, the stability analyses for Dams E-F and G-H with the strengths and extents of the liquefiable foundation soils combined with the post-liquefaction strength of the tailings showed that the factor of safety criteria were not met for the post-liquefaction condition, and that immediate stabilization measures were needed to meet stability requirements. Due to the size of the facility, the height of the dams, and the presence of key infrastructure immediately downstream of the dam toes, it quickly became evident

that these remediation measures were going to be significant and would impact the entire site. The dam remediation measures were subsequently designed to fulfill key criteria. Firstly, they should be sufficient to fulfil all stability criteria. Secondly, they should not jeopardize the dams' stability while they were being implemented. Lastly, they should not compromise production. To meet the above criteria, specific remediation measures were designed for Dams E-F, which differed from those for Dams G-H, and specific tailings and water management measures were designed and implemented. Lastly, the impacts of the remediation measures on site infrastructure were assessed and significant changes designed and implemented as part of the remediation project.

The TMF remediation project was approved by the company management and board in April 2022 and construction activities started immediately. They are expected to be completed in December 2024.

Dams E-F

An assessment of potential stabilization methods was made to review alternatives. Stabilization methods reviewed included grouting (jet grouting and soil mixing), densification (e.g., dynamic compaction and vibro-compaction), desaturation and consolidation, excavation and replacement of loose soils, and buttressing. The pros and cons of each method were evaluated at a high level; ultimately, buttressing was selected as the preferred alternative for being the lowest risk approach and the one most likely to meet the tight schedule. Other methods would require either partial or complete dewatering of the clarification pond (e.g., for excavation and replacement methods) and/or excavating or applying significant energy to the toe of the dam (e.g., densification methods), which were considered to have a risk of potentially destabilizing the dam. The buttressing sequencing was estimated to require around two years and would improve stability of the dam continuously once the initial lifts of the buttress were complete, whereas other methods would take more time to implement and could have a temporary negative effect on the dam stability. Additionally, buttressing addressed the remediation needs for both the foundation and the tailings, whereas the other remediation methods studied were focused on the foundation improvements and would have still required subsequent buttressing to address the issue posed by the loose tailings.

The main drawback to buttressing was that it extends some 300 m into the clarification pond, hence losing about 20% of capacity in the clarification pond – from 18 Mm^3 of water down to approximately 14 Mm^3 post-remediation. It also interfered with existing infrastructure (e.g., the reclaim water pump, current spillway outlet, and train terminal) and required a large quantity of rockfill to implement.

Based on the assessed strengths for the loose glacial soils and the clarification pond tailings, the overall gradient of the buttress was required to be in the order of 10H:1V. This shallow-sloped buttress was taken forward through various design phases up to start of construction over the course of six months, and the

conceptual buttress design and the final buttress construction are shown in Figures 2 and 6. The buttress design estimated that around 18 Mt of waste rock was required to meet stability requirements.

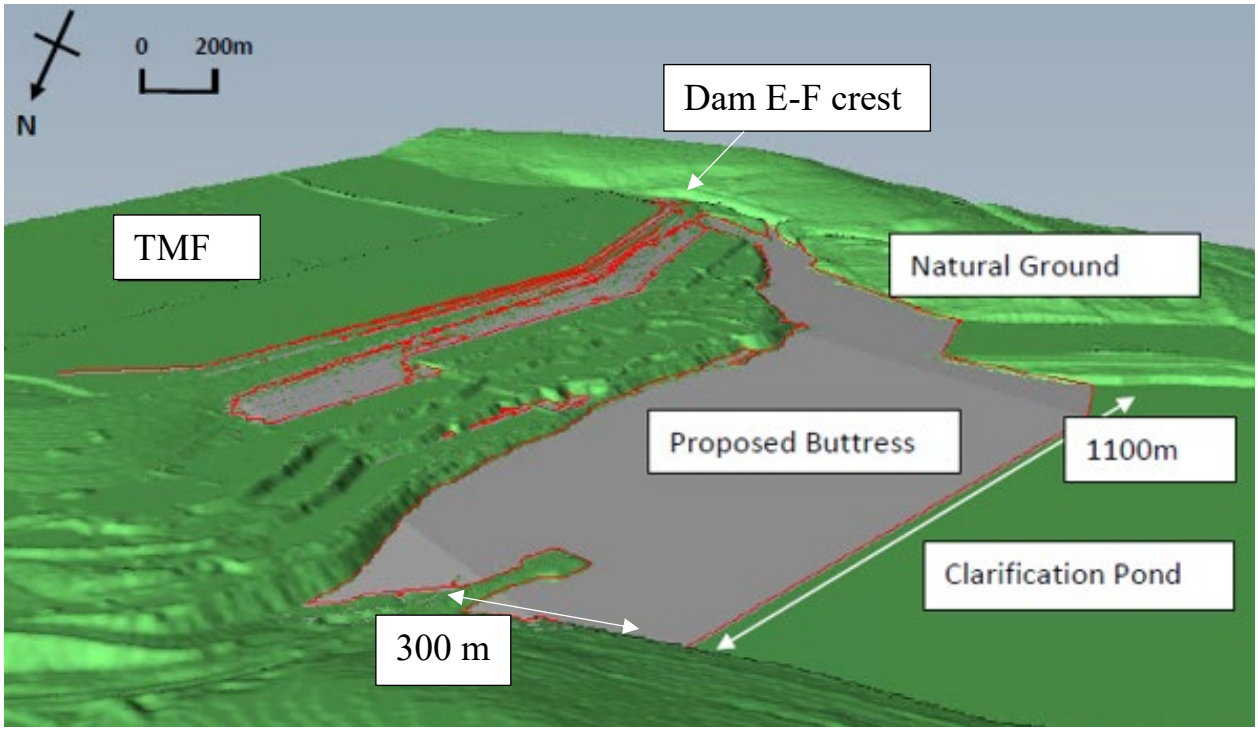

Figure 2: Oblique view of the E-F Dam buttress

Dam G-H

Like Dam E-F, stability analyses indicated that the factor of safety criteria for the post-liquefaction stability cases were not met with the strengths and extents of loose foundation soils identified from the site characterization. To increase stability at Dam G-H, different options were considered, similar to the assessment for Dam E-F, and many of the alternatives were rejected for similar reasons. However, the absence of water at the toe of Dam G-H made the option of improving the foundation conditions a more achievable and attractive option than it was for Dam E-F. Therefore, the solution that was selected was a combined shear key (excavation of unsuitable soils and replacement by suitably competent fill material) and subsequent buttressing, addressing the stability issues from the weak foundation soils and the weak tailings, respectively. This was selected as the preferred option because it reduces the land and fill requirements compared with constructing a shallow sloped buttress, and it was deemed that construction could be achieved safely within the timeframe available.

Figure 3 shows a typical section of the proposed remediation solution, while Figure 4 shows the extents of the shear key and buttress at conceptual level. The shear key dimensions are approximately 40 m base width, with 1V:3H side slopes, 8 to 10 m deep and approximately 1,500 m long alongside the Dam G-H toe. The subsequent buttressing work required placement of buttress fill some 40 m high, totaling around

16 Mt of material. The buttressing does not extend to the full width of the constructed shear key to allow for potential extension of the shear key in the future without destabilizing the existing buttress.

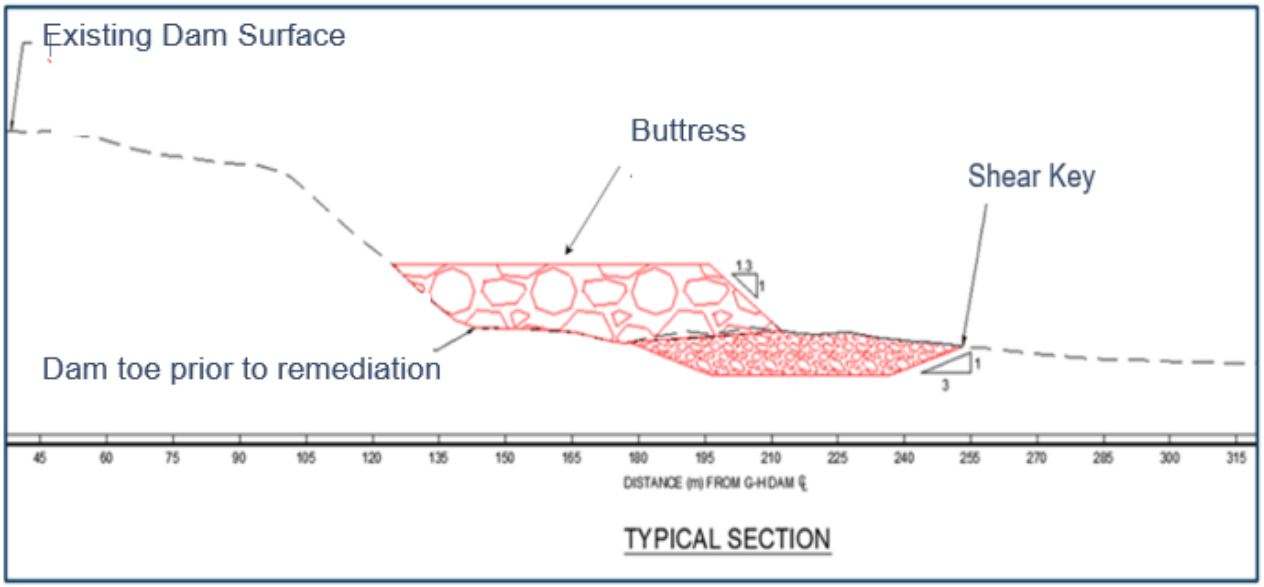

Figure 3: Proposed concept of Dam G-H shear key and buttress section

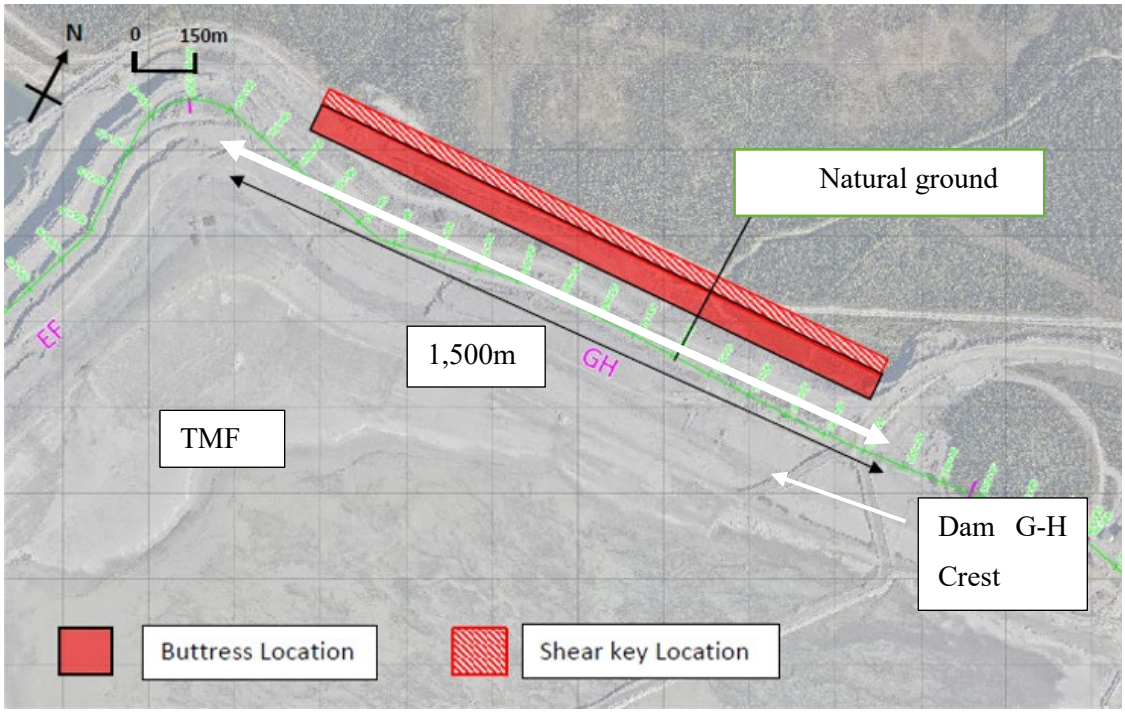

Figure 4: Proposed Dam G-H shear key and buttress location

Dam stabilization measures: construction, sequencing and risk mitigation

Dam E-F

The construction of the buttress was sequenced to allow Boliden to relocate key infrastructure while the buttressing work was ongoing. In particular, the outlet of the U2 spillway as well as the existing pump station in the clarification pond, had to be kept in operation for 4 months and 14 months, respectively, until alternative infrastructure could be built, allowing for this existing infrastructure to be decommissioned. Also, prior to the buttress construction, it was necessary to construct a new haul road to the dam area to achieve the shortest possible haulage distance to the dams, while also keeping the road out of the Life of Mine dam footprint. This haul road was also intended to avoid traffic on the dams' existing buttresses to improve dam and worker safety from the large number of trucks that were going to be used to haul the material. The construction of the haul road took place from May 2022 to October 2022 and required 4 Mt of waste rock to be placed.

The buttress was constructed from run-of-mine or stockpiled waste rock, typically a minus 500 mm material, hauled by contractors using 100 t and 160 t trucks with bulldozers receiving and spreading out the material. This material was placed loose in large lifts when deposited into water in the clarification pond, and subsequently placed in 3 m lifts and compacted with haul traffic once the buttress surface was out of the water. Ice build-ups in the clarification pond were removed ahead of the buttress placement working front, and snow was cleared on the buttress material during placement.

To avoid potential initialization of instability in the underlying loose sediments, the buttress construction started from a ramp located adjacent to the reclaim water pump station and advanced into the clarification pond from there, thus avoiding the need to traffic on the existing buttress. The aim was for the newly placed buttressing to provide support to the existing buttress. Subsequently, the buttress construction sequence was designed to be constructed at the farthest distance from the existing buttress before incrementally constructing inwards towards the existing buttress. This is illustrated in Figure 5. All buttressing work was then progressed from lower levels to higher levels to ensure that factors of safety were always improving with buttress placement, and not inducing potential local instability.

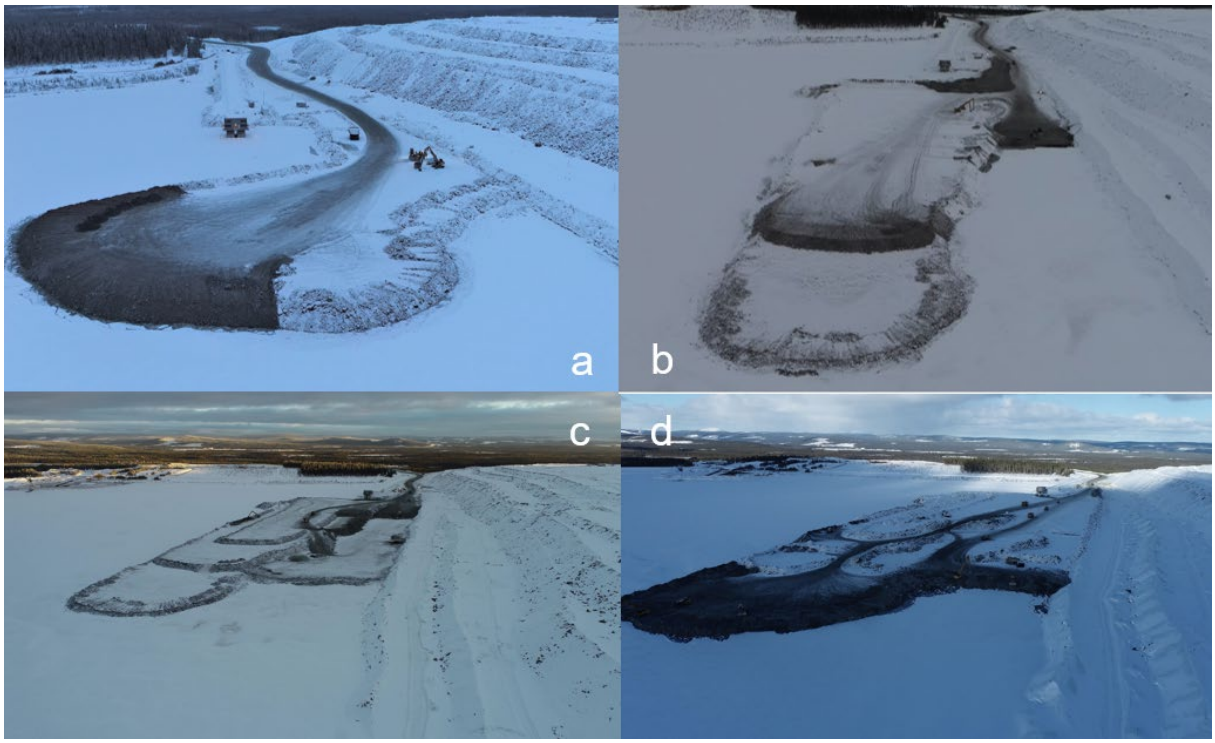

Figure 5: Early staged construction of the Dam E-F buttress in the clarification pond (a – November 2022; b – January 2023; c – March 2023; d – April 2023)

Buttressing started at Dam E-F in November 2022 and was successfully completed in May 2024. Over the 18-month period, more than 18 Mt of mine waste rock was placed and the final buttress construction is shown in Figure 6. During the most intensive construction months, up to 70,000 t were placed daily at the Dam E-F buttress area.

Figure 6: Final remediation buttress construction at Dam E-F

Dam G-H

The shear key excavation, backfilling and subsequent buttress placement was to be implemented through a construction sequence comprising three main stages.

Stage 1 was the construction enabling works, comprising the removal and relocation of existing infrastructure and dewatering activities. The infrastructure in the area comprised a pump station and associated settling basin with a lined channel, which were decommissioned in two parts to allow for a staged excavation of the shear key. The dewatering activities were done in advance of the main excavation works through the excavation of drains at regular intervals within the future shear key area to help with the lowering of the water table prior to the main excavation work, and assist with the dewatering of the excavated area (e.g., from precipitation and additional seepage) during the excavation work. This work started in May 2023 and was completed around November 2023.

Stage 2 was the excavation and backfilling of the shear key, with concurrent construction of the filter layers. Over the 10-month shear key construction period (August 2023 to June 2024), approximately 1.2 Mm^3 of material was excavated from the shear key and replaced by the equivalent volume of suitable fill (Figure 7).

The shear key backfill was designed to be free draining and dense. As such, it was specified to be constructed of coarse rockfill and compacted in 2 m thick lifts. A material of gradation between 50 mm and 400 mm was specifically produced through crushing and screening from the waste rock stockpile material. This gradation was chosen to eliminate fines in the backfill material and to maximize the effect of the compaction efforts. This rockfill is not filter-compatible with the adjacent glacial soils and requires a filter layer to prevent migration of fine particles and mitigate the potential for a piping failure mechanism. This filter layer was designed as a two-layer system comprising a “coarse filter” layer adjacent to rockfill and a “fine filter” layer adjacent to finer soil units located alongside the upstream excavation face of the shear key.

To prevent the shear key excavation causing instability of the dam or buttress slope, and to maintain stability during shear key construction, the shear key excavation area was offset approximately 40 m (calculated from numerical modeling) from the dam toe and the shear key was excavated in “panels” of approximately 50 m sections (parallel to the dam long axis), and backfilling progressively to limit the “open excavation” area to the width of the panel. The excavation slopes were constructed at the designed gradient of 3H:1V to prevent excessive erosion during construction.

To assist with winter construction and avoid the potential for ice forming at the base of the excavation that could create layers of weakness within the fill or loosen the basal foundation soils layers, the groundwater table was maintained below the base of the excavation through localized pumping and the use of previously excavated drains. Additionally, the backfilling of any excavated foundation area was

undertaken within 24 hours of the excavation and the snow and ice were removed from excavated zones or fill areas prior to fill placement using the free draining backfill material.

Stage 3 is the construction of the buttress over the shear key. This work started in June 2024 and is expected to be completed in December 2024. Over the 7-month period, over 15 Mt of waste rock will be placed to stabilize the dam, and the construction will be undertaken using a mix of the mine fleet (300 t trucks) and contractor equipment (similar to that used for the Dam E-F buttressing). In early June 2024, the rate of buttress placement exceeded 90,000 t per day.

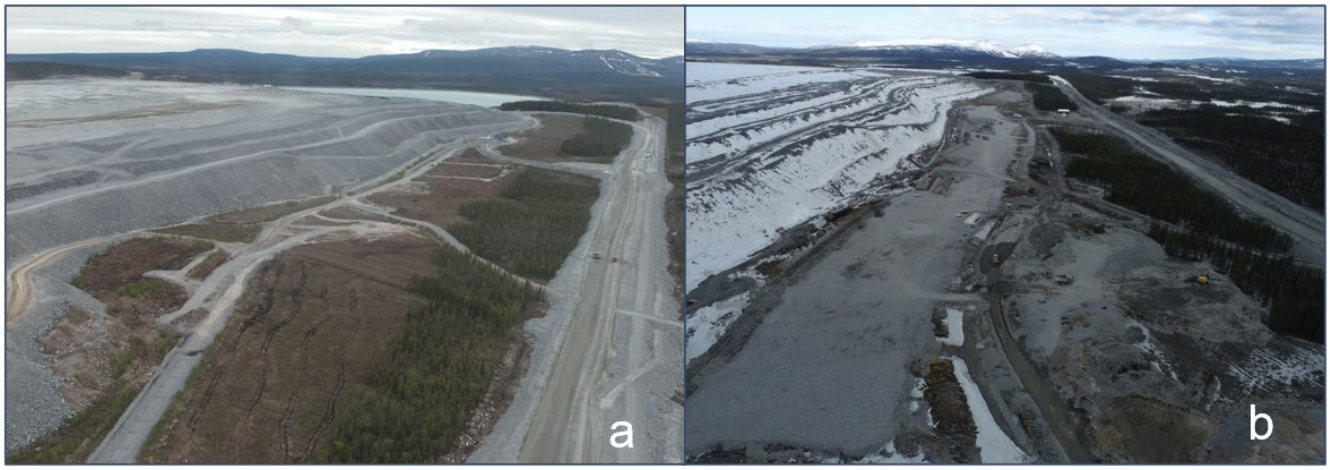

Figure 7: Toe of Dam G-H; a – during drainage work; b – at near-completion of shear key

Surveillance and monitoring during construction

Surveillance and monitoring activities were critical during the implementation of the dam safety remediation measures. A wide range and number of instruments (inclinometers, vibrating wire piezometers, survey monuments), either previously installed as part of the dam monitoring network, or specifically installed ahead of the remediation work construction, was monitored on an ongoing basis throughout the construction period, and post construction. From there, a Trigger Action Response Plan (TARP) was defined for use during construction. The TARP was based upon visual observations and instrumentation monitoring during construction. If the observations or the instrumentation were to indicate that construction activities were initiating displacements or pore pressure increases outside the pre-defined TARP threshold values, construction would have been suspended and a revised construction plan would have been developed. Additionally, regular surveillance and surveying activities (through visual inspection, regular surveying activities, drone surveys, and acquisition of satellite photos) were undertaken to assess the performance of the construction and the existing dams, and to monitor the progress of the construction work. Lastly, extensive quality control and quality assurance activities were undertaken, where required, to fulfil the technical specification requirements, which included visual inspections, surveys, and compaction records, sampling and testing of construction material, and approval of work.

Continued operation (tailings deposition and water management) during remediation

To fulfil one of the key criteria defined from the outset of the remediation project and allow continued operations while the remediation project was undertaken, an updated deposition and water management strategy was specifically designed, as shown conceptually in Figure 8.

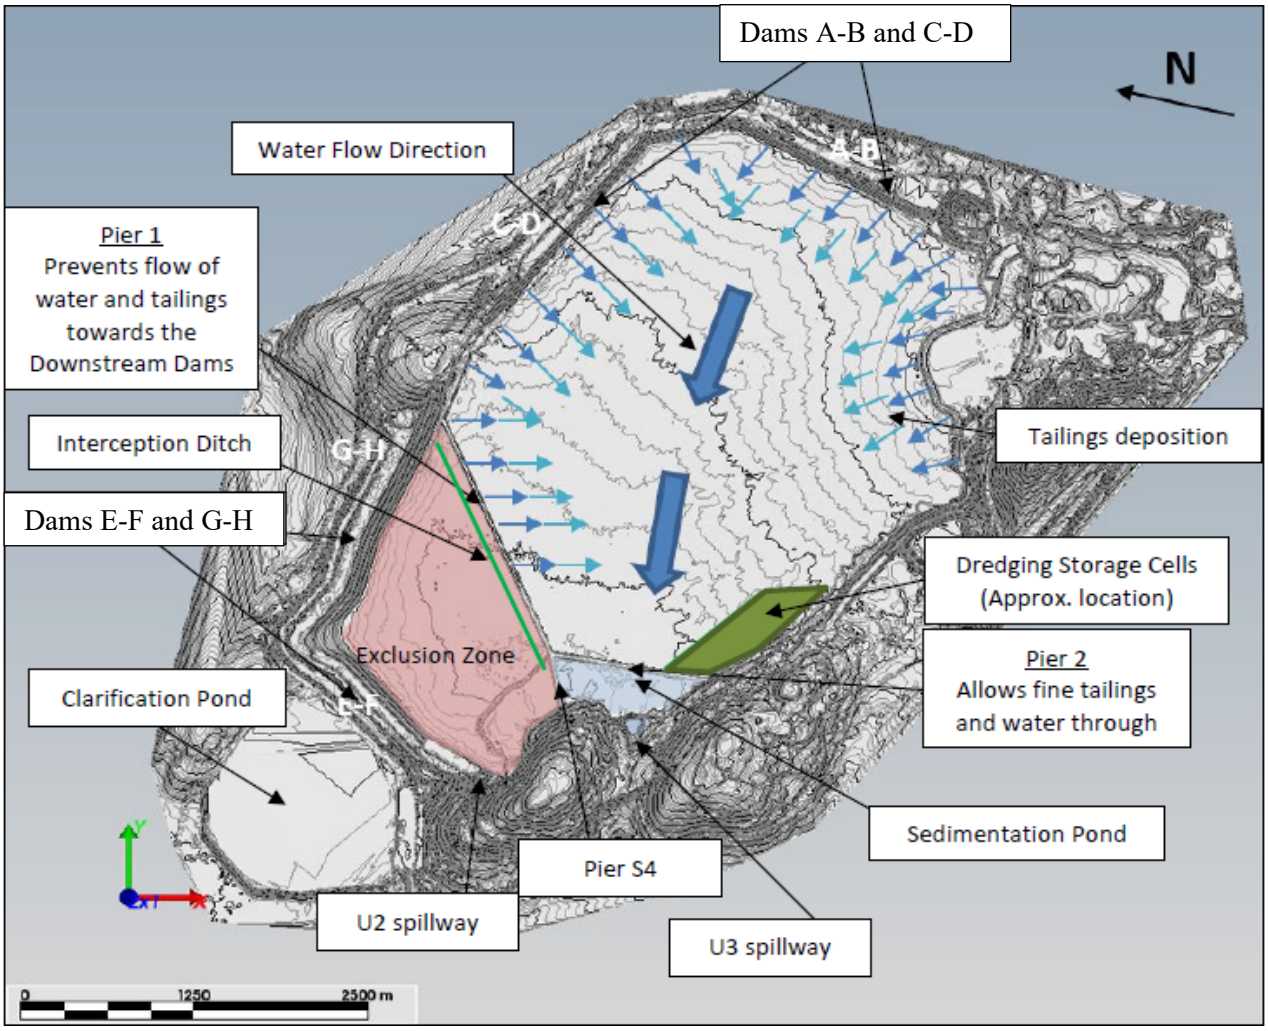

Figure 8: Deposition and water management strategy during the remediation work

An exclusion zone was demarcated on the surface of the tailings impoundment via the construction of rockfill piers to redirect deposition of tailings and water away from Dams E-F and G-H and thus prevent further loading or increases of pore pressure. These piers comprise a 20 m wide crest with a typical height of 5 m from the existing tailings surface at the time of construction.

The focus of the deposition strategy from Dams A-B and C-D was to adjust the practice of tailings deposition (which previously included extensive use of end-of-pipe deposition, leading to high velocity flows and widespread erosion) to maximize the use of the available storage volume in the facility, and

formation of a tailings beach that would gradually slope towards the U3 spillway. These strategies included alternate methods of deposition, such as more extensive, controlled, and consistent use of spigots, extending spigot lines into the facility following initial deposition, and the use of splitter boxes to minimize the impact of end of pipes flows (Thuysbaert et al., 2024). Deposition of tailings and water was directed towards the U3 spillway where Pier P2 was constructed. Water could pass through Pier P2, and the operational supernatant pond was established in the region upstream of the existing U3 Spillway pier (referred to as "the sedimentation pond").

Due to the lowest crest dam (Dam E-F) not being raised, the maximum allowable water level within the facility could not be changed and remained constant during the remediation period to keep sufficient freeboard. However, as the tailings were deposited upstream of the piers and the overall tailings level in the facility increased, it was necessary to undertake dredging operations during the summer of 2023 and 2024 in the sedimentation pond to ensure continuous pre-clarification of the supernatant water before discharge to the clarification pond. A total of approximately 1 Mt of tailings will have been dredged by the time Dams E-F and G-H are raised again in 2025. The tailings dredged from the sedimentation pond were discharged into a series of "dredging cells" located within the TMF (see Figure 8).

While remediation works were ongoing, it was necessary to add two sets of additional piers upstream of Pier P1 and P2 to enable tailings deposition to continue outside the exclusion zone. Additional piers are offset a minimum distance of 300 m upstream of Pier 1 and Pier 2 to maintain an overall slope of the piers and tailings upstream of the exclusion zone to less than 2% to limit the potential for tailings to flow into the exclusion zone should instability develop in the piers (less than typical post-liquefaction runout slopes). Also, both the U2 and U3 spillways remained open to safely convey flood water to the clarification pond.

Figure 9: View of Piers P1 to P4 used for tailings and water management

Each set of piers was constructed over an initial two-month period, and then required regular addition of fill to counter the effect of settlement (approximately 1 to 2 m of settlement were measured over the first 12 months of the piers being constructed). The total amount of material required to build piers P1 to P6 is estimated at ca 6 Mt, and the piers were constructed using contractor equipment (bulldozers and 60 t and 100 t dumpers and trucks) (see Figure 9). No major issues were encountered during the construction of the piers, with typically very little heave or cracking being observed.

Infrastructure work as part of the remediation project

The extent of required remediation work at Dams E-F and G-H and in particular the overall loss of operational water volume in the clarification pond due to the buttress construction had a significant impact on much of the site infrastructure. In particular, the overall site-wide water management had to be redesigned and several key water management components (including a spillway, pump stations, and associated pipelines) at the site required either decommissioning, rerouting, or new construction, as described earlier. In addition, the satellite pit (Salmijärvi) was intended to be used as the main clarification pond to offset the loss of volume in the current clarification pond, and significant infrastructure had to be constructed to ensure water could be pumped into and from the existing clarification pond to the Salmijärvi pit and then to the process plant. The work with the infrastructure had to be staged to meet continuous process operational demands, while ensuring the remediation work could be undertaken within the planned timeframe.

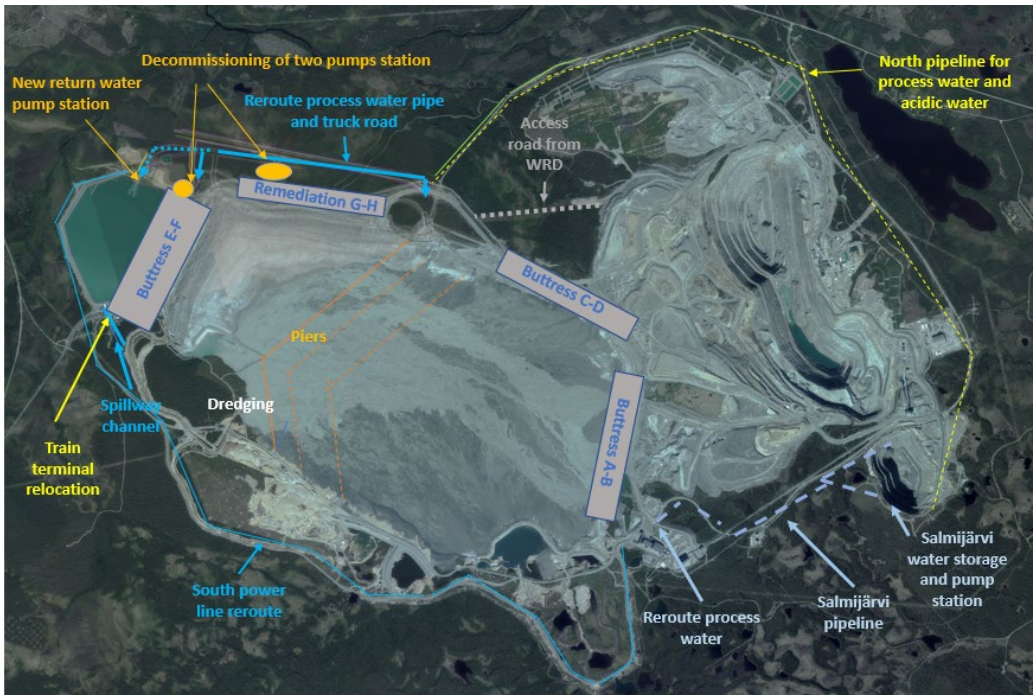

Figure 10: Overview of the remediation project scope of work

In addition, buttress construction was undertaken at Dams A-B and C-D during the remediation work, as a continuation of the buttress construction that had previously been required as part of the design requirement for the continuous safe operation of these embankments. During the period 2022 to 2024, over 5 Mt of rock was placed to buttress Dams A-B and C-D.

Figure 10 shows the overall extent of impact of the dams' remediation measures on key infrastructure. Figure 11 shows an overview of the facility in May 2024, with the following areas of interest: buttressing at Dam E-F completed, shear key excavation and backfill at Dam G-H near completion and buttressing started, successful establishment of the exclusion zone (revegetated with grass to assist with dust prevention), successful construction of Piers P1 to P6, ongoing dredging in the sedimentation pond, and the different areas of buttressing.

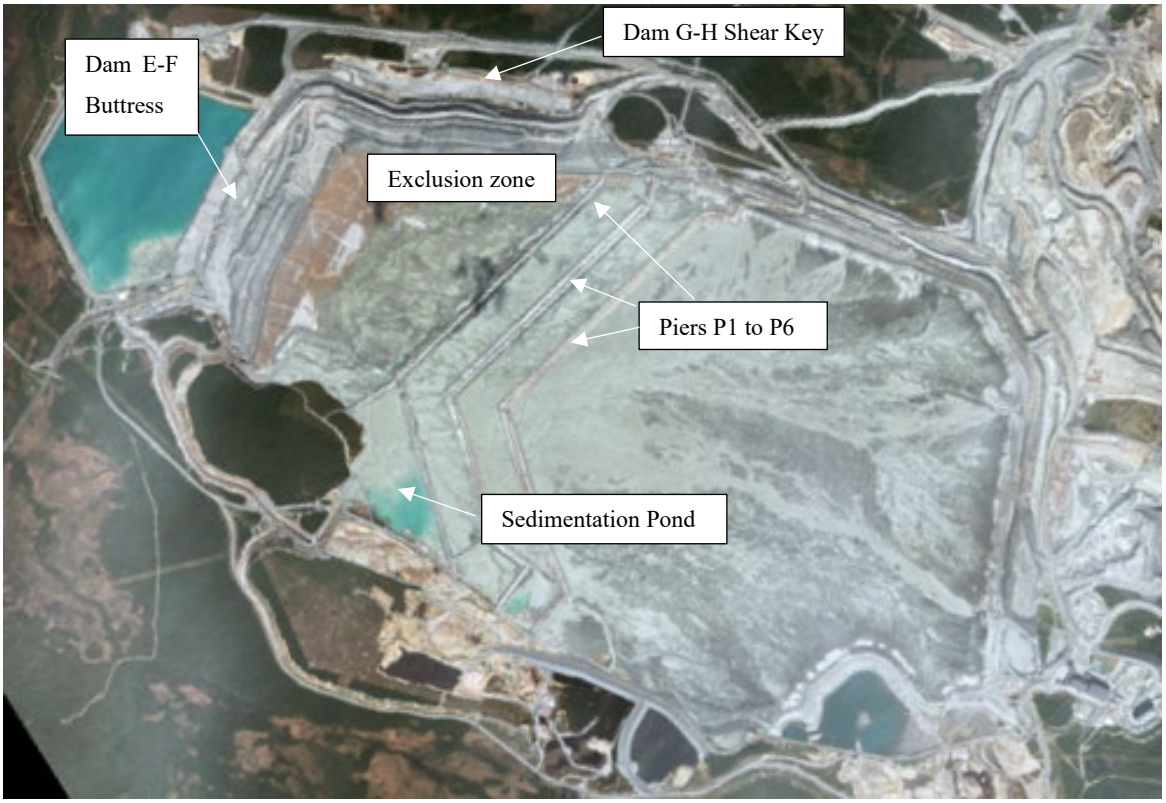

Figure 11: Overview of the Aitik TMF during the remediation work (May 2024)

Conclusion

The Aitik TMF remediation project was approved by the Boliden management and board in April 2022, and construction started immediately. The Dam E-F buttressing work was completed in May 2024, and the remediation work at Dam G-H is expected to be completed in December 2024. Deposition from these dams is planned to restart in the spring of 2025. During the 32-month project, over 45 Mt of rockfill will have

been hauled to the TMF area to allow for the remediation measures to be constructed, and the mine site will have undergone significant changes. These changes are necessary to allow for safe and sustainable storage of tailings and to prevent a loss of production while implementing the remediation works.

Abstract

An important aspect of the operation of many conventional mine tailings storage facilities (TSFs) is providing sufficient tailings pond sedimentation capacity to meet total suspended solids (TSS) water quality requirements for direct discharge to the environment or reclaim for re-use in milling. While maintaining a larger pond volume/area will typically correspond to greater sedimentation capacity (i.e., residence time), minimizing the tailings pond size can be important for reducing the risk of the facility. For sites with negative water balances/water deficits (i.e., outflows and losses exceeding inflows), managing the TSF with a small pond and maintaining sufficient water for re-use in milling can be important for operational resilience and water conservation. Previous guidance has highlighted the challenges of purely theoretical approaches for the sizing of TSF pond areas for adequate sedimentation and have suggested "rules of thumb" for minimum pond sizing that tend to be conservatively large when compared to observed pond sizes for operational facilities.

This paper presents a summary of observed tailings pond sizes and reported mill throughput for several conventional TSFs across North America and South America, and a case study for a conventional TSF at an open pit copper mine. Based on the results of the case study and observations for other sites, a practical approach is presented for setting operational targets for pond sizing in terms of tailings production rates and estimated material settling velocities, and for assessing when additional TSS controls may be required (e.g., berms to increase flow path lengths, silt curtains, or filtered intake structures).

Introduction

For many conventional mine tailings storage facilities (TSFs), providing sufficient tailings pond sedimentation capacity to meet total suspended solids (TSS) water quality requirements for direct discharge

to the environment or reclaim for re-use in milling is an important aspect of operations. While sedimentation in tailings ponds is similar to sediment ponds designed to settle out sediment loads from hydrologic events, there are several unique characteristics and uncertainties that can be challenging for the operation of conventional TSFs with TSS requirements for direct discharge to the environment or reclaim for re-use in milling. Of particular concern is the pond area available for sedimentation, which can vary significantly depending on facility geometry and natural ground topography, as well as the spatial and temporal variability in tailings deposition. Previous guidance such as that suggested by Coates and Yu (1977) has highlighted the challenges of purely theoretical approaches for the sizing of TSF pond areas for adequate sedimentation and suggested "rules of thumb" for minimum pond sizing that tend to be conservatively large when compared to observed pond sizes for operational facilities.

This paper presents a summary of observed reclaim pond sizes and reported tailings production for operational conventional TSFs in North and South America, which can be used as a screening tool for pond sizing or assessment of TSS controls for sites that have TSS requirements for water reclaimed or discharged from the facility. A case study is presented to illustrate the use of the benchmarking dataset and theoretical settling pond design calculations to assess the pond sizing requirements and TSS control requirements for a large conventional TSF.

Background

Sedimentation, or particle settling, is the process of removing solids from suspension in a liquid under the force of gravity. Sedimentation is common practice for conventional TSFs and as part of tailings thickening processes for thickened tailings applications (Li, 2024). For conventional TSFs a tailings slurry is typically deposited on a tailings beach where sedimentation of the coarser fraction of the tailings occurs; water "bleeds" down the beach slope into a tailings pond, where remaining finer particles settle out of suspension, and an overflow/decant or pumping system (e.g., a barge and pump system) is operated to reclaim water from the facility. The tailings particle settling behavior, tailings pond geometry, and the hydraulic characteristics of the system govern the design constraints of the system when there is a requirement to minimize TSS in reclaimed or discharged water.

Settling behavior can be categorized by four types depending on concentration and particle interactions: discrete particle settling (the focus of this paper), flocculant settling, hindered settling, and compression settling (Kynch, 1952). The discrete settling of a single particle in a fluid under ideal conditions can be described by Stokes' law, which can be applied to estimate settling velocities of tailings particles with adjustments for non-ideal particle shapes and fluid temperature. Laboratory testing is the preferred approach to estimate settling velocities of tailings solids (i.e., a settling column test). In practice, the sedimentation properties of any suspended material may be influenced by many factors that include

local solids content, states of aggregation or flocculation, particle size, shape, and distribution, particle specific gravity and mineralogy, and the properties of the fluid (Li, 2024; Coates and Yu, 1977).

Beyond the settling behavior of tailings particles, the sedimentation capacity of a particular pond can be heavily influenced by the pond geometry and hydraulic characteristics, which include the pond depth and surface area, pond water temperature and pH, inflow and outflow rates, and hydrodynamic conditions in the pond such as turbulence or wave-induced resuspension.

In contrast to the design of sediment ponds that are generally designed with a permanent pond geometry and sediment load driven by hydrologic events, tailings ponds can have several unique characteristics:

- The variability in when and where tailings are deposited can affect both the sediment load reaching the pond and the effective pond sedimentation area (i.e., the deposition location relative to the outflow location can vary substantially resulting in large portions of the pond being unavailable for settling, or higher sediment loads in the pond).
- The requirement for sedimentation capacity in operational TSFs can be driven by sedimentation of tailings from slurry deposition rather than mobilized sediment from extreme hydrologic events.
- The dynamic process of tailings deposition and progressive dam raises can also result in significant variation in pond geometry over the life of mine.
- Reclaim pond geometry and corresponding effective pond sedimentation area can be heavily influenced by natural topography and often cannot be practically altered in the same manner as typical sediment ponds.
- The surface area of tailings ponds tends to be quite large, and therefore more susceptible to wind impacts.

Methodology

The methodology adopted in this paper assumes TSS criteria for reclaim or discharge water (which may not be the case for all conventional TSFs) and includes the following key steps discussed in the sections that follow:

1. Conduct an initial screening of critical TSF pond configurations to assess whether a detailed analysis is warranted for the planned pond configuration, based on benchmarking for other similar sites.

2. Conduct theoretical calculation of a settling capacity factor, defined as the ratio of effective sedimentation area over the required sedimentation area, considering site-specific constraints in future TSF operations, considering the following:
    - deposition geometry (i.e., effective sedimentation area and distance from inflow to outflow);
    - tailings throughput and material sedimentation properties (inflow sediment load);
    - tailings material particle size or outflow concentration of interest (outflow sediment load).

Benchmarking

Current and historical conventional tailings operations in North and South America were assessed using Google Earth aerial imagery. Facilities are categorized as either: those with observable additional controls for TSS (e.g., rockfill filtered intake structures, or berms around the intake area), or those with no readily observable physical TSS controls and uncertain TSS constraints for reclaim or discharge.

This benchmarking exercise is based on publicly available tailings tonnage data and conditions interpreted from publicly available aerial imagery. The area of discharge into the pond was approximated for each TSF to determine the effective pond area available for settling (the "effective sedimentation area") to account for the effects of "dead storage" areas in the ponds (i.e., areas of the pond that are effectively short-circuited and provide minimal settling capacity).

For the benchmarking exercise the pond area was plotted against mill throughput. This is a simplification and does not account for situations where pond depth may also influence sedimentation capacity (e.g., in very shallow ponds) or where mill throughput is a poor proxy for the tailings loading in the pond (e.g., the potential for cycloning operations to deposit a finer fraction of the whole tailings on the beach). As discussed in the theoretical approach section, estimation of sediment loading also depends on when and where tailings are deposited on the tailings beach. In general, 100% of the tailings throughput is assumed to contribute to sediment loading in the estimated effective pond sedimentation areas. This assumption is likely to overestimate the sediment loading in some cases, since tailings deposition may sometimes be concentrated in specific areas of the beach. The information for this benchmarking exercise could be refined with additional site data (e.g., tailings deposition details, pond depths, TSS requirements for reclaim, and TSS controls).

Figure 1 presents schematics of three TSF configurations illustrating the relationship between tailings deposition locations and inflows to the pond, and approximated areas of effective sedimentation and areas of dead storage. Case (a) shows a ring-dyke facility on relatively flat terrain with a reclaim pond located at

the center of the facility and with deposition occurring from the portion of the ring dyke at a point in time such that a large fraction of the pond is not available for sedimentation. Case (b) presents a facility in mountainous terrain where the natural topography isolates a large fraction of the pond making it unavailable to provide sedimentation capacity. Case (c) presents a case in mountainous terrain where most of the pond area is effective for sedimentation.

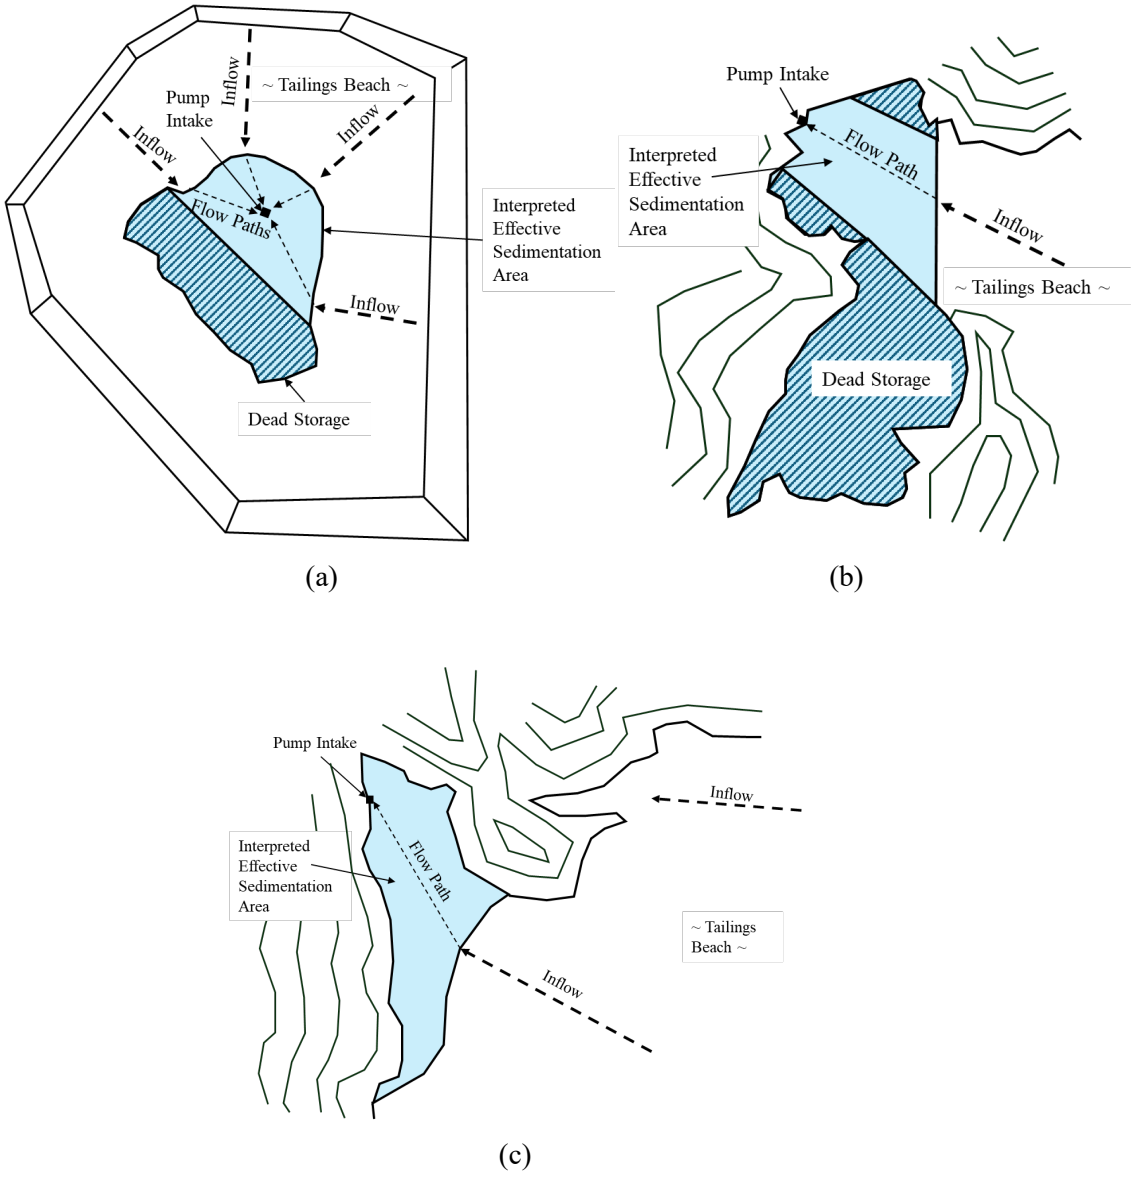

Figure 1: Interpreted effective pond sedimentation area vs. dead storage for example sites

Figure 2 presents a comparison of the trends in tailings throughput (in metric tonnes per day, TPD) vs. the estimated effective sedimentation area, divided into sites with observed physical controls for TSS and those with uncertain physical controls. The shaded blue zone represents the approximate range of most data points for sites without / uncertain physical controls for TSS. Coates and Yu's (1977) "rule of thumb"

for tailings pond sizing (15 acre/1,000 TPD or about 0.60 km^2/10,000 TPD) is also shown. Tailings throughput is compared against pond area in the plot to compare against the Coates and Yu "rule of thumb', noting that pond area is a proxy for the distance of the flow path between the inflow and outflow (i.e., pond length), assuming dead storage has been accounted for in the estimation of the pond area. An approximate length to width ratio is commonly assumed when relating pond length and width to pond area.

The site data suggests that irrespective of site-specific constraints for TSS and uncertainties, recent TSF operations tend to operate with effective pond sedimentation areas lower than that suggested by Coates and Yu. Scatter in the points reflects uncertainties in inputs (due to limitations of publicly available data) and/or differences between the sites. Uncertainties in inputs include the tailings throughput contributing to the tailings pond, and estimated effective sedimentation areas. Differences between sites could include tailings properties (e.g., particle size distribution (PSD), shape, and specific gravity), pond depth, and reclaim rates.

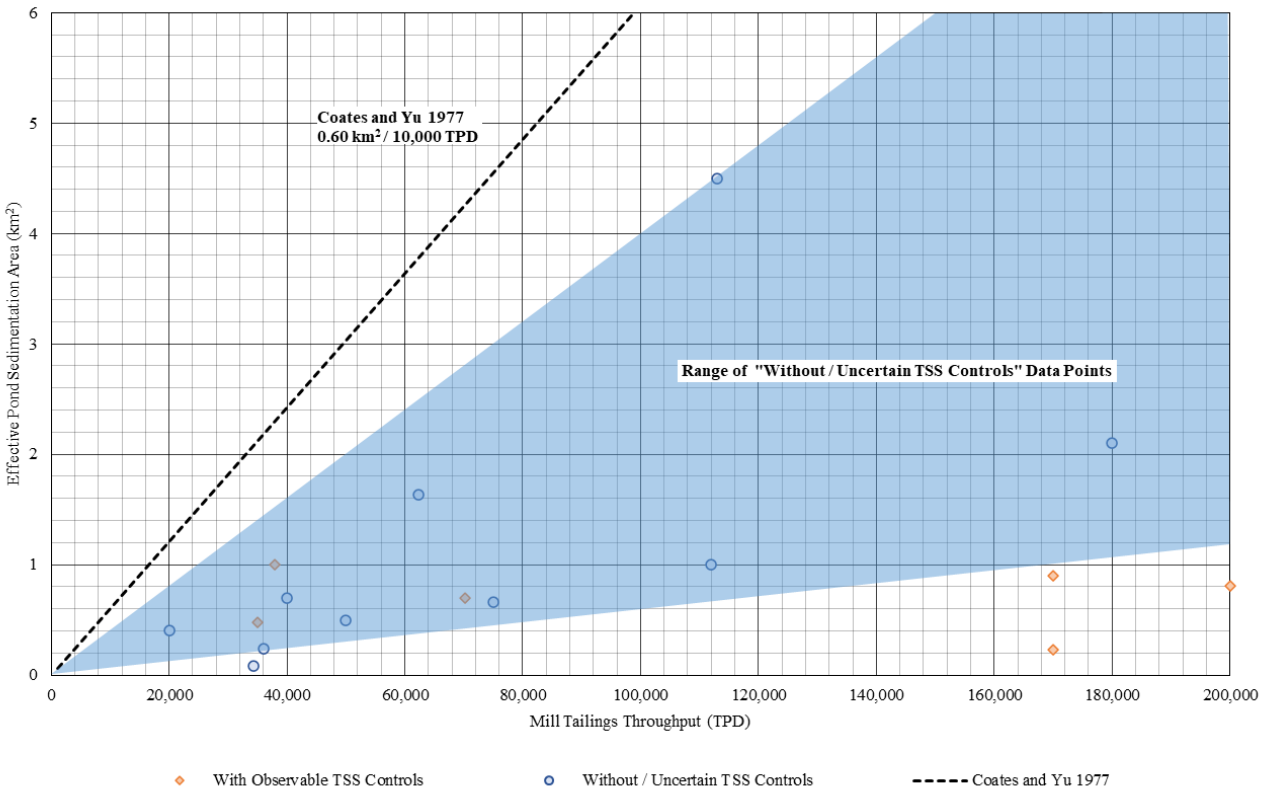

Figure 2: Effective pond sedimentation area vs. mill tailings throughput

Figure 2 could be applied as a screening-criteria for sites that have TSS criteria for mill reclaim or effluent discharge. Site estimates of the effective pond sedimentation area for future configurations of the mine life along with the estimated tailings throughput expected to contribute to the effective pond

sedimentation area should be plotted on Figure 2 and compared to the benchmarking and historical datasets. If the site data:

a. plots near the Coates and Yu (1977) line and above the blue zone, then pond sedimentation capacity is likely adequate;
b. plots within the blue zone, then theoretical analysis should be considered particularly if towards the lower end of the zone; or
c. plots near or below the bottom of the blue zone, then theoretical analysis is warranted and additional TSS controls will likely be required.

Theoretical approach

This assessment had the following steps:

1. Develop a conceptual model of the TSF and tailings pond geometry (usually based on an output of tailings deposition planning and modelling, and considering a range of possible future combinations of tailings deposition locations and pond geometry to identify critical configurations throughout the life of mine):
    a. Estimate the locations where tailings deposition is concentrated; and
    b. Estimate the effective pond sedimentation area (i.e., non-dead storage area) based on the facility and pond geometry, and considering a range of length to width ratios (values between 3:1 and 5:1 are typically recommended in literature (ENV, 2015; EPA, 1976)); and
    c. Estimate the corresponding total tonnage deposition contributing to the area of interest.
2. Estimate settling velocities of the tailings material of interest using settling column testing including testing of TSS for the settling column supernatant water (or, if no settling tests are available, using Stokes' law).
3. Calculate a "pond settling capacity" factor based on the ratio of effective pond sedimentation area vs. required pond area to settle out a particle size of interest.
    a. The required pond surface area based on the following equation (EPA, 1976):

$$A = F_s \frac{Q}{v_s}$$

Where Q is the outflow rate from the pond, m^3/s
A is the effective sedimentation area of the pond, m^2

F_s is a settling factor to account for short-circuiting or other non-ideal settling conditions (typically assumed to be between 1.2 and 2.0; ENV, 2015), unitless

v_s is the settling velocity of sediment particle size of interest, m/s

b. The effective pond sedimentation area as estimated in (1) above.

In general, particles sizes smaller than about 4 μm diameter cannot practically be removed by discrete settling (Haan et al., 1994), and it is common to assume that removal of 5 μm to 10 μm particles will result in sufficient water quality (ENV, 2015). However, it is important to understand the PSD of the tailings in question – if the tailings contain a high proportion of silt and clay-sized particles the water quality requirements may not be met if relying on only discrete particle settling. Laboratory testing to estimate the material PSD and settling velocity is recommended to inform the settling velocity of the particle size, which is critical to meeting the target water quality criteria.

Case study

The case study is for an open pit copper mine that produces and deposits tailings in a conventional TSF at a rate of about 77,000 TPD. Since around the mid-2000s, the TSF supernatant pond volume has been progressively reduced from a volume of about 70 Mm^3 to a volume of about 16 Mm^3 to support overall risk reduction for the facility, with the objective of operating the facility with a small supernatant pond of about 5 Mm^3. The water quality in water pumped from the TSF supernatant pond is required to meet a TSS criterion of 25 mg/L.

The objectives of the case study were to assess the feasibility of operating the TSF with a reduced pond volume considering the planned tailings production and deposition plan, and to set operational targets for if and/or when additional physical TSS controls (e.g., rockfill berms or protection of the pump intake structure) would be required.

For future configurations, the estimated critical (i.e., smallest) effective sedimentation area is estimated to be 0.14 km^2, which plots close to the benchmarking data where additional TSS controls were observed, and substantially lower than the Coates and Yu suggested pond sizing. Therefore, a theoretical approach was adopted to assess the feasibility of the planned pond sizing to meet TSS constraints. Major assumptions made for this assessment included:

a. Guidelines for sediment pond design recommend that 5 μm to 10 μm particles be settled out of suspension to meet water quality standards (ENV, 2015). Results of settling column test results were assumed to represent sufficient water quality for reclaim water, i.e., the settling velocity of the supernatant and solids interface is assumed to represent approximately the tailings d_{10} (approx. 5 μm), and the supernatant water quality is sufficient to meet water quality

requirements. The pond depth is assumed to be sufficient for settling to be primarily discrete particle settling.

b. The tailings loading assumed for this assessment assumes that the effects of varying solids contents on settling velocities could be neglected since tailings inflows to the pond will generally be at or lower than solids contents of whole or cyclone overflow tailings.
    - A key uncertainty in this process is the estimation of the effective pond sedimentation area and corresponding length to width ratios. Ratios of approximately 4:1 were assessed for historical pond areas. For future configurations, a ratio of 5:1 was conservatively assumed (i.e., pond area was calculated based on the estimated distance from inflow to outflow and the assumed 5:1 length: width ratio). Future configurations of the TSF were based on tailings deposition modelling that are subject to uncertainties in tailings beach slopes and potential changes to tailings deposition strategies.

c. A pond settling capacity factor of 2.0 was adopted for this assessment, considering the possibility of non-ideal settling conditions such as wind and wave action on the pond surface or scouring and sediment resuspension. Resuspension of solids due to influence of the pump intake is considered by including a buffer below the pump intake.

Figure 3 (on the next page) presents a schematic of the case study tailings beach and pond configuration, illustrating the pond area available for sedimentation considering a critical configuration of tailings deposition near the pump intake. In this case, due to both natural topography and tailings deposition strategies, a large portion of the pond is unavailable for sedimentation.

Table 1 summarizes the results of the case study calculations. The base case considers an estimated future critical configuration of the facility considering a relocated barge and pump; sensitivity cases were considered for a higher outflow rate and a reduced effective pond sedimentation area. The results were benchmarked against historical TSF pond configurations using the same methodology.

Table 1: Base case and sensitivity cases for future operations and historical benchmarking

Parameter	Base case	Sensitivity cases		Historical benchmarks	
		Increased outflow	Reduced pond sedimentation area	June 2023	October 2023
Effective sedimentation area (km^2)	0.14	0.14	**0.12**	0.11	0.07
Pond length:width ratio	5:1	5:1	5:1	4:1	4:1
Equivalent distance to outflow (m)	850	850	**800**	670	510
Outflow rate (m^3/s)	2.0	**2.5**	2.0	1.8	1.9
Settling capacity factor	1.3	1.0	1.1	1.1	0.7

Note: **Bold** text indicates differences for the sensitivity cases compared to the base case.

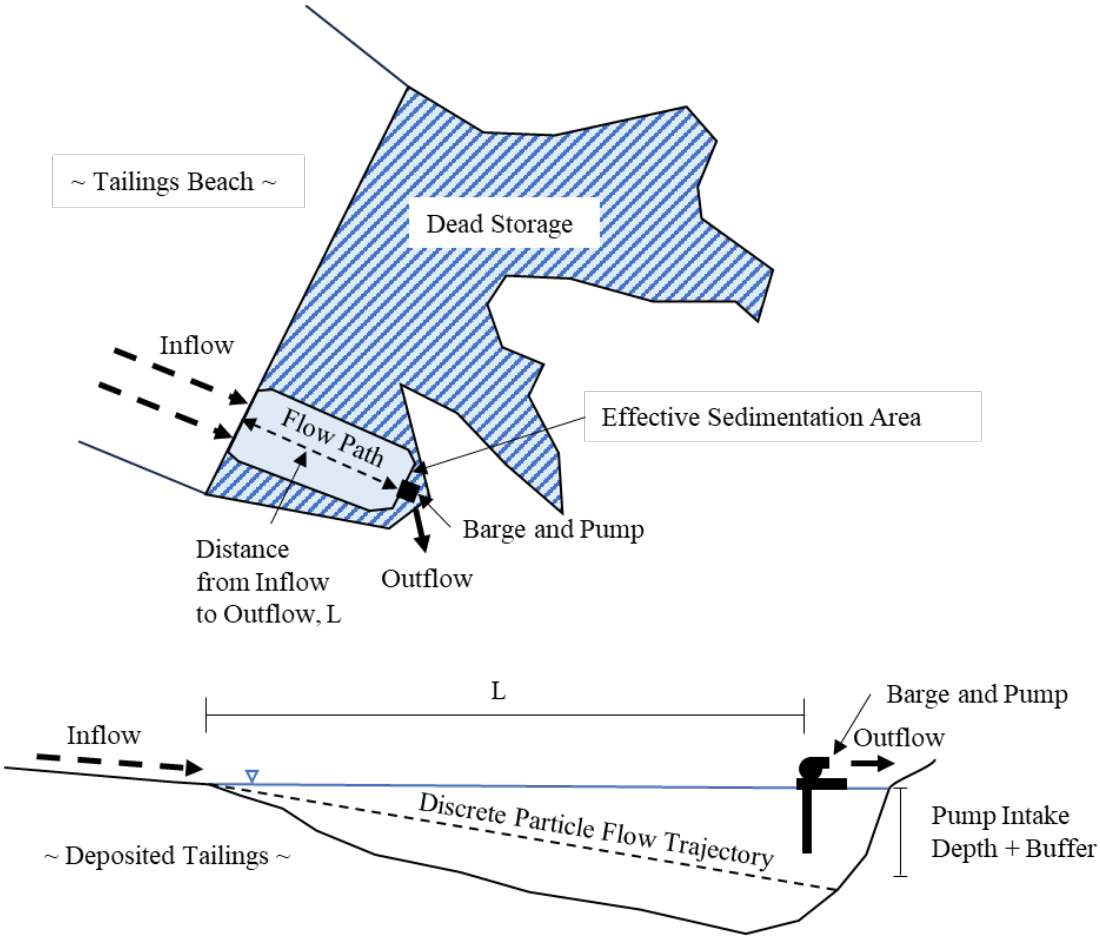

Figure 3: Schematic TSF plan and section illustrating sediment flow trajectory

The results suggest that an increased outflow rate and reduced effective pond sedimentation area both significantly affect the settling capacity, as reflected by the reduced settling capacity factor. The historical benchmarking cases demonstrate that the reduction in distance from tailings inflow to outflow between June 2023 and October 2023 resulted in a settling capacity factor below one, which is supported by TSS data: June 2023, pond TSS was about 12 mg/L, and October 2023, pond TSS was about 32 mg/L, which validates the adopted approach for estimation of pond settling capacity for the future TSF configurations.

The results of this assessment suggest that the planned future operations are likely to be close to a settling capacity factor of one, and therefore it is probable that additional physical or chemical controls to reduce TSS in the pond will likely be required assuming even minor deviations compared to the assumed tailings deposition properties and plan. Considering these results, the barge and pump has been moved to a more favorable and protected location farther from the tailings beach edge, and the distance from inflow (i.e., beach edge) to outflow (i.e., the barge and pump location) has been adopted as a target metric for ongoing tailings deposition and water balance planning.

Conclusion

The capacity of tailings ponds to settle out solids in dynamic TSF beach and pond systems is a complex process subject to many uncertainties. Assessment of pond settling capacity should consider the settling properties of tailings materials (ideally estimated via laboratory testing), and critical configurations of the facility over time, considering tailings throughput and deposition locations, effective pond sedimentation area, and outflow rates. While it may be preferred to operate with a small supernatant pond considering the facility risk and/or site hydrologic conditions, in many cases, pond geometry and tailings deposition strategies will dictate that large fractions of the pond area will not contribute to pond settling capacity (i.e., be dead storage areas).

The benchmarking data presented in this paper for North and South American copper mine TSFs could be used as a screening tool to assess whether significant further study is warranted for proposed facility configurations. The theoretical approach adopted for this study is a practical (and simplified) approach based on methods commonly used for sediment pond design. It could be used to inform key performance indicators for tailings deposition planning, and to inform decision-making for long-term pond sizing and potential requirements for additional chemical controls such as flocculants, or physical controls such as protected or pump intakes or berms to increase the flow path of tailings on the beach.

A more detailed analysis may be warranted where an estimated outflow sediment concentration or actual pond sedimentation efficiency is needed (e.g., to inform water treatment design), or for shallow ponds where discrete particle settling may not govern and where resuspension is more likely. The approach in this paper requires several assumptions for aspects of sedimentation that cannot be readily measured or observed, notably the application of idealized settling behaviors in a non-ideal setting environment, the potential for non-quiescent pond conditions and resuspension of solids (particularly around intake structures), and variability in sediment loads reaching the pond. Careful consideration should be paid to these uncertainties given the site context, and sensitivity or uncertainty analysis should be conducted to inform the sensitivity of any conclusion to variability in key input assumptions. These uncertainties could be used to inform key performance indicators for tailings deposition planning and for pond shape and location management, e.g., the distance from pond edge to pump location.

Thatyane Martins Gonçalves, Vale S.A., Brazil
Frank Pereira, Vale S.A., Brazil

Abstract

The mining industry has increasingly prioritized the use of tailings dry stacking as an alternative to traditional tailings disposal methods. This shift aims to minimize the potential for dam failures and tailings runout, offering both environmental and safety advantages. However, it is important to note that the behavior of tailings dry stacks can vary significantly due to differences in site conditions such as temperature, humidity, precipitation, and seismic activity across various regions. Brazil, Peru, and Australia are among the countries that have implemented tailings dry stacking disposal, each facing unique challenges and adopting specific approaches to address them. This study seeks to examine how the operation of a tailings dry stack is affected by different environmental conditions and evaluate its effectiveness as a method for disposing of tailings.

In Peru, the dry stacks are at a high altitude and in mountainous regions, which can present challenges such as low temperatures and increased risk of landslides. In contrast, in Brazil, where tropical conditions prevail, the main concerns are heavy rainfall and the potential for erosion. Additionally, in Australia, where drought conditions are common, high temperatures and lack of precipitation have an impact on the stability and drying behavior of the dry stacks.

By analyzing international practices and case studies, several key parameters have been identified that significantly influence the operation of tailings dry stack disposal, such as the type and density of the tailings material, the moisture content and compaction of the stack, and the design for closure considering local conditions and climate change scenarios. Understanding and properly considering these parameters is crucial for ensuring the successful and sustainable operation of tailings dry stack disposal facilities. In summary, the operation of tailings dry stack disposal is influenced by various key parameters such as

environmental conditions, site-specific challenges, and proper design and implementation that need to be carefully considered and addressed to achieve optimal environmental and safety outcomes.

Introduction

Dry stacking is an innovative method of tailings disposal that involves the dewatering of tailings to create a stable, low-moisture material that can be stacked and compacted. This approach reduces the risks associated with traditional tailings impoundments, such as embankment failures and tailings runout, and offers significant environmental and safety advantages by minimizing water usage and potential contamination. This study compares the operation of tailings dry stacks at three different sites located in distinct climates: high altitude and mountainous regions of Peru, tropical conditions in Brazil, and arid, drought-prone areas of Australia. Each site presents unique environmental challenges, necessitating tailored strategies and design adjustments to accommodate changes to mine plans and ensure the stability and effectiveness of the dry stacks.

Site I: Minas Gerais, Brazil

Overview

The site is an operating 68,000 tonne-per-day open pit iron ore mine located in the state of Minas Gerais, Brazil, approximately 200 km east of Belo Horizonte. During the dry season, about 8,000 tonnes per day of filtered tailings are stored in a filtered tailings storage facility (TSF). This decreases to 3,000 tonnes per day during the wet season. Figure 1 depicts the tailings dry stacking facility.

Figure 1: Tailings storage facility in Minas Gerais (source: Google Earth)

Site conditions

The site is located in a high rainfall, temperate climate environment. The mean annual precipitation is approximately 1,200 mm, which is roughly equivalent to the local evaporation rate. Periods of heavy rainfall lasting several days are common. The mean annual temperature is approximately 22° C. The site does not have high seismicity.

TSF operations

The tailings have a specific gravity of approximately 3 g/cm^3 and a P80 ranging from 0.1 to 0.2 mm. The tailings contain around 15 % hematite. The TSF operation and monitoring are conducted by the operator, with periodic inspection carried out by external consultants. During the engineering design phase, a trial field was created to evaluate the thickness layer, velocity of roller compactor, water application and compaction, in order to ensure that the final tailings deposit will achieve the desired slope and moisture content for a stable dry stack (Rodari Gutierrez and Agustin Oldecop, 2021). The stacking of filtered tailings involves dumping by trucks, while the fill construction consists of building embankments and placing compacted approved material in areas where unsuitable material has been removed. The tailings are placed in controlled, compacted layers not exceeding 30 cm (compacted) using approved compaction equipment, ensuring uniform raising and achieving a minimum compaction level of 95 percent maximum dry density. During fill placement, there is continuous full-time observation, and field tests are performed under the supervision of an QA/QC team. If the required compaction is not recorded during testing, additional effort has to be exerted, along with adjustments to moisture content, until at least 95 percent compaction is achieved. The TSF is constructed above a drainage system designed to collect seepage and rising water tables. The global slope for the TSF is 15º and the local slope is 2.5H:1V (22º).

Site II: Cerro Lindo, Peru

Overview

The Cerro Lindo Mine is situated in the province of Chincha, department of Ica, approximately 200 km south of Lima, Peru. The mine currently processes 7,000 metric tonnes per day to extract polymetallic minerals including zinc, lead, and copper, utilizing the sub-level stoping mining method. The mineral processing results in the generation of concentrates that account for roughly 10% of the processed material. Of the generated tailings, 55% is used for underground paste backfill, while the remaining 45% is deposited on the surface as filtered tailings.

Figure 2: Cerro Lindo TSF (source: Google Earth)

Site conditions

The mine is located in the occidental Andes at an average elevation of 2,000 masl. The yearly average precipitation and evaporation are 200 and 1,500 mm, respectively. The zone has an arid climate, with average yearly temperatures of 19°C, and with some rain concentrated in the months of December to March. For the rest of the year precipitation is rare and sporadic (Lara and León, 2011).

The mine is located in a high seismicity area, less than 100 km from the Peru-Chile trench. Earthquakes in the area are expected up to a magnitude of Mw = 9.0 (for the maximum credible earthquake) with maximum accelerations at a basal rock level of 0.45 g (Lara and León, 2011). In 2007 a significant seismic event of magnitude Mw = 8.0 occurred, considered as a maximum operation earthquake for the project area, with a return period of 500 years. The Cerro Lindo tailings TSF sustained no damage during and after this earthquake.

The TSF is located in the Quebrada Pahuaypite, which has an approximate watershed area of 0.45 km^2. The average gradient of the bottom of the Quebrada Pahuaypite is 20–25%, and the valley side slopes are also variable between 25 and 45%. From a hydrogeological point of view, the quebrada does not have water flow at all times of the year and there is no evidence of water seepage. The groundwater level is more than 40 m deep in the area of the tailings deposit (Lara and León, 2011).

TSF operations

The filtered tailings deposit is composed of two desiccation platforms of approximately 2,250 m^2 and 14,050 m^2 each, located at elevations 2,028 and 2,082 masl, respectively. In these platforms, filtered tailings are discharged, spread by sectors to obtain desiccation and to allow further compacting. The tailings deposit has been designed to store 14 Mt of tailings and is built as a large fill that will have an overall slope of 2.8H:1V (19°). The tailings storage construction has benches that have a minimum width of 10 m each, and are 20 m high. As a part of the tailings deposit, a basal drainage system has been provided for seepage collection from the tailings deposit. The filtered tailings require compaction in layers due to the elevated site topography and the high seismic activity of the location.

Site III: Karara, Australia

Overview

The Karara mine is a magnetite mining and processing facility situated in the Mid-West region of Western Australia, approximately 225 km east-southeast of Geraldton and 320 km north-northeast of Perth. The mine operation comprises an open-pit mining excavation, a beneficiation processing plant, a waste rock disposal area and TSFs.

Figure 3: Karara TSF (source: Google Earth)

Site conditions

The local climate is characterized by an extended dry season lasting seven to eight months, accompanied by cold, wet winters and hot, dry summers. Average temperatures during the warmer months in Morawa range from a daily minimum of 13°C to a maximum of 38°C, while in the cooler months, the average temperature span is 6°C to 28°C. The average annual precipitation is 300 to 400 mm, fluctuating from a monthly low of 8 mm in December to a high of 60 mm in June. Extreme rainfall events exceeding 160 mm can be anticipated, and a 1-in-20-year, 72-hour rainfall event could produce over 100 mm of precipitation. The number of days with measurable rainfall varies significantly, with less than 2 days per month on average during the November through February period, compared to approximately 8 days per month during the winter season.

TSF operations

The mineral processing at the Karara mine generates tailings characterized by a high silica content and fine to ultrafine particle size. Due to limitations within the processing plant, the mine operator has implemented a tailings management approach utilizing both conventional wet tailings facilities and a dry stack tailings facility. The dry tailings are deposited at a moisture content of approximately 15%, while the wet tailings are pumped to the tailings dam at around 45% solids. The dry tailings are stacked using a radial stacking technique involving a series of conveyor extensions that sweep across the deposition area. The conveyor system operates in an arcing motion, depositing the dry tailings in layers. As each arc is completed, the conveyor is shifted to the next arc, and the tailings deposition continues. The tailings storage facility is surrounded by toe drains to collect any runoff and seepage, which are then directed to drainage collection sumps. The slopes of the tailings facility are maintained between 43° and 45° during construction and tailings placement. Upon closure, the tailings facility landform will be shaped to achieve a stable slope configuration.

Key parameters influencing tailings dry stack operation

By analyzing international practices and case studies, several key parameters have been identified that significantly influence the operation of tailings dry stack disposal. These are discussed below.

Environmental and site-specific challenges

Brazil: tropical conditions

Brazil's tropical conditions pose challenges. Heavy rainfall can lead to erosion and increased moisture content in the tailings, which affects their stability and compaction. Additionally, the high humidity levels

can slow down the drying process, making it difficult to maintain the desired moisture content in the tailings.

Peru: high altitude and mountainous regions

In Peru, tailings dry stacks are often located in high-altitude and mountainous regions. These areas present unique challenges, such as low temperatures and an increased risk of landslides. The cold climate can affect the dewatering process and the compaction of the tailings, potentially leading to stability issues. Furthermore, the steep terrain increases the risk of landslides, which can compromise the integrity of the dry stack.

Australia: drought conditions

In Australia, drought conditions are a primary concern. High temperatures and lack of precipitation can accelerate the drying process, potentially leading to overly dry and brittle tailings. This can cause dust generation and pose a health hazard. Moreover, the arid conditions can affect the stability of the stack, as excessively dry materials may not compact well.

Table 1: Average annual rainfall and evaporation in studied sites

Site	Average annual precipitation	Average annual evaporation
Minas Gerais	1,200 mm	1,200 mm
Cerro Lindo	200 mm	1,500 mm
Karara	400 mm	2,000 mm

Type and density of the tailings material

The type of tailings material and its density are critical factors in the design and operation of dry stacks. Different minerals and processing methods result in tailings with varying particle sizes, shapes, and densities. These properties influence the stack's stability, permeability, and compaction behavior. Accurately characterizing the tailings material is essential to design a containment structure that can accommodate its specific properties. Table 2 summarizes the type, specific gravity, and fines content of the tailings material in the three sites.

Table 2: Type and density of tailings material

Site	Tailings type	Specific gravity, Gs	Fines content, %
Minas Gerais	Iron ore	2.95 – 3.10	40 – 65
Cerro Lindo	Zinc, Copper, Lead	4 – 4.2	56 – 58
Karara	Iron ore	2.94 - 3	75 – 90

Moisture content and compaction

The moisture content of the tailings is a vital parameter affecting the stack's stability and behavior. Proper dewatering is necessary to achieve the right moisture content for compaction. Overly wet tailings can lead to instability and erosion, while overly dry tailings can become dusty and difficult to compact. Regular monitoring and adjustment of the moisture content are crucial for maintaining the stack's integrity. Table 3 summarizes the average moisture content (MC) and average in-situ dry density of tailings in the sites.

Table 3: Moisture content and in-situ dry density of tailings

Site	Average MC after compaction	Average in-situ dry density	Layer thickness
Minas Gerais	10.5 – 13 %	1.9 – 2 tonne/m^3	0.3 m
Cerro Lindo	5 – 7 %	2.7 – 2.8 tonne/m^3	0.3 m
Karara (Amoah et al, 2018)	13 – 15 %	1.7 tonne/m^3	24 – 26 m

Design and construction of the containment structure

The containment structure's design and construction are fundamental to tailings dry stacking's success. The structure must be engineered to support the tailings' load and withstand environmental stresses such as rainfall, temperature fluctuations, and seismic activity. Proper drainage systems, erosion control measures, and reinforcement techniques must be incorporated to ensure long-term stability. Table 4 presents the key design parameters of the dry stack in the studied sites.

Table 4: Key design parameters

Site	Stacking rate Tpd	Volume Mm^3	Area Ha	Max height m	Global slope H:V
Minas Gerais	3,000 – 8,000	8	42	60	3.75:1
Cerro Lindo	5,000	4.93	60	160	2.8:1
Karara	33,000	449	486	60	2.6:1

Conclusion

The operation of tailings dry stack disposal is influenced by various key parameters such as environmental conditions, site-specific challenges, and proper design and implementation. Understanding and properly considering these parameters is crucial for ensuring the successful and sustainable operation of tailings dry stack disposal facilities. Each region presents unique challenges that require tailored approaches to achieve optimal environmental and safety outcomes.

Ongoing monitoring and maintenance are essential for the sustainable operation of tailings dry stacks. Regular inspections and monitoring of the stack's moisture content, compaction, and structural integrity can help identify potential issues before they become critical. Implementing a robust maintenance plan that includes erosion control, dust suppression, and stability monitoring can enhance the stack's performance and safety.

By learning from international practices and adapting strategies to local conditions, the mining industry can enhance the effectiveness of tailings dry stacking as a safer and more environmentally friendly disposal method.

Characterization of Flocculated Fluid Fine Tailings Using On-line Microscopy

Paul Mikula, Kalium Research, Alberta, Canada
Nan Wang, Syncrude Research, Alberta, Canada
Adeola Bello-Hamilton, Syncrude Research, Alberta, Canada
Randy Mikula, Kalium Research, Alberta, Canada

Abstract

Oilsands fine fluid tailings (FFT) can be processed using flocculation to separate water from the tailings by adding polymer to a coagulant treated FFT. Variations of this process are in use at the Suncor and Imperial surface mined oilsands operations. At the Syncrude oilsands facility this process is called Floc-T. The degree of flocculation in the FFT, and the effectiveness of the dewatering process, are determined by the polymer dosage and how well it is mixed. Presently the performance of the Floc-T process is measured using capillary suction time (CST) tests roughly every three hours, so adjustments to the process can be made. Using online microscopy imaging technology to determine the performance of the flocculation process allows for adjustments to be made more frequently in response to changes in the FFT feed. Computer analysis of the optical images is used to determine key statistical quantities such as the median brightness and the inter-quartile range, which can be correlated with FFT feed and mixing parameters and ultimately used to control the polymer dosage and mixing conditions. Unlike the CST test, the image analysis gives a direct assessment of the degree of flocculation independent of the feed density. The microscopic image analysis therefore provides a real-time assessment of the mixing and flocculation in the FFT, without the need for sample testing, allowing for a rapid response to changes in the FFT feed. Results from full-scale commercial application of the technology are presented along with a strategy for automation.

Introduction

The Syncrude Floc-T process involves mixing polymer into the fine fluid tailings (FFT) to flocculate or clump the solid mineral particles together, allowing easier separation of the solids and the water. For this process to work effectively, the polymer dosage needs to be correct, and it needs to be sufficiently mixed into the FFT. Figure 1 shows a schematic of the Floc-T process as operated at Syncrude. The residence time tank shown was used in the pilot testing, but not in the commercial operation since there is enough pipeline

residence time to ensure proper coagulant treatment of the fluid fine tailings. Since the polymer used is a significant cost, optimizing this process involves keeping polymer dosages as low as possible as well as ensuring the FFT is properly flocculated. The current procedure for measuring the effectiveness of the process involves taking samples at regular intervals and measuring the capillary suction time to determine how easily water drains from the sample. This does not allow for rapid changes in the process to be made to account for changes in FFT feed that could vary significantly between sampling intervals. Using an on-line imaging device to take pictures of the FFT in the pipe can inform operators of real-time changes to the FFT mixing and flocculation without relying on sampling.

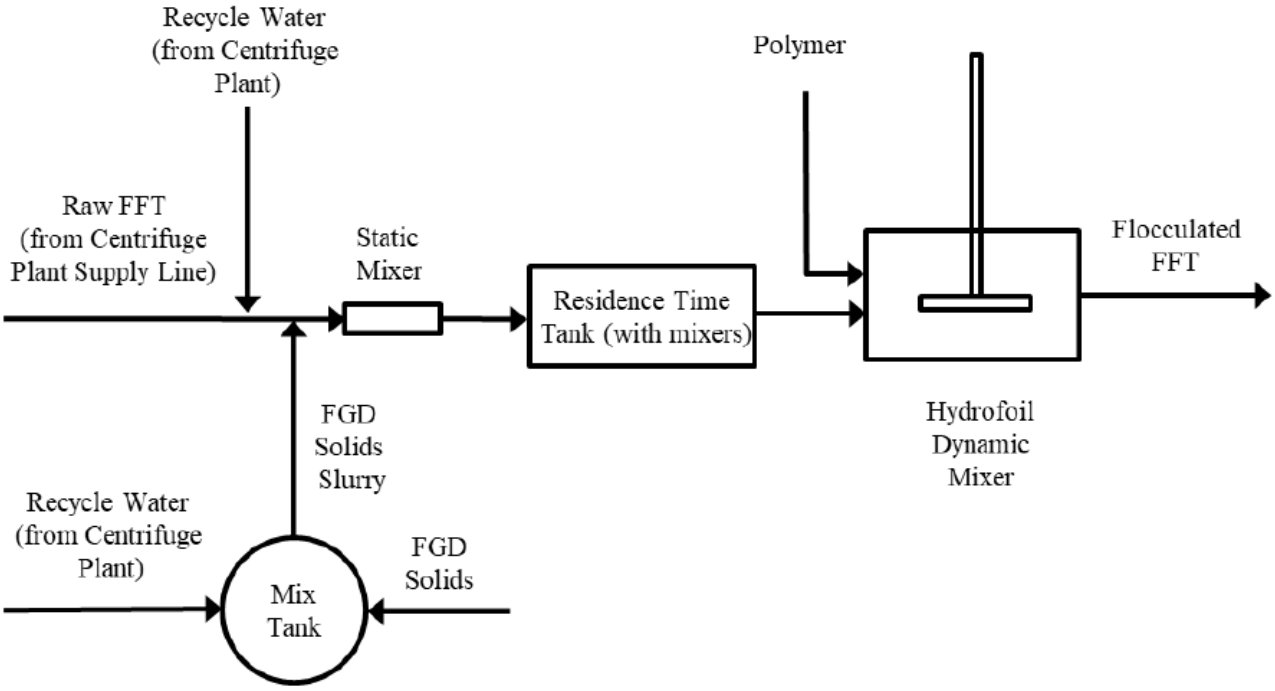

Figure 1: Schematic of the Floc-T tailings treatment process at Syncrude

The image capture system used for the Syncrude Floc-T process testing was a Mettler Toledo PVM system. This has the capability of automated illumination to maintain consistent image brightness, or the option of fixed illumination. Images can be captured and stored in files that can be accessed to perform the necessary image analysis to quantify the degree of flocculation. The image time interval can be modified to match the process dynamics or process response time. The probe was mounted approximately 15 m downstream of the in-line dynamic mixers and perpendicular to the flocculated FFT flow. The probe in the PVM is a 19 mm steel tube approximately 40 cm in length with a sapphire window in contact with the FFT flow. The optical system is controlled by a head unit at the end of the steel tube. The head unit is connected to a power supply and image acquisition unit by a fiber optic cable about 3 m in length. The power supply and image acquisition unit is in turn connected to a laptop computer for image output and general system

control (illumination level, image capture interval etc.). The power supply, optic control unit and associated laptop computer were housed in a weatherproof enclosure, while the probe was mounted on the pipe and exposed to the elements. It is important to note that the probe was left in place throughout the three-month program and there was never any evidence of blinding or contamination of the optical window.

In the images, brighter regions represent higher solids concentrations and dark regions represent water. A well flocculated sample will show clumps of solids separated by water, while poorly flocculated samples will appear more homogeneous. Previous work with imaging of FFT has shown that there is a clear difference in the distribution of pixels in images of FFT depending on the level of flocculation in the sample. Figure 2 shows an image with poor flocculation, along with the distribution of pixel brightness. Figure 3 shows a sample with good flocculation along with the distribution. The average and inter-quartile range (IQR) of each distribution are indicated.

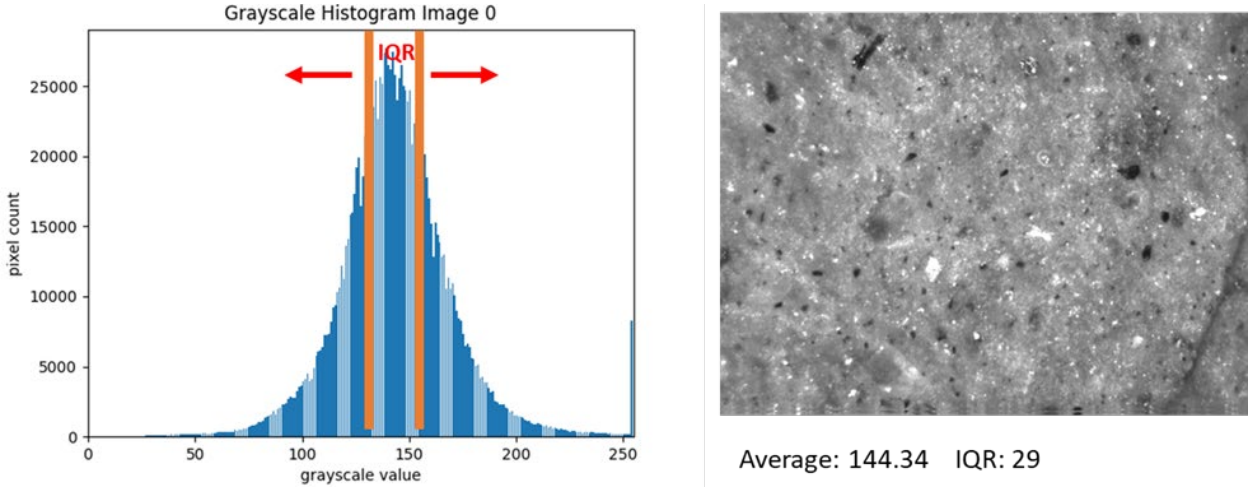

Figure 2: Image and pixel distribution for well flocculated MFT

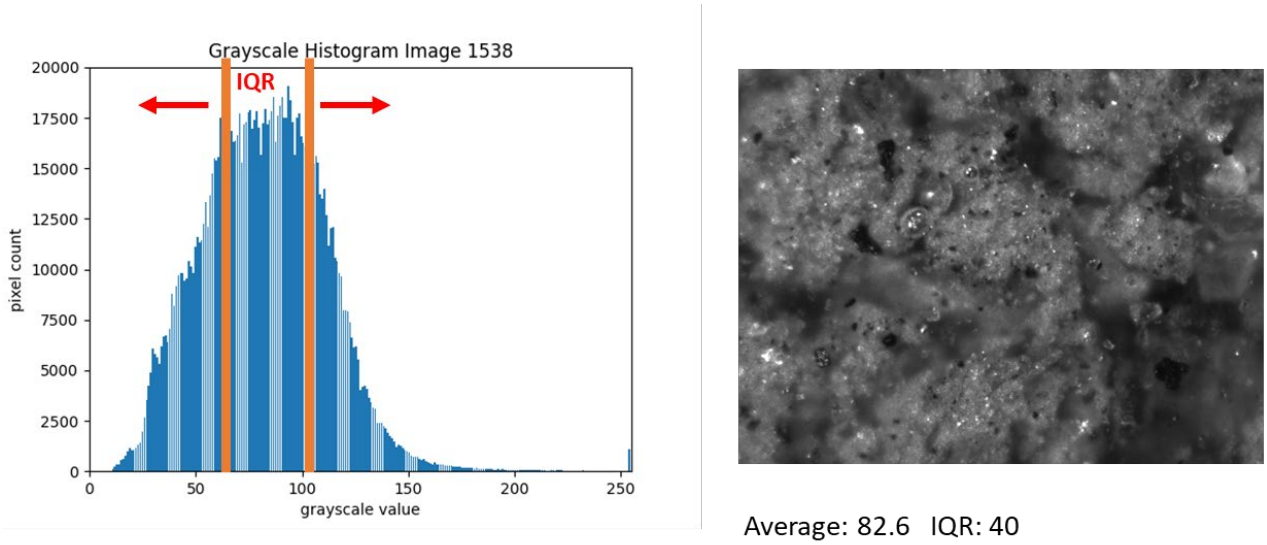

Figure 3: Image and pixel distribution for ideally mixed polymer and MFT

The analysis of images collected during the Floc-T process allows for real time adjustments to mixing and polymer dosage that can optimize the process without relying on infrequent CST testing. Furthermore, it represents a significant improvement over other proposed methods for on-line process monitoring. Previous suggestions for controlling the flocculation process involve near infrared spectrometers and density gauges to determine clay content and therefore polymer dosage, as well as instruments to measure flocc size (Junaid, 2020). All this complication is avoided with this direct assessment of the degree of flocculation using image data.

Results and discussion

PVM images were collected on train 1 in Syncrude's Floc-T process plant for 11 different intervals between September 14th and 25th. Most of the data was collected while changes were being made to the mixing speed, to see the effect of mixing on the PVM images. The 11 intervals (or runs) are labelled A through K in chronological order. This study will only discuss intervals B, C, and D in detail; the results of the other intervals agree with what is found in those three. During each of these intervals changes were made to the mixer speed, resulting in changes to the degree of flocculation observed.

The two quantities used to describe the image pixel distributions are the median brightness and the IQR. The median is an indicator of the overall brightness of the image, and the IQR is an indicator of the width of the distribution. Data from the Floc-T process (mixer speed, flow rate, etc.) is collected roughly every 10 seconds while images are taken as fast as twice a second in some cases. In order to match images with process data, a linear interpolation is used between pairs of data points. In this report, the FFT density and the mixer speed are compared with median brightness and the IQR from the images.

This section will highlight the important features of the imaging data. To reduce some of the variability in the imaging data, the charts in this report plot the data as a 20-point running average. For the runs considered here this is an average over 10 seconds, which is the same interval over which most of the flocculation process data is collected. The first run considered is run B, where images are collected with a variable brightness gain determined by the PVM software.

Figure 4 shows how the median brightness compares with the mixer speed over the run, and Figure 5 shows how the median brightness compares with the density over the run. Figure 6 shows the IQR and the mixer speed during the run. The important part of this run is the changes to the mixer speed, which starts at 30% of the maximum (roughly 525 RPM), then is dropped to 0, and increased by 10% of the maximum in 1-minute intervals up to 70%, then decreased in the same intervals back to 30%.

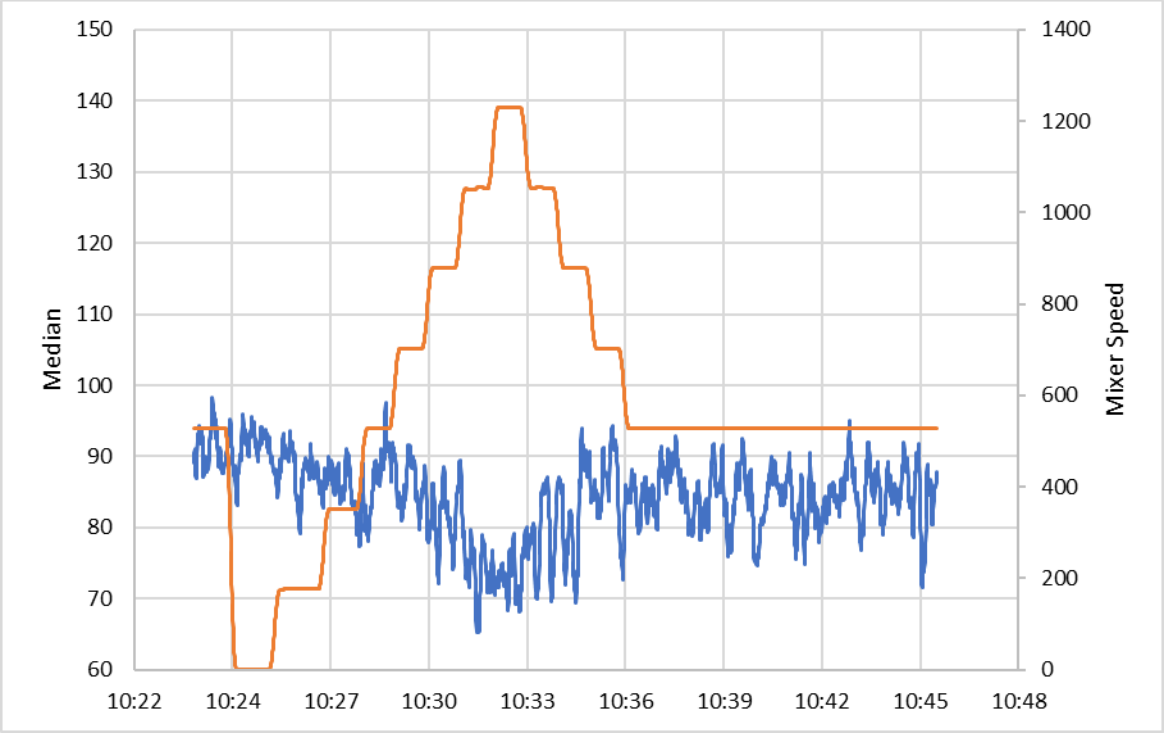

Figure 4: Median brightness (blue) and mixer speed (orange) for run B

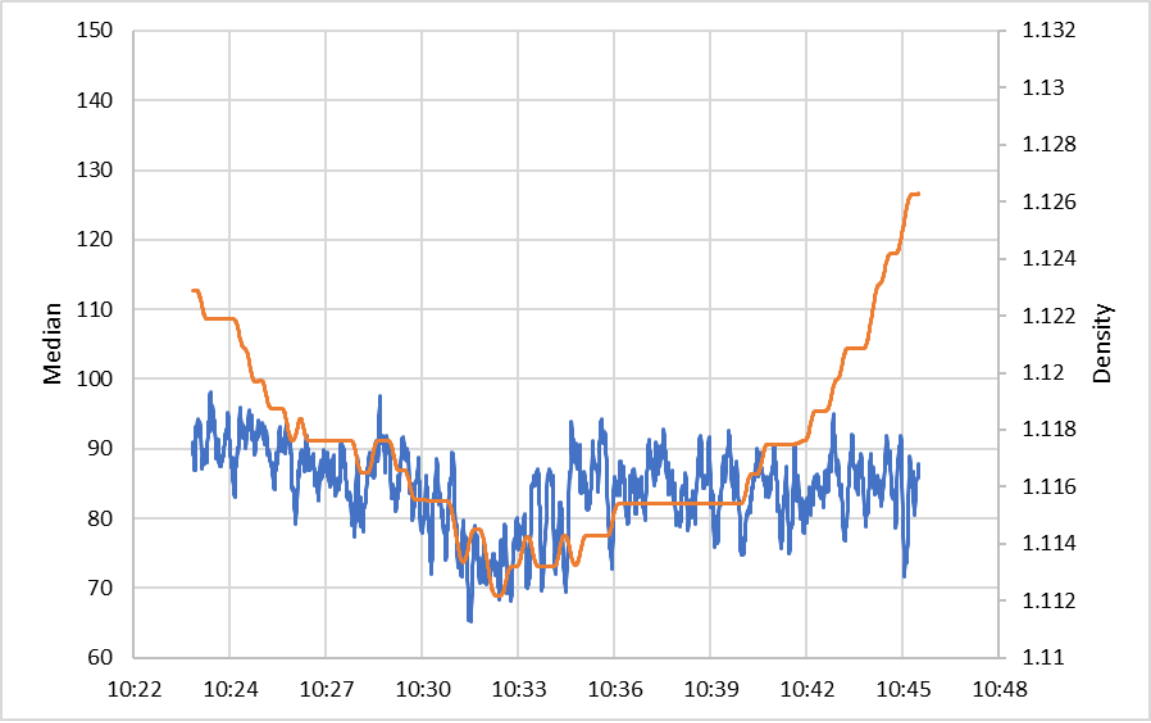

Figure 5: Median brightness (blue) and density (orange) for run B

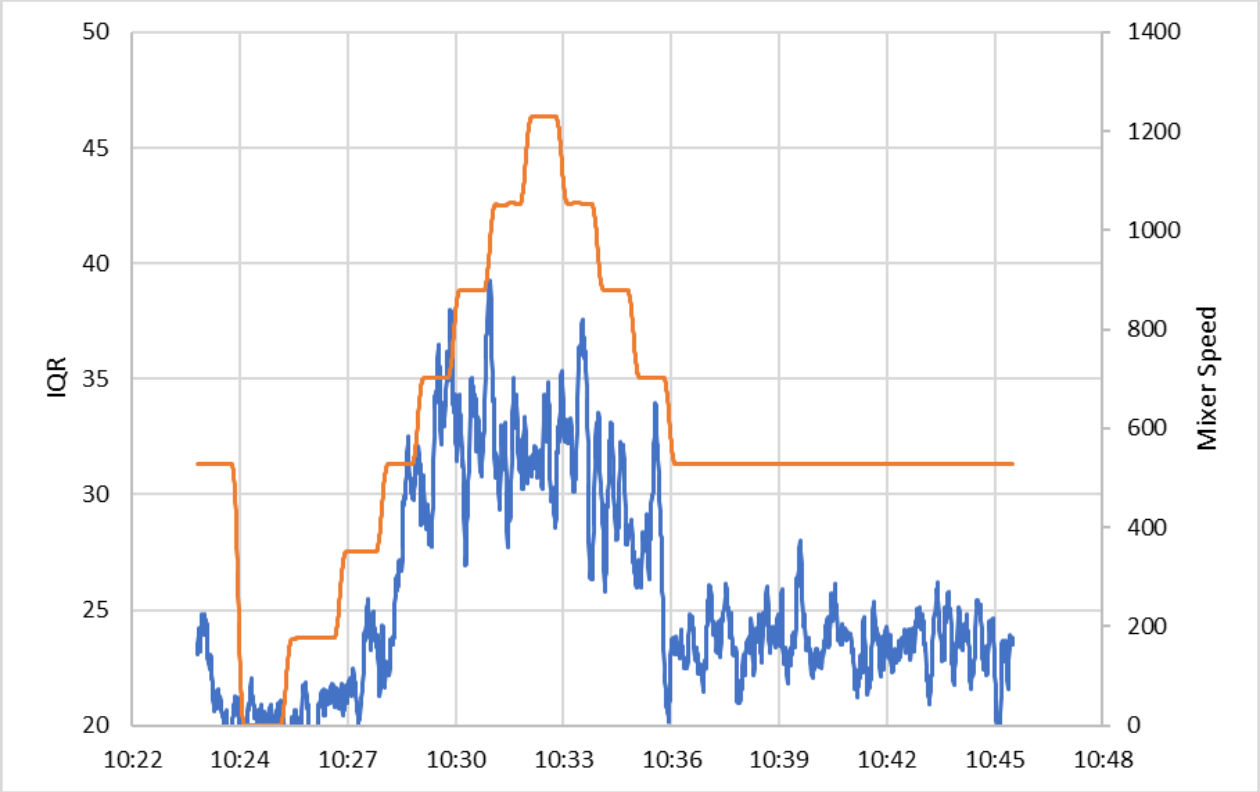

Figure 6: IQR (blue) and mixer speed (orange) for run B

Figure 4 shows only a slight dip in the median brightness during run B despite the changes to the mixer speed and density. The lack of change in the median brightness for run B is due to the PVM imaging software applying a variable gain to the images. For all the runs after A and B, a fixed imaging gain was used so that changes in average brightness could be observed in the images, which might better reflect changes in flocculation. Despite the variable gain, the width of the distribution as measured by the IQR still correlates with the mixing speed. Increased mixing leads to a wider distribution of brightness in the image, indicating better flocculation. It is also worth noting that the IQR representation of flocculation was also sensitive to the flocculation differences at low mixer speeds.

During run C, a similar test with the mixer speed is performed, with the speed increased by 10% increments from 0% up to 70% of the maximum speed, then back to 0. For this run the mixer speed begins and ends at 20% (roughly 350 RPM), and the PVM images are collected with a fixed gain. Figure 7 and Figure 8 show how the median brightness and IQR vary with the mixer speed. In addition to showing changes to the median brightness, fixing the gain has also reduced the variability in both the median and IQR from image to image.

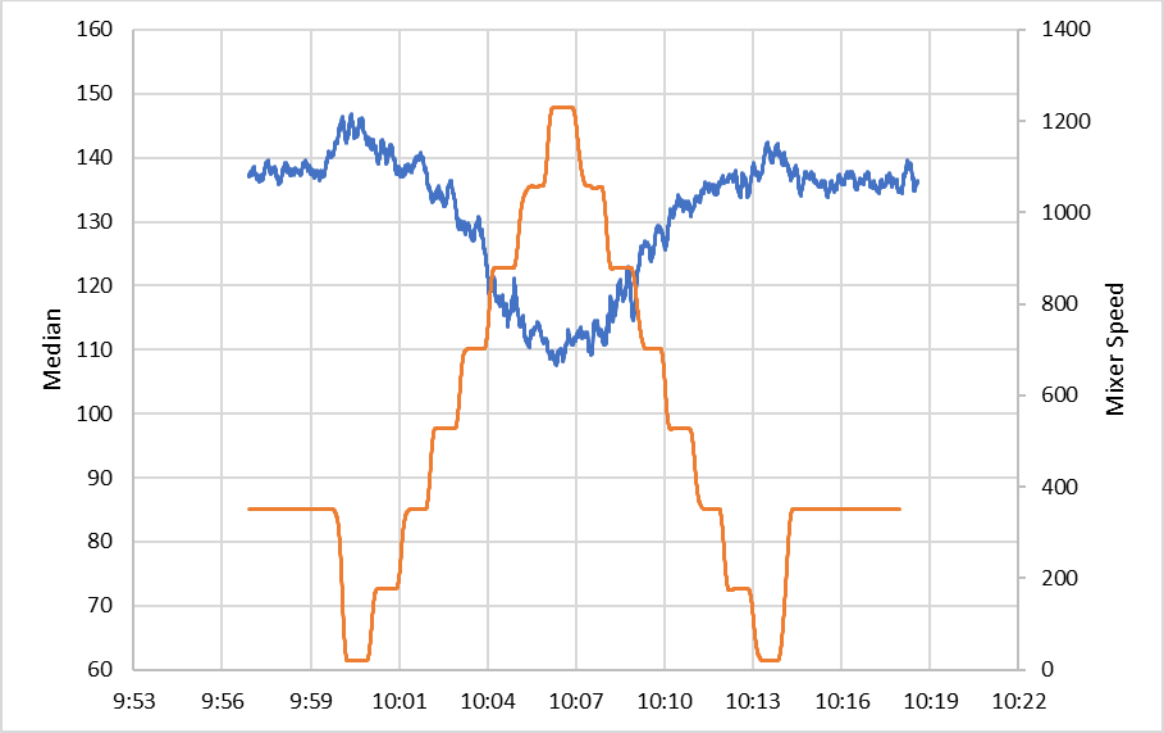

Figure 7: Median brightness (blue) and mixer speed (orange) for run C

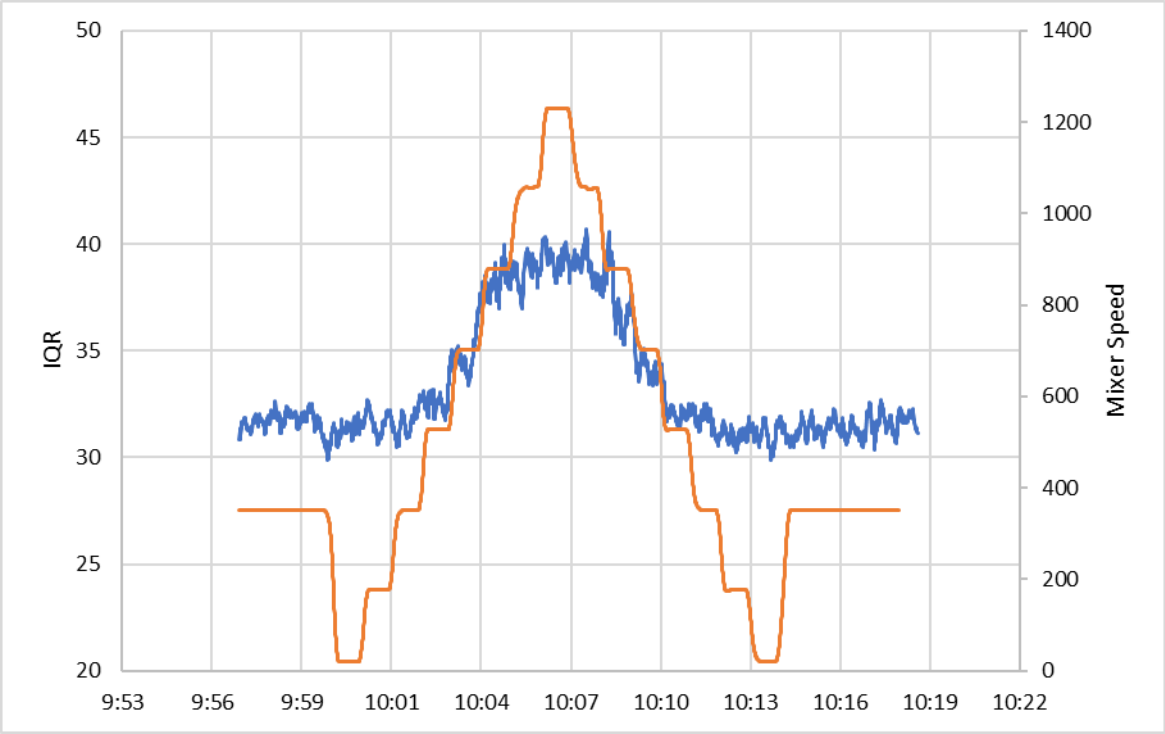

Figure 8: IQR (blue) and mixer speed (orange) for run C

From Figures 7 and 8, the effect of the mixing speed on the median and IQR image data suggests that the flocculant mixing performance can be improved by increasing the mixing speed. Figure 7 shows an obvious effect of the mixing speed on the median brightness compared to Figure 4 with variable gain. Lower median brightness (darker image with more water) and higher IQR (a wider distribution is a less homogeneous image) are both indicators of improved flocculation performance. In Figure 8, there is no significant effect on the IQR from reducing the mixer speed to 0; this is due to the short time period for the changes to mixer speed. For this run the IQR levels off once the mixer speed reaches 50%. This suggests that in this case optimal mixing has been achieved, and even higher mixing speeds may lead to overmixing and decreased flocculation performance.

Like the previous runs, run D also features significant changes to the mixer speed throughout; however, during run D the changes in the feed density are also significant. Figures 9 and 10 show the median brightness and IQR respectively along with the density throughout the run. Figures 11 and 12 show the median brightness and IQR respectively along with the mixer speed during the run. Although most CST data is collected every three hours, during run D CST tests were conducted at three different times, corresponding to different mixing speeds. The results of the CST tests for this run are indicated on Figure 12 and summarized in Table 1, which shows clear variation in the CST as the mixing speed changes.

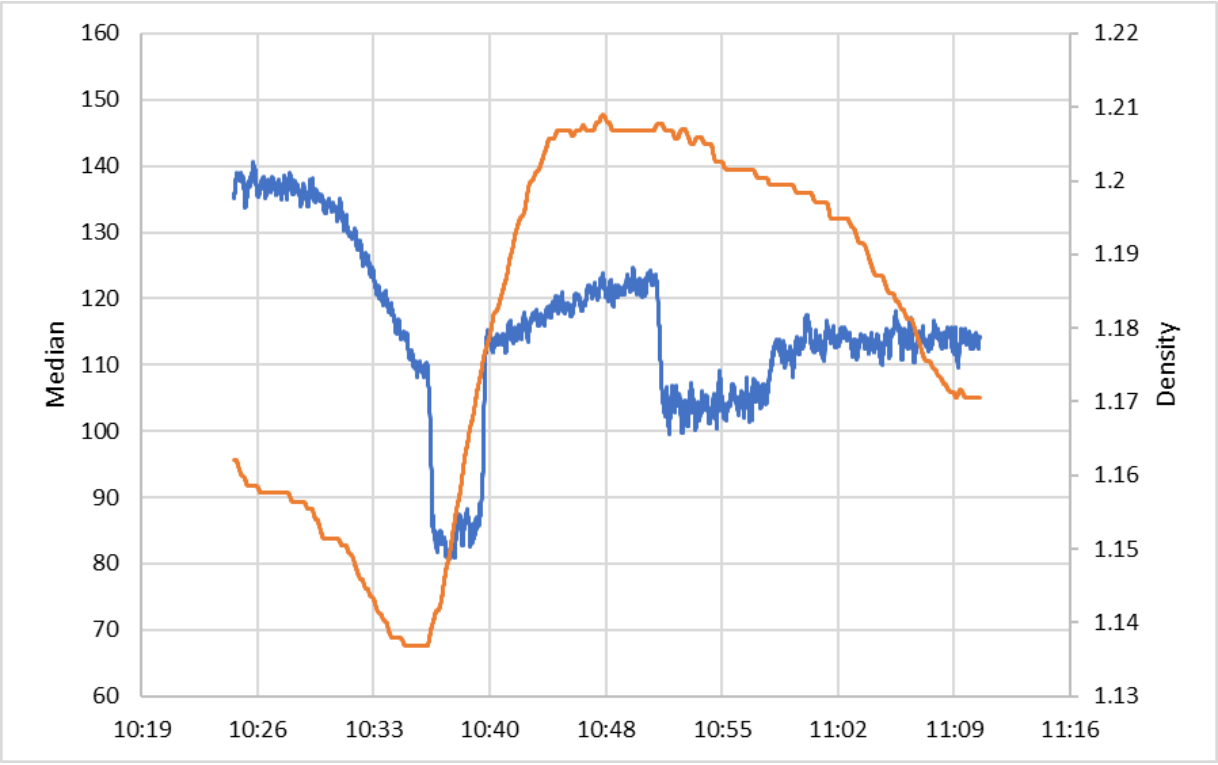

Figure 9: Median brightness (blue) and density (orange) for run D

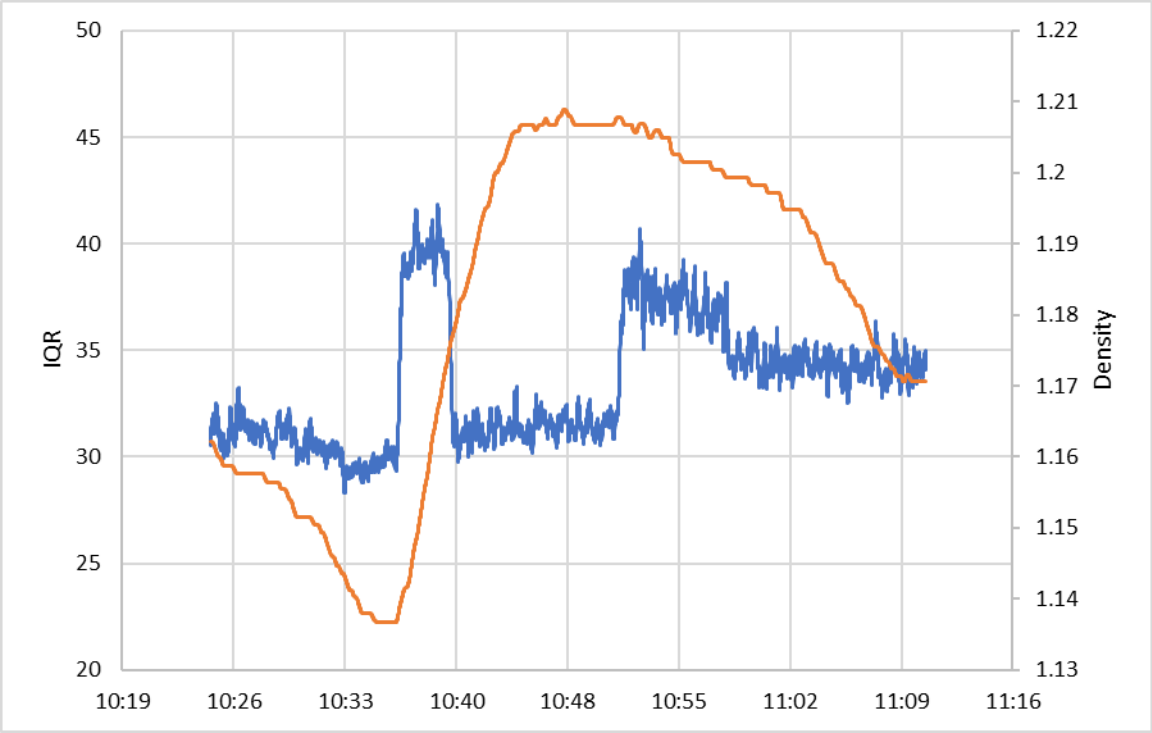

Figure 10: IQR (blue) and density (orange) for run D

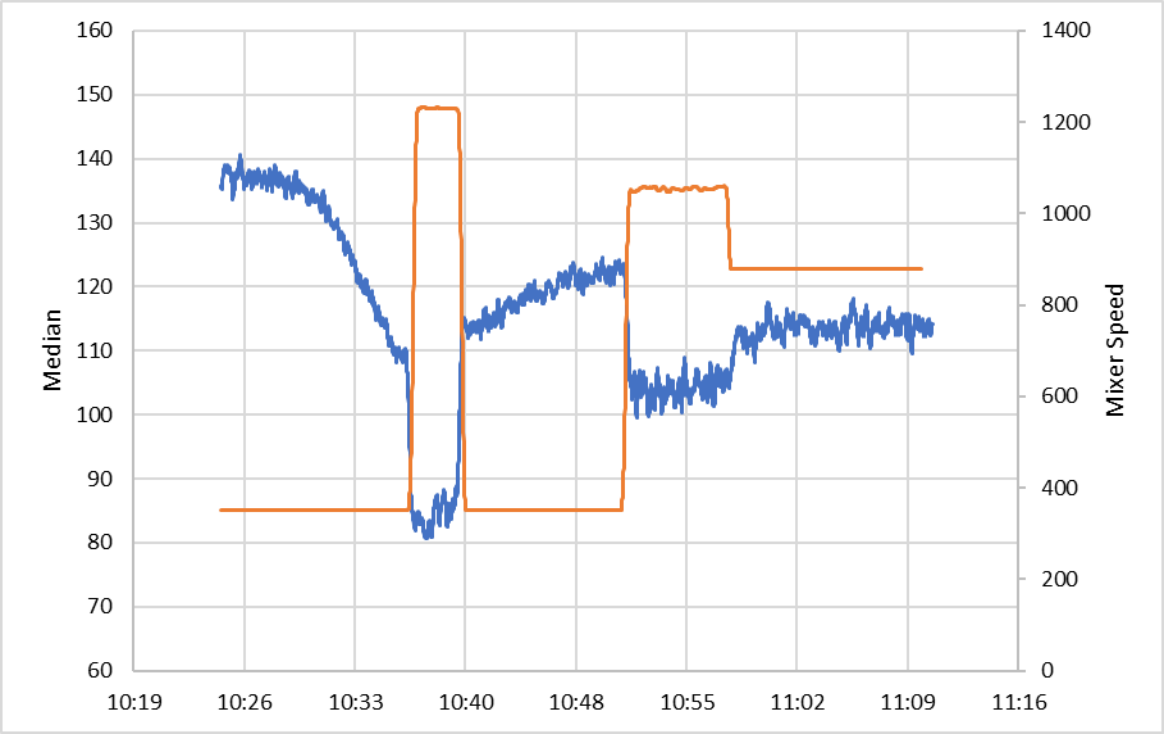

Figure 11: Median brightness (blue) and mixer speed (orange) for run D

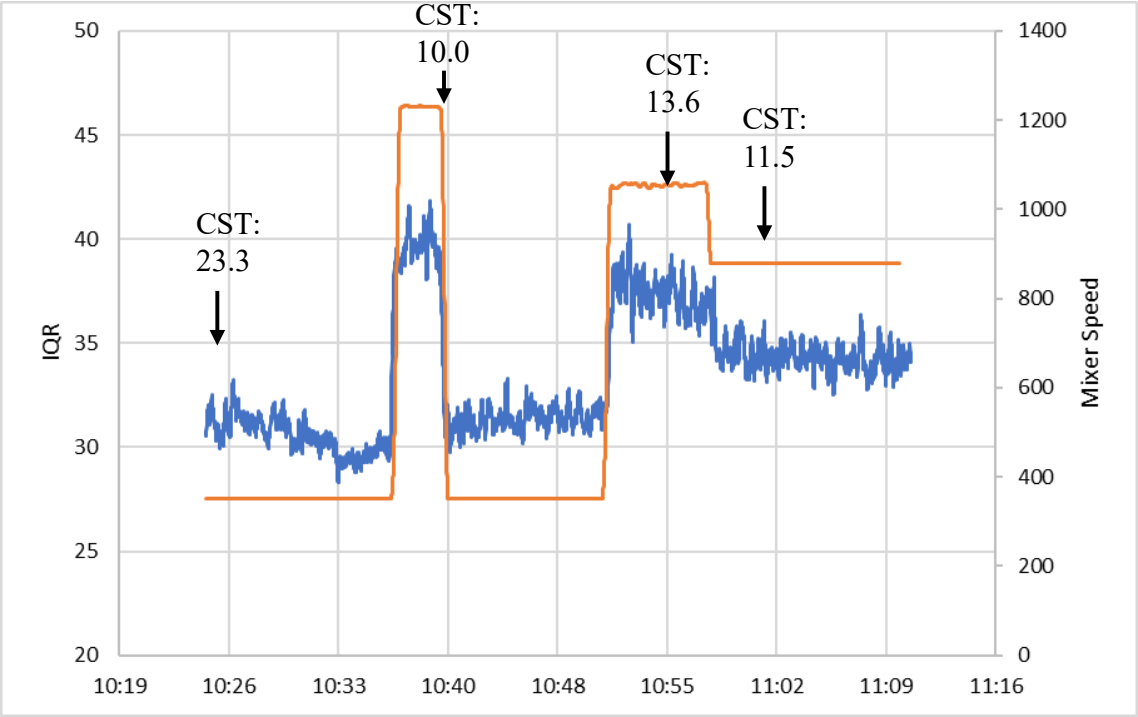

Figure 12: IQR (blue) and mixer speed (orange) for run D, with CST values

Table 1: CST data for run D

Time	Mixer speed	Average CST
10:25	20%	23.3 s
10:40	70%	10.0 s
10:55	60%	13.6 s
11:00	50%	11.5 s

In Figure 9 the effect of the density variations on the median brightness can be clearly seen at the start of the run before the mixer speed begins to change; however, the IQR does not change significantly with the density, as shown in Figure 11. Although lower density will typically result in a lower CST, the feed density is outside of the operator's control and this lower CST does not necessarily represent improved plant operation. Since the IQR does not significantly change with density, changes to the IQR are a better representation of changes to the flocculation in the FFT, which can be optimized through control of polymer dosage and mixer speed by the operator.

This result is extremely important since it shows that the IQR representation of the sample image is independent of FFT density. Figure 13 shows sample images corresponding to each of the recorded CST values over the run.

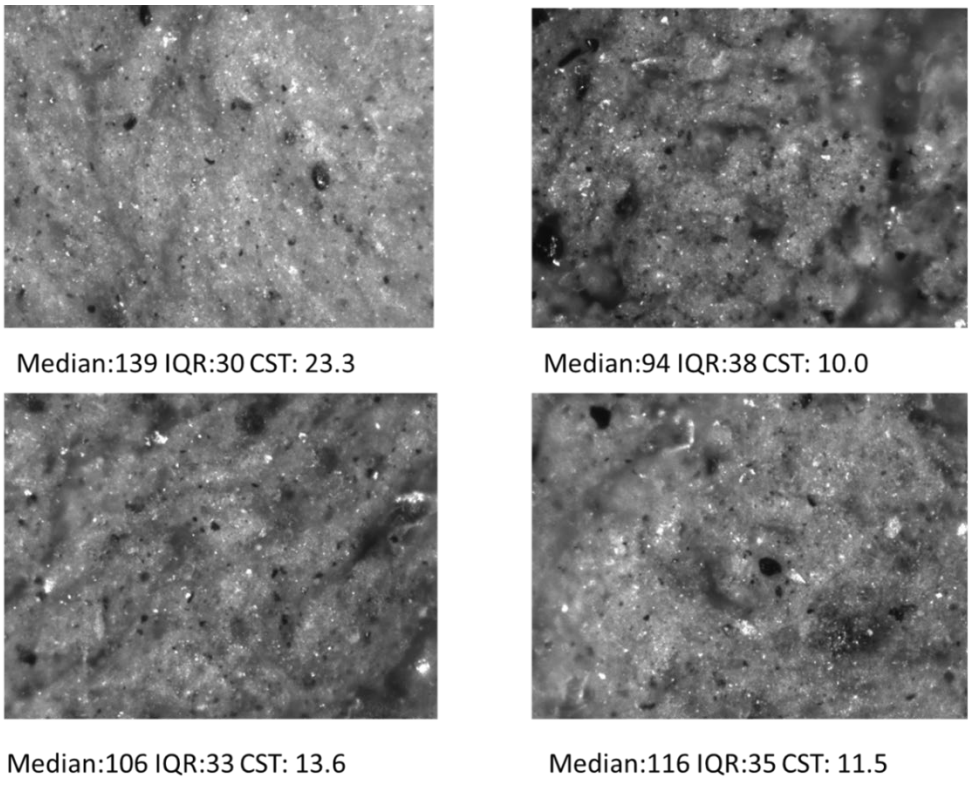

Figure 13: Sample images corresponding to each recorded CST value

Process or flocculation optimization is determined by establishing the lowest possible CST value, and this is challenging when the density is changing because lower FFT density will result in a lower CST. The link between CST and density can then cloud the optimum mixing and polymer dosage. Using the IQR data from the image allows for optimization of the flocculation independent of FFT feed density.

Conclusion

The PVM image analysis provides an on-line method for measuring Floc-T performance that could allow for changes to the process to be made in real time to optimize performance. The main feature of the PVM images that correlates with the flocculation in the FFT is the width of the distribution of pixel brightness, which can be quantified using the IQR. Reducing the images to a single number (the IQR) allows for the development of simple algorithms to guide (or eventually automate) control of the mixing and polymer dose. These types of algorithmic process controls could also be used to reduce overall polymer usage without negatively impacting the flocculation mixing performance.

Reducing Mine Closure Cost Risks by Employing Effective Construction Management Strategies

Michael Nahir, Parsons Inc., Canada
Marie Rousseau, Parsons Inc. Canada,
Geoff Karcher, Crown Indigenous Relations Northern Affairs Canada, Canada

Abstract

Mine closure projects have several complex and multidisciplinary construction activities. Typically, these include construction of water treatment plants, tailings and waste rock covers, diversions, development of landforms, demolition and disposal, excavation, and remediation of contaminated soils. Managing these construction works, often in remote areas, is complex with very significant costs and schedule risks. Most large civil projects employ staff with construction management expertise, which is recognized as an important skill set to drive project goals and reduce costs and schedule risks.

Driven by the goal of averting such consequences and risks, our paper aims to present strategic and proven approaches for effective project execution. Using recent experiences and a case study, the authors wish to offer comprehensive insights into the intricacies of managing mine remediation and closure projects. Examples of tailored strategies that will be discussed are the critical role of logistics and supply chain management, adaptive scheduling methodologies, constructability assessments, workforce safety and equipment resilience in extreme climates, the functional delineation of roles within the construction management team and the importance of aligning contractor expertise with the unique challenges presented by remote projects. We examine the seasonality of work in remote regions, delving into the types of tasks feasible under varying climatic conditions and the optimal sequencing of these activities. The construction manager is primarily responsible for delivering on the objectives of the owner.

Construction management

After completion of site assessments, options analysis and preliminary design, it is time to start planning for the implementation of the mine site remediation and closure works. A construction project is defined by having a scope, schedule and a budget. Of primary significance is to ensure that the objectives of the client are met in all aspects of the project delivery. The scope of the project is determined by the design team using science and engineering principles to solve problems. However, the project must be constructable.

The importance of constructability requires that the designers work collaboratively with the construction managers to ensure that the work is feasible to implement. Feasibility is not only determined by schedule and budget but also by adherence to building codes, safety requirements, and labor compliance.

Construction management is a specialized field within the construction industry that involves overseeing and coordinating all aspects of a construction project from inception to completion. It encompasses a wide range of activities and responsibilities aimed at ensuring that projects are completed on time, within budget, to the required quality standards, and meeting other expectations required by the owner. The following sections highlight key aspects and considerations for construction management in mining remediation and closure projects including a Case Study on the Faro Mine Remediation Project, Yukon Canada, North Fork Rose Creek Diversion Project.

The following are key aspects of construction management:

- **Project Planning and Development**: Construction managers are involved in the early stages of a project, working with clients, engineers, and other stakeholders to develop project plans, establish goals and objectives, and define project scopes. They help create realistic timelines and budgets, taking into account factors such as site conditions, regulatory requirements, and client preferences. In all cases a Project Execution Plan is prepared to layout the project and the processes.
- **Budgeting and cost control**: Construction managers are responsible for managing project budgets and controlling costs. They develop cost estimates, track project expenses, and monitor financial performance throughout the project lifecycle. They identify potential cost overruns, implement cost-saving measures, and ensure that the project stays within budget.
- **Scheduling and sequencing management**: Construction managers create project schedules, set milestones, and sequence activities to ensure that the project progresses according to plan. They monitor progress, identify potential delays, and implement strategies to keep the project on schedule. They also manage critical paths and prioritize tasks to optimize project timelines.
- **Design integration and constructability**: Construction managers are brought in to review the project design at key milestones. This is to reduce the likelihood of constructability or omission surprises and subsequent change orders at the construction stage.
- **Resource management**: Construction managers oversee the allocation of resources such as labor, materials, equipment, and subcontractors. They ensure that resources are used efficiently and effectively, coordinating deliveries, managing subcontractor relationships, and resolving resource conflicts as they arise.
- **Quality assurance and control**: Construction managers are responsible for ensuring that work is performed to the required quality standards and specifications. They conduct quality inspections,

enforce quality control measures, and address any issues or deficiencies that arise during construction. They also monitor compliance with building codes, regulations, and industry standards.

- **Safety management**: Construction managers prioritize safety on the job site and implement safety protocols to protect workers, subcontractors, and the public. They develop safety plans, conduct safety training, enforce safety regulations, and investigate accidents or incidents to prevent recurrence.
- **Communication and stakeholder management**: Construction managers serve as the primary point of contact for the main stakeholders involved in the project. They communicate project updates, address concerns, resolve conflicts and effectively manage interactions to ensure that all parties are aligned and informed throughout the construction process.
- **Risk management**: Construction managers identify, assess, and mitigate risks associated with the project. They anticipate potential challenges, such as weather delays, supply chain disruptions, or labor shortages, and develop contingency plans to minimize their impact on the project.

Overall, construction management requires a combination of technical expertise, leadership skills, communication skills, and project management capabilities. Construction managers must possess strong communication, problem-solving, and decision-making skills to effectively manage all aspects of the construction process and deliver successful projects.

The complexity of mine remediation and closure construction

Mine remediation and closure projects are typically multi-year and multimillion dollar projects with high cost and schedule risk. Designs are often based on imperfect assessments where a hundred percent characterization is nearly impossible. As a result, there is significant uncertainty in the extent of the mine waste issues such as volumes and depth as well as subsurface and hydrogeological conditions. Surface water management is also based on projections that are changing with changing climate estimates.

Coupled with design uncertainty is construction uncertainty and risk. As risks increase so does the potential for large cost increases and schedule slippage. Table 1 describes the multidisciplinary aspects of the various remediation and closure components, typical solutions and construction methods involved in mine remediation and closure. The sequencing of various trades and specialties requires a high degree of coordination and management. In the construction industry the construction manager is responsible for this aspect of the work.

The standard of mine remediation and closure has increased in the recent past and as a result the construction standard is higher. Early days of mine closure entailed simple solutions like waste

consolidation and basic soil covers. Whereas today's designs are science based with detailed engineering of complex solutions such as hydraulic designs of diversions, multilayered cover systems and water treatment plants. The role of the construction manager is now seen as an important way to reduce costs and schedule risks.

Table 1: Mine closure components, closure options and construction skill sets

Closure component	Example closure options	Construction skill sets
Underground workings	Seal the openings Flood Fill with tailings/waste rock	Concrete Piping Mechanical Conveyance Electrical Pumping
Open pits	Berms Fill with water Fill with tailings/waste rock	Heavy civil Piping Mechanical Conveyance Pumping
Rock and overburden piles	Shape Shape and simple cover Shape and complex cover Relocate to pit	Heavy civil Surveying Liners Conveyance Hydraulic monitoring
Tailings impoundments	Upgrade dams Simple cover Complex cover Revegetate	Expert civil Heavy civil Surveying Liner placement Conveyance Hydraulic monitoring Revegetation
Water management and treatment facilities	Diversions WTP Passive treatment Groundwater collection Surface water collection	Heavy civil Instrumentation Operations Electrical Mechanical Structural Drilling Well installation Pumping Piping
Buildings and equipment	Resell Demolition	Heavy civil Hazardous material removal

Closure component	Example closure options	Construction skill sets
	Nonhazardous landfills	Liner placement Surveying
Wastes, hazardous materials, and contaminated soil	Onsite treatment of contaminated soils Offsite disposal of contaminated soils Onsite disposal of hazardous materials Offsite disposal of hazardous materials	Bioremediation Hazardous soils Heavy civil Liner Placement Surveying
Infrastructure	Resell Onsite disposal	Heavy civil Liner placement Surveying
Environmental Monitoring	Applies to all components	Environmental science

Remote construction risks

Construction management risks in mine closure projects like the Faro Mine are significant due to their complexity and environmental impact, particularly in remote settings.

Remote work locations are characterized by their physical or geopolitical isolation, resulting in labor, materials, plant, and communication risks. The availability and accessibility of human resources are major factors that pose challenges to organizations attempting to manage projects in remote settings effectively. Figure 1 shows an example of a logistical challenge associated with remote work in northern regions.

Figure 1: Subcontractor welding ice cleats on excavator in the winter

Remote construction sites, such as the Faro in the Yukon Territory, are subject to higher risks than those located in well-developed areas. These risks include extreme working conditions that can negatively impact productivity and make it difficult for off-site management staff to track workforce productivity.

Additionally, remote teams may take advantage of the situation, leading to inefficiencies and cost overruns. Faro is known for its harsh weather conditions, which can include long and cold winters with temperatures dropping as low as -40°C (-40°F) and very short summers with temperatures ranging from 10°C to 20°C (50°F to 68°F). See Figure 2. The area also experiences heavy snowfall and strong winds during the winter months. Snow can be expected from around end of September / beginning of October until mid-April. Winter daylight hours are short, as they range from 4.5 hours in December to 15 hours in April. These extreme conditions can pose significant challenges for workers and construction projects in the area and the picture below provides an example.

Figure 2: Subcontractor working in the dark and the cold

Remote projects are also vulnerable to unexpected weather conditions, geological factors, and natural disasters. The 2023 wildfires in Yellowknife are an example of a natural disaster affecting a remove site and delaying construction at Giant Mine.

Communication can be challenging at remote sites due to limited cell service and Wi-Fi coverage. Time-sensitive decisions may also be delayed due to physical distance and communication challenges.

Remote sites are often far from law enforcement and emergency services, which can increase response times in emergencies. Workers may also have difficulty communicating for help due to poor mobile signal or data coverage.

Logistics can represent a significant challenge due to underdeveloped road infrastructure, limited local suppliers, harsh weather conditions, and poor communication and coordination. This leads to longer lead times for deliveries at site that must be planned accordingly.

Security risks include theft and vandalism due to a lack of constant supervision or surveillance options. Harsh weather conditions and wildlife can also pose unique security challenges.

In addition to these risks specific to remote sites, typical construction management risks include occupational health and safety hazards such as exposure to hazardous materials like zinc and lead in Faro; ensuring adherence with environmental laws; managing contaminated soils; implementing appropriate remediation and closure techniques; addressing community concerns; obtaining necessary approvals including from affected First Nations and dealing with bureaucracy.

Effective risk management requires meticulous planning, robust monitoring, adaptive strategies that mitigate multifaceted challenges ensuring successful sustainable mine closure projects. Strategies to mitigate project risks. Figure 3 shows the CM managing risks associated with specialized skill sets.

Aside from technical challenges, the owner's objectives often include the socio-economic needs of a project which provide benefits to the local communities including the indigenous peoples. Having an adequate supply of trained labor and construction resources is often limited and add a degree of uncertainty.

Figure 3: Installation of transformer supported by CM experts

Mitigating construction risks

While planning and managing construction risks, the CM considers a number of factors that will affect the success of the closure project. These factors are described below.

Skilled workforce management at site

In remote construction projects, having a 3rd party entity on site 24/7/365 to provide care and maintenance, procurement, and construction management services on behalf of the client is essential. To maintain high productivity and quality, it is necessary to recruit and retain skilled workers, on rotation, while providing ongoing training. Project progress and overall performance by subcontractors are closely monitored, no matter what the expertise required.

Construction maintenance in a remote location requires a team at site that includes a director, project managers, project coordinators, a quality manager, superintendents, inspectors. Adequate accommodation, transportation and welfare facilities for workers on remote sites are also provided. For example, an older hotel facility was purchased along with some housing at the Town of Faro and there is also a work camp at the mine site.

Service level agreement

Detailed and comprehensive Service Level Agreements are a useful tool that are often developed by a CM in collaboration with the client. The purpose of these agreements is to define the overarching principles of the relationship between CM and client, the vision, roles and responsibilities, and the exercise of decision-making authorities with respect to the delivery of specific work packages.

They include agreements on subjects like: Submittals, RFIs, Shop Drawings, Change Management, Quality Management, Commissioning, Reporting, As-built drawings.

Comprehensive planning and risk assessment

The CM conducts thorough constructability and risk assessments before executing every single work package, to identify potential issues early. The CM goes through the process of identifying every possible threat that creates potential loss exposure for our client, categorizes them and assesses the impacts. Detailed cost estimates are prepared for budget and procurement management. The CM develops project plans, including mitigation measures and contingency plans for those risks we identify.

Technological integration and innovation

Advanced technologies such as drones, GPS, aerial mapping, a construction management software (Kahua) and AI technology are in use at the Faro Mine Complex for better oversight in this remote location. The project team is also getting ready to implement remote monitoring systems to track progress and detect

issues promptly. Examples of innovation recently used include:

1. The CM, the owner and their Engineer of Record, and subcontractors use project management software for efficiently managing construction. The CM often has their own project management software and offers a sophisticated construction management tool for the delivery of all work packages.
2. Drones are used for dam and pit inspections and photogrammetry.
3. The software Propeller Aero is used, which offers cutting-edge drone technology and data solutions for construction. This tool is used for aerial mapping, data capture and analysis and surveying. Propeller brings real-time precision and efficiency to work packages at the Faro Mine Site.
4. The OpenSpaceAI Enterprise system and software are used for construction supervision, as-built drawings verification, quality reviews and project audits.

Procurement

One of the critical CM functions is the procurement of subcontractors to execute work packages. The CM works to identify and put in place the right tendering process and contractual arrangements. This work starts well in advance of the contract start date to make sure the design and procurement are well prepared and tested.

For most work packages, the CM conducts online bidders meetings to reduce cost and time commitment. Meetings include drone footage and photography. For complex and high risk work it is necessary to bring contractors to site.

The CM conducts frequent quality assurance inspections and audits to ensure compliance with the requirements set out in the plans and specifications.

Regulatory compliance management and environmental protection

The CM must ensure regulatory compliance on site at all times. Commonly the CM will have an environment team which overseas that all the environmental requirements are met. This could include all the monitoring of water and air as dictated in environmental permits. If there are water treatment plants, then discharge criteria must be met. Reporting requirements are tracked and adjustments made to meet compliance.

The CM is required to inspect, monitor, and document any environmental impacts should they occur. They also assist in adjusting practices to minimize harm. For subcontracts, the environmental team ensures to provide a detailed orientation to all new staff scheduled to work at site and their work is inspected daily to ensure compliance.

Budget and financial management

Budget and financial management is critical for the success of any construction project, particularly in remote locations such as the Faro Mine. To ensure that budgets are managed effectively, detailed work breakdown structures (WBS) are developed and agreed upon with subcontractors for each work package. This allows for a clear understanding of the scope of work and associated costs, enabling accurate budgeting and cost control.

Monitoring expenses closely is also essential to avoid overruns. This involves tracking actual costs against budgeted costs on a regular basis to identify any discrepancies and take corrective action as needed. Upon written approval, adjustments may be made to budgets based on changes in scope or unforeseen circumstances that impact project costs.

Change happens. Particularly in mine remediation and closure there are many site components which are uncertain due to the limitation of assessments. Costs are very sensitive to volume estimates such as in cover material and borrow sources. Due to these assessment limitations appropriate contingencies must be rationalized and budgeted. The change control process must be transparent and timely in order to avoid further costs due to work stoppage and extended review of unacceptable invoices. As a best practice the CM meets with the owners representatives and the subcontractors on a regular basis to ensure smooth and efficient account management.

In addition to WBS development and expense monitoring, effective budget and financial management at the Faro Mine Site also involves establishing clear communication channels with all stakeholders involved in the project. This includes regular reporting on project progress, financial performance, and any issues or risks that may impact budgets.

Community and stakeholder engagement

The project team engages with local communities and stakeholders to better understand their interests and expectations for the project. To meet owner's socio-economic objectives the CM may do a market study to evaluate the labor supply and required skill sets for the project are locally available. Based on the study specific objectives can be determined and built into the procurement plan. To give local community's contractors time to plan for major works, the CM presents their master schedule at community sessions. Feedback from the community is important to validate resource assumptions.

Supply chain and logistics optimization

Reliable supply chain strategies are essential for managing the timely delivery of materials and equipment in remote construction projects. To this end, agreements are required for deliveries of various supplies such as water treatment lime, diesel, gasoline, drinking water, spare parts, and other critical items. Local supply chains are also utilized where possible to reduce dependency on distant suppliers.

To ensure appropriate testing and quality assurance prior to shipping to the sites, the CM will visit suppliers and plants where infrastructure is fabricated for construction purposes. This approach eases logistics planning and helps to ensure that materials meet required standards. For instance, the CM's quality manager may visit an office complex trailer manufacturer before trailers are shipped to the site to better evaluate construction approach and adherence to specifications.

Health and safety protocols

Stringent health and safety protocols have been implemented to protect workers. There is also a detailed process for site access by visitors, and for consultants and subcontractors planning to work at sites. The CM provides regular safety training and ensure access to medical facilities and emergency services.

Case Study: Faro Mine Remediation Project, North Fork Rose Creek Diversion Project

The Faro Mine Site, referred to as Tse Zul by the local Indigenous community is located approximately 15 km from the town of Faro Yukon, and is within the traditional territory of the Kaska Nation. The Ross River Dena Council is located approximately 90 km from the site and is the closest Kaska community. The Faro Mine site is in a remote area approximately 4 hours from the City of Whitehorse. The mine ceased operation in 1998 having once been one of the largest lead zinc mines in the world. It is considered one of the most complex mine remediation projects in Canada. While the project navigates the regulatory process to allow for implementation of the final remediation, the completion of urgent works is required to ensure protection of the environment. In this context, urgent works can be considered as the implementation of all, or components of, select final remediation measures before the full remediation project. The North Fork Rose Creek (NFRC) Realignment Project was identified as an urgent work and has two parts, the non-contact water diversion channel (NCWD) and the contact water collection system (CWS). See Figure 4 for the NFRC and mine layout.

The need for the NFRC realignment was based on seepage from the adjacent waste rock creating an exceedance of zinc concentrations in the receiving environment beyond the requirements established in the Fisheries Act.

Based on the inability of investigative drilling and interim measures to identify and mitigate the source of the contaminants and considering a Letter of Direction from Environment and Climate Change Canada; a decision was made to advance the design and implementation of a 1.9 km section of the clean water diversion channel accompanied by an associated contact water collection system.

Crown Indigenous Relations Northern Affairs Canada (CIRNAC) engaged a design engineer to provide options, design, and specifications for the diversion. The designer acted as the owner's engineer

throughout the life of the project. CIRNAC also contracted a construction manager (CM). In this capacity the CM was responsible to support constructability review, cost estimates, sequencing, and work package structure to meet project procurement technical objectives, support project socio-economic objectives, provide project oversight and to take on responsibilities related to quality and environmental management.

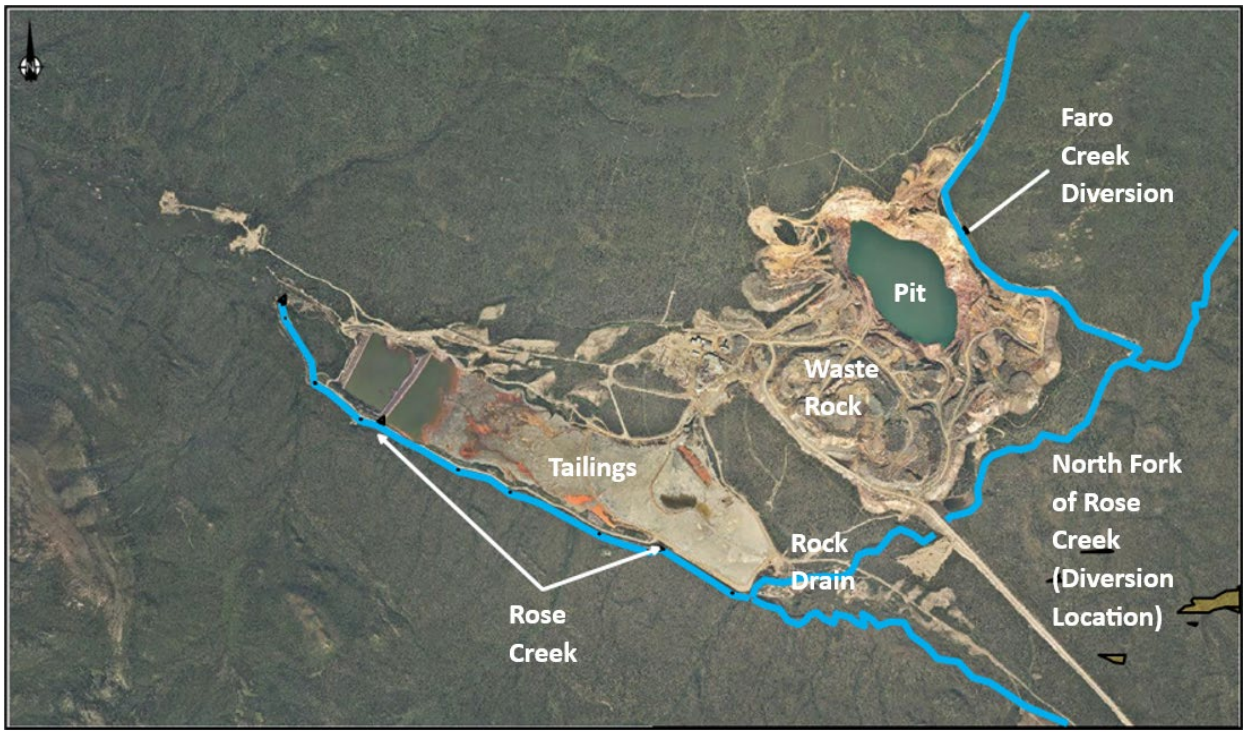

Figure 4: New diversion construction area

The issue for tender (IFT) package for the NCWD was developed as a single contract during the design phase. To meet socio-economic requirements within Parsons' CM contract that had been established by CIRNAC, Parsons as CM broke out the work into thirteen smaller packages to provide greater opportunity for Indigenous and local contractors to be successful in bidding on the work. The CM played an instrumental role in reviewing the work and determining how best to deconstruct the work to meet the CIRNAC objective. This approach helped the project to achieve one of its over-arching objectives to maximize local and Yukon socio-economic benefits. While it resulted in significant additional work for the designer and Parsons at the outset, some associated delay and increased implementation complexity, the result provided for positive owner outcomes.

The primary planned source of non-acid generating clean fill (NAG) for the new channel was from the existing haul road which needed to be excavated to facilitate the construction of the diversion. However, the haul road was found to have insufficient NAG rock requiring development of new sources of borrow at greater expense and increased project risk since many of the potential source locations had not yet been

evaluated for their geochemical and structural properties based on the early state of overall remediation plan development. To facilitate this work the CM supported the evaluation of options and recommendations for the development of an alternative borrow source. Because of borrow delays some of the planned winter work had to be rescheduled to the spring where the increased risk of perma-frost thaw created other challenges such as loss of thermal blanket (an insulating rock layer that protects existing permafrost) . When permafrost thaws, it settles and become unstable: so, winter work are preferable in this case. Also, construction restrictions due to conflicts with the bird nesting window (May 3rd – Aug 23rd) and the fish spawning window (April 1st – July 1st) became a factor. However, the CM was ultimately able to work with the design team to design and fast track the construction of a new borrow source to support the continued advancement of the urgent work.

In addition to the above, and obviously unplanned, was the onset of the COVID 19 Pandemic during construction. Recognizing the urgency of completing this work for the client, the unknowns and risks associated with a pandemic and the need to effectively manage safety at site, Parsons worked closely with their subcontractors and CIRNAC, as owner, to consider and develop options that would allow for the safe continuation of work. Through the implementation of reduced shift rotations, two-week isolation in Whitehorse for all out-of-territory staff, prior to coming to site to meet health requirements of the Yukon Territory, and diligent management on site Parsons was able to continue the construction of the project through the pandemic keeping workers safe while minimizing additional delays to the urgent work.

Completion of the realignment of the North Fork Rose Creek represented a critical step in ensuring that clean water and valuable fish habitat are protected from the contaminated water originating in the nearby waste rock. The delivery of this project using the CM model provided the client, CIRNAC, with delivery sequencing and structures that helped them to achieve their socio-economic objectives for the local First Nations and Yukoners in general. The construction manager was able to effectively identify challenges such as acid generating rock in the haul road, insufficient borrow, and even the COVID 19 Pandemic and The CM identified and recommended solutions and mitigations to the client that recognized the urgency of the project and supported its continued advancement limiting delays and cost impacts.

Figure 5 shows the construction channel to the right alongside the permanent channel running through the old haul road and rock drain to the left.

Figure 5: Completed new channel along-side temporary construction channel on right

Conclusion

With more mine site remediation and closures taking place and the complexity of the construction increasing, the deployment of a construction manager is a necessary value add to control project schedule and costs. The following is a summary of the benefits of having a construction manager.

Prioritize owner's interests: The CM acts as the Owner's Representative to ensure all decisions are to the benefit of the project.

Provide benefit to the project: by prioritizing the owner's interests, the CM can prevent scope creep, manage expectations, and ensure that the project delivers the desired outcomes without incurring additional costs.

Front-end loading: Good planning up front by the CM reduces risk of cost, change orders, and schedule overruns. The cost devil is in the details.

Reduce risks: By addressing potential issues early, the CM can mitigate risks related to cost overruns, change orders, and schedule delays. Detailed planning helps identify and resolve problems before they escalate, leading to more accurate budgeting and fewer surprises.

Develop construction costs alongside design: The CM oversees competitive bidding and develops realistic budgets to ensure the project is completed cost-effectively through the efficient use of resources.

Ensure cost-effective completion: By integrating cost considerations into the design phase, the CM ensures that the project is designed within budget constraints. This approach helps avoid costly redesigns and ensures efficient use of resources.

Commence construction as design is completed: The CM works closely with the Owner's design team through the design phase and in transition to construction stage to ensure the project is buildable and cost-effective.

Ensure a smooth transition to construction: By ensuring that the design is complete and feasible, the CM can avoid delays and additional costs associated with design changes during construction.

Maximize communication and minimize conflict: The CM uses a collaborative and inclusive approach to build mutual trust during the project's early stages. As the design develops, the CM provides expertise on the main requirements of constructability, cost, schedule, value engineering, and material selection.

Provide expertise on key requirements: The CM provides expertise on constructability, cost, schedule, value engineering, and material selection. This guidance helps avoid conflicts and ensures that the project is executed efficiently and within budget.

Provide a central point and single line of communication, control and responsibility: The CM is the one who has a thorough understanding of the project's big picture. They receive input from multiple sources, manage the flow of information, integrate project participants, and ensure the work is completed on schedule and on budget.

Effective management: by having a single point of control, the CM can ensure that the project stays on schedule and within budget. This centralized approach reduces the risk of miscommunication and ensures that all project participants are working towards the same goals.

Provide a highly qualified project team: The CM applies extensive industry knowledge to advise on which contractors are best suited to deliver the needs of the project. This greatly reduces the risk of change orders as there are fewer surprises.

Reduce risk of change orders: By selecting the right contractors and ensuring that they understand the project requirements, the CM can minimize surprises and reduce the likelihood of change orders, which can significantly impact the project budget.

Proposal for Guidelines on Filtered Tailings Disposal: Detailing the Hypothetical Rupture Studies

Elaine Soares, AECOM, Brazil
Waldemar Felitti, AECOM, Brazil
Fernando Pereira Aguilar, AECOM, Brazil
Alex Castro, AECOM, Brazil
Luiz Vilas Bôas, AECOM, Brazil

Abstract

AECOM has amassed considerable expertise in mining tailings management through intensive analyses and inspections in collaboration with Brazilian authorities. The catastrophic dam failures in 2015 and 2019 spurred the strengthening of countries' legislation and underscored the need to adhere to global standards to prevent future disasters. The pursuit of new technologies, such as filtered tailings storage facilities (FTSFs), is growing, although in-depth studies and standardization are still needed. Tailings disposal demands technical rigor and governance, considering long-term risks and environmental adaptability.

The multidisciplinary team at AECOM developed technical guidelines for the disposal of filtered tailings. The guidelines cover the entire life cycle of the projects, including conception, operation, and post-closure phases. The process involved multiple stages of drafting, validation, and review, enhanced by input from an external committee. The guidelines span preliminary studies, site and material characterization, hydrological and hydrogeological studies, numerical analyses, and Hypothetical Rupture Studies (HRS).

This paper provides detailed information on HRS to highlight the developed methodology, as the existing literature is very limited for this type of analysis. HRS evaluate the potential impact and necessary emergency actions in case an FTSF fails, with a focus on defining the Impact Zone. They are based on premises such as the uncertainty of the rupture location, the long lifespan of such structures, and the immediate impact in case of rupture while considering the worst-case damage scenario. The studies require understanding the mobilizable volume, defined by the failure mode, critical scenarios, and sectorization of the FTSF. A mass flow similar to landslides is expected for the propagation analysis, but methodologies and references on the subject are still sparse. The Impact Zone must graphically represent the maximum extent of impact. The proposed methodology seeks to standardize practices and should be refined as knowledge as this field grows.

Introduction

Over the past eight years, AECOM has collaborated with a multidisciplinary team of experts working alongside Brazilian authorities in emergency response, impact assessment, and post-breach reparations. This collaboration has generated an extensive and independent database resulting from more than 1.5 million hours of analysis, field inspections, and technical presentations, culminating in approximately 60,000 conclusions and recommendations in Technical Reports and Notes submitted to government authorities. This experience has revealed various possibilities for contributions to tailings management based on lessons learned.

The catastrophic dam failures in Brazil in 2015 and 2019 highlighted a discrepancy between documented information and these structures' actual stability and risks. AECOM has identified a lack of technical understanding of the real risks during construction, inadequate documentation, and insufficient financial resources for secure closure and repair as key lessons from these incidents. Consequently, these events have cause significant strengthening of local legislation, positioning it among the most stringent worldwide. They have also underscored the importance of adopting global standards and compliance initiatives, particularly in environmental, social, and corporate governance (ESG), to ensure responsible industry management and prevent future disasters. Equally important to establishing standards is the verification process, which must be robust, transparent, and supported by documentation, inspections, interviews, and independent analyses in line with advancements in legislation (Neri et al., 2024).

Furthermore, these developments have driven the development and adoption of innovative tailings management technologies, catalyzing demand for solutions that ensure operational continuity and mitigate associated impacts and costs. In this context, FTSF have become an alternative of interest, primarily due to their ability to reduce liquefaction risks and environmental impacts by minimizing water content in tailings, leading to an increased need for research, licensing, and implementation of such structures.

While pursuing new technologies represents progress, the practice of filtered tailings disposal has not yet been extensively studied or standardized. Overlooking the lessons learned from previous tailings dam failures could lead to repeating past mistakes, potentially creating new risks for communities.

Historically, the stacking of materials in mining has been a practice mainly limited to waste rock and has also been related to global catastrophes, such as the Aberfan tragedy in 1966. However, filtered tailings disposal demands more stringent technical rigor than waste rock disposal alone. Concerns such as the risk of tailings liquefaction, chemical safety, and the potential synergistic effects with downstream structures in the event of a breach are paramount. Furthermore, adopting FTSFs as an alternative for tailings disposal introduces additional governance challenges, requiring careful adjustment of production rates to ensure the safety of construction and operation (Neri et al., 2024).

The long-term nature of tailings disposal structures is also noteworthy. These structures provide a final destination for waste materials, with implications that extend well beyond the immediate future, potentially lasting decades or centuries, alongside associated risks. Consequently, it is vital to plan mining complexes with a complete life-cycle perspective of these structures, designed, constructed, and operated with the foresight of secure closure, considering their long-term presence and adaptability to current and future environmental changes. This planning must include allocating and accumulating the necessary resources for closure throughout the operational life cycle.

Considering these risks, AECOM developed technical guidelines for the disposal of tailings in FTSFs to initiate technical discussions, regulation, and standardization. This initiative, part of a broader project addressing tailings management, aims to provide a proactive framework for mining waste structures. The summary presented here reflects the outcomes of work completed in June 2023.

Methodology

A multidisciplinary team of experts developed the guidelines, identifying technical criteria and drafting initial guidelines. These drafts underwent rigorous review by an expert panel, ensuring robust validation. The multi-phased process included successive drafting, validation, and content review stages. The final version was enriched by the evaluation and contributions of an external committee of consultants, culminating in the definitive set of guidelines.

Technical guidelines for filtered tailings disposal

The development of the guidelines aimed to encompass the entire life cycle of tailings disposal in FTSF, from project conception to the post-closure phase, including existing structures.

The guidelines also sought to address not only the disposal of tailings alone but also the disposal of mixtures of tailings and waste rock, as this is a common practice in the industry that presents significant challenges due to its complexity. The two major methodologies for tailings disposal in the industry are: (i) shared or segregated disposal when there is no mixing of the two materials, which remain separated in distinct compartments of the structure, such as sectors, layers, or cells, with the disposal of these materials not necessarily being contemporaneous; and (ii) co-disposal or blending where there is a mixture of materials during the disposal activity (Aragão, 2008; Silva, 2014).

Both methodologies present complexities related to the proportion of the mixture of these two materials; the definition of representative parameters of the resulting material in the case of co-disposal; and the dimensions and definition of a representative geological-geotechnical model that allows for a realistic analysis of the structure.

The technical guidelines are composed of 17 chapters covering the following topics:

Preliminary Studies: Key preliminary studies include evaluating tailings dewatering alternatives, which should encompass economic and environmental cost-benefit analyses. Initial tests should be conducted on a smaller scale in the laboratory, followed by real-scale tests considering the local conditions. This stage should also involve studying locational alternatives to identify conditions to be avoided or those that would favor implementing the structure at the site (Neri et al., 2024).

Investigation and Basic Data: Basic information necessary for the development of studies should be collected from the initial phases, with a gradual increase in detail as the studies progress. Key data includes information related to detailed and up-to-date topography and cartography. Site characterization involves stages of existing data research, geological mapping, direct and indirect investigations, sample collection, and field tests. These activities aim to develop a local geological-geotechnical and hydrogeological model. Material characterization involves characterizing and parameterizing the materials of the geological-geotechnical model. This includes field and laboratory tests and evaluation of the susceptibility of these materials to liquefaction. Chemical characterization aims to determine the chemical composition, physical properties, and mineralogical composition of the materials placed. It helps define disposal practices, operational management of the structure, and environmental control involving geochemical characterization and the potential for acid drainage. Trial embankments should be conducted before the start of operations and whenever there are variations in operations. This aims to characterize the procedures and criteria to be adopted during disposal and compaction activities to support operational quality control. Seismic studies aim to determine the seismicity of the structure's location. When necessary, they should include a Probabilistic Seismic Hazard Analysis (PSHA) and Deterministic Seismic Hazard Analysis (DSHA) to define the design of earthquakes to be considered (Neri et al., 2024).

Hydrological Studies: Developed to support the design and verification of the hydraulic structures of a FTSF, including internal and surface drainage. They involve studies and surveys of hydrometeorology, design flows, intense rainfall, and probable maximum precipitation (PMP) (Neri et al., 2024).

Hydrosedimentological Studies: These studies are necessary to design sediment containment structures originating from the FTSF (Neri et al., 2024).

Hydrogeological Studies: These studies aim to characterize the water dynamics within the FTSF, the effects of groundwater presence on the structure, and the potential impacts on surface and groundwater resources due to the structure’s installation. They are based on understanding the hydrogeological behavior of materials, surface runoff, subsurface flow systems, and the interaction of these factors with the structure. This involves developing a conceptual hydrogeological model during the conceptual design phase and numerical models to simulate specific scenarios (Neri et al., 2024).

Water Balance: The water balance aims to account for the inflows and outflows of water within the system, providing a foundation for determining the design flows used in sizing the FTSF internal drainage.

Drainage: The FTSF's drainage may be divided into two main groups. Surface drainage aims to manage surface water, reducing infiltration into the FTSF and minimizing damage caused by concentrated water flow. Internal drainage is constructed along with the FTSF and is designed based on water balance studies. This includes basal drainage at the interface between the foundation and the FTSF and, if necessary, intermediate drainage constructed along the structure's elevation, as well as deep drainage.

Numerical analyses: Numerical analyses are conducted to verify the safety conditions of the FTSF regarding physical stability, demonstrating compliance with minimum acceptance criteria stipulated by engineering standards and best practices while optimizing geometry and construction sequence. This requires defining the geological-geotechnical model, specifying material parameters involved in the analyses, and understanding potential failure modes. Typically, these analyses involve limited equilibrium methods, necessitating the establishment of methodologies, criteria for defining analysis sections, scenarios, and acceptance criteria. Percolation analyses should also be developed to estimate percolation rates, neutral pressures, suction gradients, and hydraulic gradients that may develop within the mass and foundation, supporting the verification of structure safety conditions, with attention to material saturation risks. In cases of complex geometry, high stresses, and stratified foundations, stress-strain analyses should be elaborated to determine displacements, deformations, and stress accumulation regions (Neri et al., 2024).

Instrumentation and Monitoring: Monitoring is an essential activity to ensure safe operating conditions. It involves developing a geotechnical monitoring plan that includes the necessary actions and instrumentation for monitoring. This plan must be included in the structure's Operation Manual and should define routine in situ visual inspections and the instrumentation systems installed for monitoring. The monitoring systems should include instrumentation for measuring deformations, pore pressures, groundwater levels, internal drainage flow rates, surface water, hydrometeorological data, and hydrogeochemical monitoring (Neri et al., 2024).

Safety Evaluation: The safety evaluation aims to verify if the structure's performance aligns with the design assumptions. It is based on the collection of inspection information and historical monitoring data, providing support for new stability analyses, which should be conducted periodically (Neri et al., 2024).

Hypothetical Rupture Studies: These studies evaluate the potential damage associated with the structure in case of failure. It aims to define the area that could be impacted in the event of a failure, known as the Impact Zone. This involves understanding the Mobilized Volume, Propagation Analysis, and characterizing the area downstream of the FTSF (Neri et al., 2024).

Risk Analysis: This activity focuses on identifying, analyzing, and evaluating risks, aiming to reduce or mitigate the effects of uncertainties on the safety of structures (Neri et al., 2024).

Climate Change Resilience: This phase aims to develop more robust projects to address changes caused by extreme climatic events. This includes sensitivity analyses and adaptation actions.

Project Phases: This chapter aims to establish the minimum recommended contents for each project phase. To this end, a phased approach has been proposed, divided into Conceptual Design, Basic Design, and Detailed Design. Accompanying these stages, some primary documents should be included, such as Technical Specifications, As Built, As Is, Operation Manual, and Monitoring Levels (Neri et al., 2024).

Implementation and Construction: This phase includes activities related to preparing the foundation and necessary structures for the start of operation, including the initial stacking stage until a level working platform is reached. The activities involved in implementation include Preliminary Services for Vegetation Removal and Site Clearing, Topographic Surveying and Earthworks, Construction Access, Foundation Preparation, and the Construction of Internal Drainage (Neri et al., 2024).

Operation: The operation phase begins after completing all activities related to the implementation of the FTSF. It includes only the activities associated with the placement of materials and related services until the structure reaches its final design geometry. Key activities during this phase include constructing operational accesses, technological monitoring and ensuring construction quality, operational procedures, sediment management, temporary coverings, planning for the rainy season, and preparing periodic As Built reports. Technological monitoring aims to ensure that the quality and assumptions specified in the design are met and to assist in quality management (Neri et al., 2024).

Closure: Deactivating and closing the structure should result in the area being functionally reintegrated into the environment, considering that it will remain at the site for an indefinite but extremely long period. Closure criteria should account for the physical permanence of the structure and the inherent risks of its existence. The closure project should define the closure concept and the necessary monitoring to ensure the physical and chemical stability of the FTSF. Activities involved in closure include the Closure Project, Final Covering, Final as Built, Post-Closure Inspection, and Performance-Based Post-Closure Monitoring (Neri et al., 2024).

Detailing the Hypothetical Rupture Studies (HRS)

The topic of filtered tailings disposal is relatively recent, with limited published references, especially regarding Hypothetical Rupture Studies (HRS). AECOM proposed a specific methodology for conducting these studies to develop the guidelines. HRS for FTSFs are essential for assessing potential damages in the event of a structural failure and establishing necessary emergency actions. These studies are driven by these structures' inherent risks and impacts, and their findings should form the basis for project risk assessments. Therefore, HRS results must meet these expectations. The proposed methodology identifies key questions that HRS should address to provide relevant data for risk analysis:

- Where: What area might be impacted?
- When: Is it possible to define a time frame within which the event might occur?

- Duration: Once the event has started, will there be time for action?

The study's primary goal is to identify the Impact Zone, the area potentially affected by a rupture.

A primary concern regarding the stacking of tailings is their liquefaction potential. The guideline is based on the principle of making tailings stacking feasible, ensuring that the materials placed will not undergo liquefaction. This requires that they (i) display dilatant behavior, achieved through rigorous compaction methods, and (ii) remain unsaturated. Current experience indicates that filtered silty-sandy tailings have achieved the best outcomes. However, the required characteristics of the tailings for their disposal and compaction to meet these conditions may vary depending on the specific properties of each material. They should be evaluated on a case-by-case basis. There is consensus that proper compaction involves layering these materials in thin strata with moisture content close to the optimal level.

Assuming that FTSF will not be susceptible to liquefaction, the expected failure modes are related to mass instability, typically assessed through limit equilibrium analyses. Nevertheless, the potential for operational errors or deficiencies in adhering to design criteria during the construction process cannot be overlooked. Therefore, the potential for liquefaction of the disposed material or other credible failure modes should be evaluated whenever plausible.

Based on these considerations, eight premises were defined to guide the development of the proposed methodology and studies (Neri et al., 2024):

- uncertainty in defining the location of the rupture;
- defining the zone with the greatest possible damage, regardless of the probability of occurrence;
- considering the time of arrival of the impact wave as instantaneous when the adopted methodology does not allow the definition of the arrival time of the impact wave;
- predicting interaction with or impact on other structures;
- considering the long lifespan of this type of structure, including the post-closure period;
- adherence to project phases and construction stages, with continuous data updates;
- defining geological-geotechnical sections and material parameterization based on projects, investigations, and technological controls; and
- overcoming uncertainties inherent in the applied methodologies by adopting conservative criteria.

Additionally, discussing the distinctions between FTSF and traditional tailings dams concerning HRS is essential. While there is a tendency to compare them and draw parallels from tailings dams to FTSF, such comparisons are not always applicable. Dams typically feature linear structures with a predominant slope direction, designed to contain materials that lack self-support in the upstream reservoir. In contrast, FTSF exhibit complex geometries with multiple slope directions and are constructed using the same materials they are intended to hold, necessitating self-support.

When considering the rupture of these structures and the sequence of events involved, dams go through a complex sequence of events, from the dam breach to the propagation of the reservoir material downstream. In contrast, when transferring this analysis to FTSF, these elements do not directly apply. The rupture process is simpler, focusing on the mass rupturing and propagating downstream from the breach area. However, pinpointing the rupture location in FTSF is more intricate than in tailings dams due to their complex geometry. In tailings dams, the critical location is typically the highest section. Minor variations in the location do not significantly affect the outcome or the affected area, as it primarily relates to reservoir dynamics rather than breach location. In contrast, for FTSF, the rupture involves only the structure mass, making the outcome highly dependent on the rupture location. Additionally, as there are multiple slope directions, there are numerous critical sections to consider.

To conduct the HRS, primary data need to be acquired. This includes topography/cartography of the entire FTSF and adjacent areas, FTSF projects, material characterization (including the disposed materials and those of the foundation and internal drainage structures), and data on structures that could be affected by the rupture, such as sediment containment dams or other FTSF (Neri et al., 2024).

The HRS development involves understanding three main components: Mobilized Volume, Propagation Analysis, and the Downstream Area.

Mobilized volume

The mobilized volume refers to defining the volume that will be mobilized during a rupture. This involves the FTSF geometry and material characterization (obtained from basic data). It also includes determining the failure mode, critical scenarios, location of the critical section, and rupture wedge (Neri et al., 2024).

Failure modes

The definition of the Failure Mode, which is usually expected to be mass destabilization, must be individually assessed based on the specific characteristics of each structure. HRS should evaluate all possible failure mechanisms, even if they are unlikely, to identify the most critical scenarios regarding the generation of the Impact Zone. For existing FTSFs, if materials with contractive behavior are present due to design or construction quality control errors, rupture by liquefaction should be assessed, even if these materials are not saturated (Neri et al., 2024).

Critical scenarios

To consider the most critical scenarios for potential rupture, various factors that could lead to FTSF failure should be evaluated, including operational non-compliance with the project plan and malfunctions such as improper material disposal, inadequate compaction, and internal and surface drainage systems failures. Stability analyses should account for the most critical conditions the structure may face throughout its lifespan, such as earthquakes, water table fluctuations, pore pressure generation, changes in materials, and

uncertainties in resistance parameters.

After conducting stability analyses across different failure modes and scenarios, various failure surfaces will likely be identified. However, the surface with the lowest safety factor might have smaller dimensions compared to others. In such cases, the designer should determine which scenarios to use for the propagation study, even if they do not represent the lowest safety factor. Similarly, the scenario with the highest mobilized volume may not be the most critical regarding the Impact Zone. For instance, the rupture propagation from a larger unsaturated deep wedge might be less severe than the liquefaction of a smaller volume. Another crucial aspect is the formation of successive rupture surfaces following initial instability. After the first failure, it is necessary to assess whether the remaining surface remains stable (safety factor > 1). If not, the formation of a second rupture wedge should be evaluated, and so on, i.e., a cascading failure scenario (Neri et al., 2024).

FTSF sectorization

Due to the spatial configuration and the topographical and construction characteristics of a FTSF, there can be several critical sections that, in the event of a rupture, may generate different affected areas. It should be considered that the rupture can occur at any location within the structure, not just in the most critical section (Neri et al., 2024). Therefore, sectorization of the FTSF must be performed to define sectors with homogeneous characteristics based on specific criteria, such as:

- geometry (height and slope inclination);
- disposed material;
- foundation conditions;
- downstream topographic condition;
- original topographical configuration;
- stability conditions and failure modes.

For each sector, the location of the critical section should be evaluated, considering possible failure modes and the Impact Zone to be generated.

Propagation analysis

Gravitational forces primarily drive the movement of the mass. However, propagation analysis is a physically complex phenomenon influenced by other variables such as topography, climate, geological and geotechnical properties, rheological properties, groundwater level, etc.

Analysis methods

The choice of the model to be used and the data parameterization for the analysis should consider the failure mode, volumetric concentration, and saturation of the mobilized mass. In this context, the types of flow, as

proposed by O'Brien and Julien (1985), can be classified into: (i) aqueous, (ii) mud flood, (iii) mudflow, and (iv) landslide. Aqueous and mud flood flows exhibit more fluid characteristics, whereas mud flow demonstrates plastic and cohesive deformation. Conversely, landslide flow is characterized by block sliding or granular flow. For FTSF, it is anticipated that the flows resulting from a potential rupture will be based on the landslide type, where the ruptured mass primarily consists of earth or rock materials with low water content. According to the classification by Cruden and Varnes (1996) for mass movements in natural slopes, the expected landslide types in FTSF would predominantly be translational or rotational landslides or debris flows, depending on the material involved and the modes of movement.

The methods for analyzing rupture propagation in slopes, which can also be applied to FTSF, are divided into two main categories: (i) empirical-statistical and (ii) analytical/numerical. For the design or evaluation of a FTSF, both methods can be employed depending on the project's stage of development. Empirical-statistical methods are based on correlations from historical events. Due to their simplicity, they can be used for initial estimates. However, because of their low accuracy, the propagation of the mobilized volume should be estimated using analytical/numerical methods as the project advances. Analytical/numerical methods involve solving equations that describe the movement of masses. These methods consider the geometry and mechanism of potential slippage and can provide information such as flow velocity, depths, and the distribution of the rupture area (Neri et al., 2024). Table 1 presents some models that can be used for rupture propagation studies in FTSFs.

Table 1: Examples of models that can be used for propagation studies

Model	Description
FLO-2 D	Two-dimensional hydrodynamic model
Flow-R	Empirically based model for regional susceptibility assessments of debris flows
D-Claw	Open-source software for modeling granular fluid flows (landslides, debris flows, etc.)
HEC-RAS	One-dimensional and two-dimensional hydrodynamic model
MADFLOW	A two-dimensional numerical simulation tool for analyzing the mobility of tailings, soil, rock, and/or gravity-driven water mixtures
RAMMS	Two-dimensional hydrodynamic model
RiverFlow2D	Two-dimensional hydrodynamic model
Flow-3D	Three-dimensional hydrodynamic model
Anura3D	Software for modeling large deformations and soil-water-structure interaction using the material point method (MPM)

Hydrological scenarios

Assessing the hydrological scenarios in HRS is fundamental for both recharge studies and defining the intensity of rainfall that should be incorporated into the rupture hypothesis. This directly impacts the analysis of the propagation of mobilized and drained material.

There may be sediment retention dams or other structures downstream of the FTSF. If credible or possible, the cascading rupture scenario of the FTSF and downstream dams should be evaluated. In such cases, to assess the scenario with the greatest possible damage, it is recommended to consider at least one rupture scenario under severe hydrological conditions. This includes considering intense rainfall with a return period (TR) of 10,000 years or the Probable Maximum Precipitation (PMP) event in the upstream contributing basin and a natural flood in the downstream valley, with a TR of 100 years for the rainy-day rupture and a TR of 2 years for the sunny-day rupture. The premise of overlaying the rupture hydrograph onto the peak of the reference natural flood should be used, as it is impossible to predict whether there will be an overlay of these two hydrographs or where it will occur (Neri et al., 2024).

Interaction with other structures

Assessing the interaction with other structures is necessary when evaluating areas that may be affected by a rupture, in addition to the topographic characterization and the survey of land use and occupancy. The mass movement generated by the rupture of the FTSF can impact downstream structures. When these affected structures have mobilizable volumes, there is an interaction between the mass movement originating from the FTSF and the movement of the newly mobilized mass. In cases where the cascading mobilization of a dam is plausible, the HRS should incorporate the dam rupture into the model. During the design phases, preliminary HRS can define expected impact areas and facilitate the planning and implementation of structures with potential interaction in the event of a rupture, such as sediment retention dams, in areas outside the anticipated impact zone (Neri et al., 2024).

Impact zone

The Impact Zone should be represented cartographically as the result of an HRS corresponding to the maximum boundaries around the FTSF. The final Impact Zone of the FTSF will be the cumulative boundary of the various impact zones defined for each analyzed sector and those resulting from secondary impacts.

The final impact zone should be considered during various project stages, assuming the complete construction of the FTSF. However, during operation, it is recommended that the impact zone for each stage of raising is continually updated. This allows for predicting the expected impact zones for each stage based on updated information on geometry, material characterization, and downstream area conditions, optimizing the use of impact areas and the resources required for preventive actions when necessary. For the closure stage, the final impact zone should also be updated, considering the most current information and data obtained during the structure's operation.

The definition of the impact zone will facilitate the identification of potential impacts, risk management, the planning of alert systems, the formulation of emergency plans, and the determination of downstream land uses and activities (Neri et al., 2024).

Conclusion

The development of these guidelines was driven by a need to proactively address the technical standards applicable to mining waste structures. Through broad stakeholder discussions, this work aims to contribute to a comprehensive standardization and regulation of filtered tailings storage facilities (FTSF). It emphasizes the importance of a complete life-cycle approach to ensure quality and safety in the construction and operation of disposal systems. While some topics are emerging and evolving, such as HRS, the proposed methodology serves as a starting point for best practices that will be refined as the body of knowledge expands. Crucially, the stability of a tailings disposal structure relies on appropriate engineering, governance, operation, monitoring, maintenance, and closure practices. The multisectoral approach has left a lasting impact on society, contributing to improving safety and preserving life, reinforcing the Culture of Safety and Prevention.

Acknowledgments

We would like to express our sincere gratitude to the Public Prosecutors Office of the State of Minas Gerais (MPMG) for their initiative in promoting the development of guidelines for filtered tailings disposal. Their commitment to integrating technical knowledge into the Brazilian mining sector and supporting discussions on the subject is invaluable and essential for enhancing practices and standards in our industry, as well as improving socio-environmental safety.

The Use of an O-pile System for Foundation Seepage Control during Tailings Dam Construction: A Case Study

Rui Couto, WSP Canada Inc., Canada
Siavash Farhangi, WSP Canada Inc., Canada

Abstract

Seepage control is a critical aspect in the design, construction, and operation of a tailings dam to ensure the stability of the dam and to limit the amount of pond water that can pass through the foundation. This becomes apparent when unexpected field conditions are encountered during construction, which occurred during the raising of a tailings facility at a mine site in Northern Ontario, Canada.

Due to uncertainties about the long-term performance and durability of the PVC and GCL membranes in one of the main dikes, raising of the facility necessitated the construction of a new till-core earthfill dike downstream of the existing dike, founded on dense glacial till and/or bedrock. During the foundation excavation, a boulder field was encountered within the glacial till layer, preventing safe excavation to the required foundation depth and construction of the "keyed-in" core that would provide seepage control. Test pit and borehole investigations were initiated to confirm both the elevation of the bedrock along the dike centerline and the hydraulic conductivity of the boulder field to best inform alternative design options. Based on the results of the site investigations and numerical seepage and stability assessments, an O-pile (modified sheet pile wall) system was selected for the seepage cut-off, as it provided the lowest risk to the project schedule, while maintaining the original dike alignment and design intent.

The O-piles consisted of a steel tube installed via percussive rotary drilling. Upon completion of the O-pile installation, grout was injected through the bottom 0.6 m of the pile, encasing it within the bedrock, while the remainder of the O-pile was backfilled with a bentonite-amended sand. Once construction of the dike was completed, data collected from instrumentation installed within the foundation upstream of the dike indicated progressively rising water levels, providing confidence that the O-piles were functioning as intended.

Introduction

Seepage control is a critical aspect in the design, construction, and operation of a tailings dam to ensure the stability of the dam and to limit the amount of pond water that can pass through the foundation. This

becomes apparent when unexpected field conditions are encountered during construction, which occurred during the raising of a tailings management facility (TMF) at a gold mine in Northern Ontario, Canada.

An aerial view of the TMF is shown in Figure 1. The TMF consists of two ponds: a Primary Pond and a Secondary Pond. Tailings are deposited in the Primary Pond, while the Secondary Pond acts as a polishing pond, providing time for additional clarification prior to discharging excess water into the environment. The Primary Pond consists of five Dikes, numbered Dikes 1 through 5, that contain tailings within a historical lake. An offline dike barrier (ODB) was constructed downstream of Dikes 1 and 4 in order to reclassify the TMF as an "offline" structure (i.e., not overprinting/impacting any existing waterbodies) within the provincial regulatory framework, and to minimize Dike 1 seepage to the environment.

Figure 1: Tailings management facility plan view

The original dike (Dike 1) was an earth fill dam, constructed in 1988 to an elevation of 416 m, employing a 30 mil PVC membrane beneath the upstream slope as the main water retaining element. Additional dikes were built during mine operations, as shown on Table 1, raised by the downstream method of construction, as dictated by the tailings deposition requirements. Figure 2 shows a typical cross-section of the Dike 1 raises. In 2011, Dike 1 was raised by the downstream method to a crest elevation of 418.3 m (AMEC, 2012). At that time, a geosynthetic clay liner (GCL) was used as the water-retaining barrier, which was overlapped (minimum 1.0 m) with the existing PVC membrane, with bentonite placed between the seams. A second raise to a crest elevation of 424 m also continued the use of the GCL. Due to uncertainties in the long-term performance and durability of the PVC and GCL membranes, raising of the facility necessitated the construction of a new till-core earthfill dike, downstream of the existing dike.

Table 1: Construction history for primary pond

Year	Construction history
1988	• Construction of Dike 1 starter dam
2011	• Raising of Dike 1 to elevation 418.3 m and construction of Dike 2 to an elevation of 420 m and Dikes 3 and 4 to an elevation of 418.3 m • Emergency spillway constructed along Dike 3 to invert elevation of 417 m • Construction of seepage collection ponds
2015	• Raising of all dikes to a crest elevation of 424 m • Emergency spillway raised to invert elevation of 422.8 m
2019	• Construction of an Offline Dike Barrier to a crest elevation varying from 410.5 m to 409.5 m
2020 – 2021	• Completion of dike raise to a crest elevation of 427 m, including construction of new Dike 1 downstream of the existing Dike 1

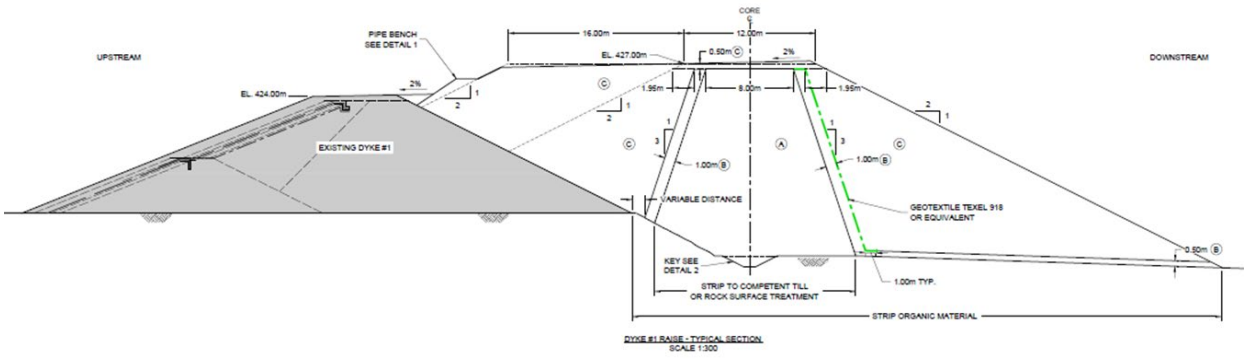

Figure 2: Typical section for Dike 1 raise (Wood, 2018)

Excavation for the new Dike 1 foundation commenced during the summer of 2020. During the removal of organics and unsuitable soils along the central portion of the proposed Dike 1 footprint, a zone consisting of sand and gravel till with cobbles and boulders (up to 2 m in diameter) was encountered at an elevation of about 407 m, spanning a length of about 40 m from Sta. 0+232.5 m to Sta. 0+272.5 m. Steeply dipping bedrock was encountered both to the south and north of the excavation. The groundwater table was also at about elevation 407 m. Attempts to excavate into the boulder zone were hampered both by the density of boulders and the rapid inflow of water into the excavation. At the time, the ultimate depth to bedrock was unknown, though it was estimated to be anywhere from 6 m to 10 m based on a historical borehole log (BH-04-15) advanced in 2015. Figure 3 provides a borehole stratigraphy profile for Dike 1 that indicates the borehole in question.

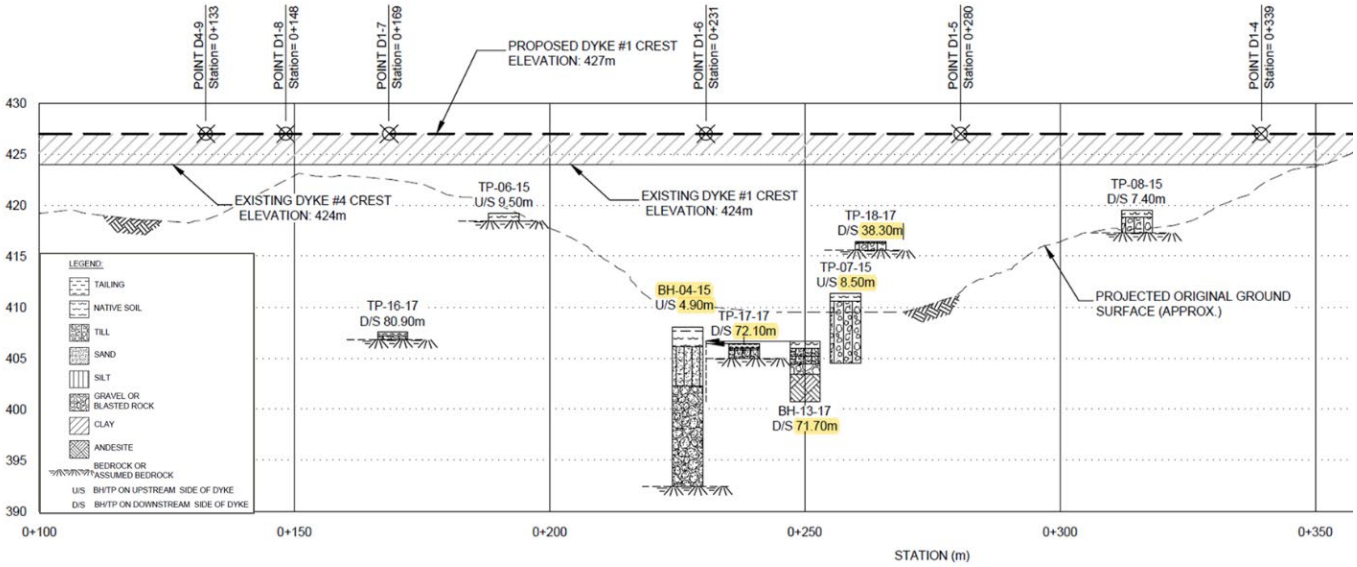

Figure 3: Dike 1 stratigraphy profile

Geotechnical investigations

To better ascertain the depth of the bedrock in the area of the boulder zone, a bedrock probing investigation and well installation program was undertaken in early September 2020. A total of eight boreholes were advanced to competent bedrock; five were located along the centerline of the proposed Dike 1 and three were located approximately 10 m downstream of the centerline. Figure 4 provides an inferred bedrock profile based on the data collected during the investigation.

The investigation indicated that the depth of bedrock varied from about 2 m below the subgrade level at the north and south ends of the boulder zone, dipping down to a maximum of 8 m below subgrade at an elevation of 399 m.

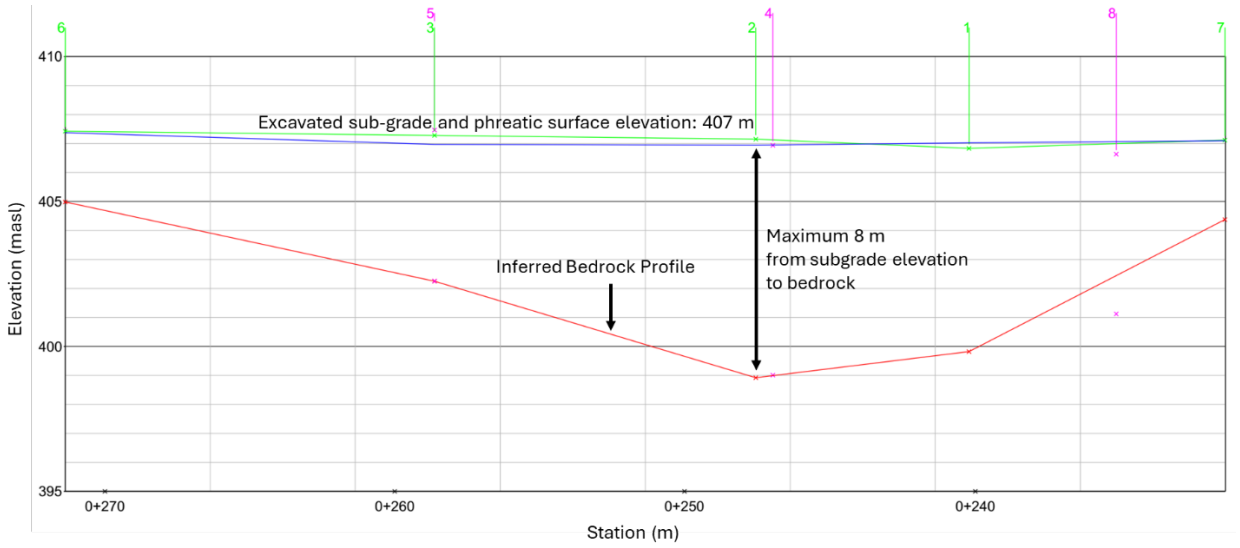

Figure 4: Dike 1 centerline bedrock profile

Stability and seepage analyses

Using the available historical data and the results of the bedrock probing investigation, a series of stability analyses were undertaken to confirm the stability of the existing Dike 1 under the temporary excavated condition at the toe. In addition, seepage analyses were completed to analyze what the effect would be on seepage rates through the foundation between construction of the new Dike 1 on top of a treated versus untreated boulder zone.

Stability analyses were carried out using the limit equilibrium modelling software slope/W, which was coupled with the finite element seepage modelling software seep/W, both of which form part of the GeoStudio modelling package developed by Geoslope International Ltd.

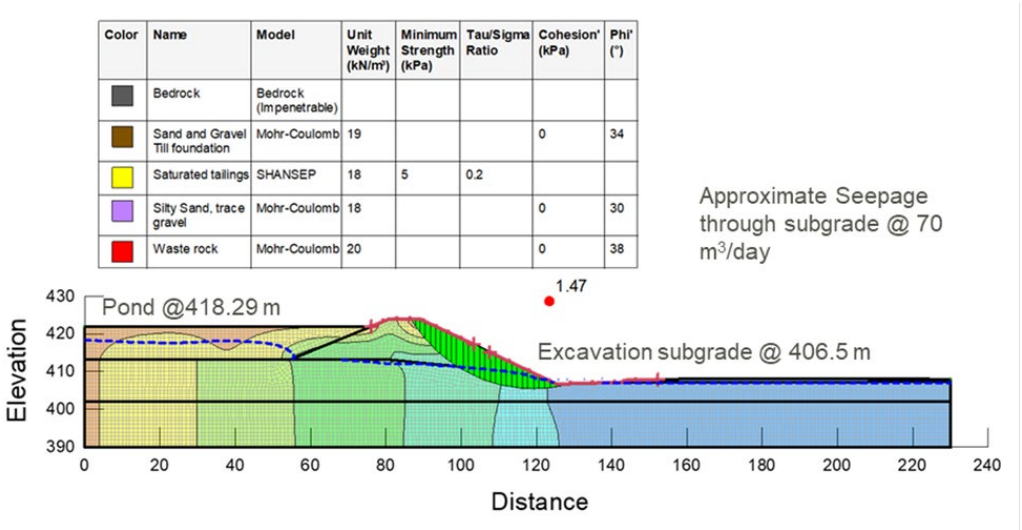

Figure 5: Dike 1 stability and seepage – temporary excavated condition

Figure 5 shows the seepage and stability analysis results for the static loading conditions at Dike 1 based on the pond level and toe elevation during construction. The analysis indicated a factor of safety against slope failure of 1.47 and a seepage rate at the toe of the dike of around 70 m3/day across the exposed length of the excavation. This seepage rate is consistent with the amount of seepage that was reporting to the downstream seepage collection station.

Figure 6 and Figure 7 provide the seepage and stability analysis results for a fully constructed new Dike 1 at a crest elevation of 427 m with upstream pond elevation of 423.5 m (approximate normal operating pond elevation) for an untreated and treated boulder zone, respectively.

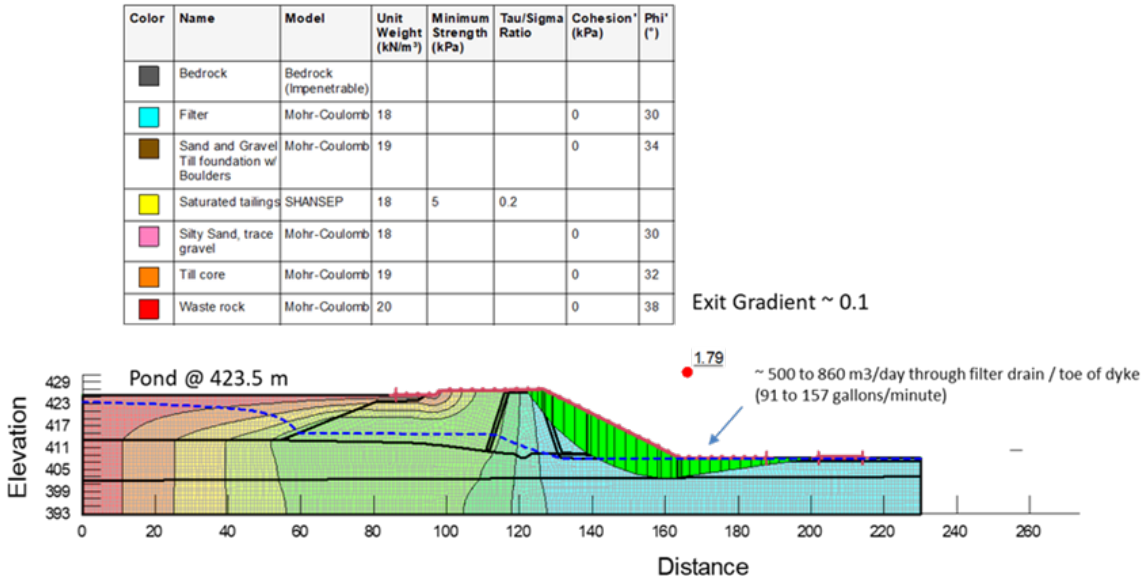

Figure 6: Dike 1 Seepage and stability – crest elevation 427 m with untreated boulder zone

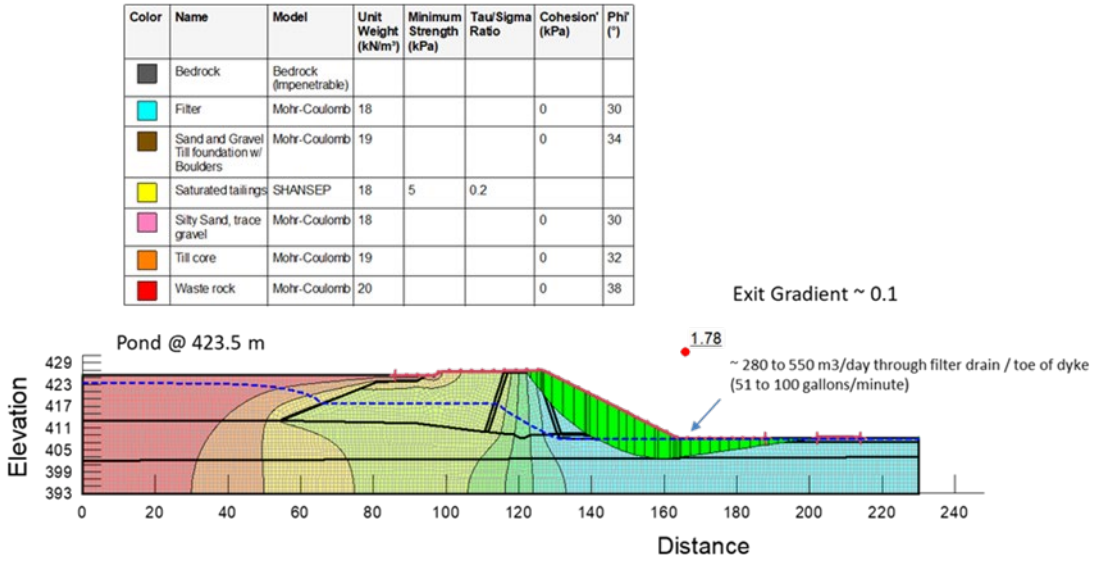

Figure 7: Dike 1 seepage and stability – crest elevation 427 m with treated boulder zone

In this case, the treated boulder zone was modelled with a hydraulic conductivity (k) of one order of magnitude less than the untreated boulder zone (10-6 m/s compared with 10-5 m/s). The results indicated that stability of Dike 1 is not a concern and that by treating the boulder zone to reduce its permeability, the long-term seepage rates through the dike foundation can be approximately halved.

Seepage cut-off wall options assessment

Various options to treat the Dike 1 foundation were reviewed in discussions with earthwork and specialist contractors, which included the following:

- A stepped excavation down to bedrock with upstream dewatering well points. The excavation would be backfilled with compacted till borrow. For stability of the excavation, this option would require a downstream step-out of the Dike 1 centerline of anywhere from 6 m to 12 m.
- Jet-grouting of the boulder zone down to bedrock.
- An engineering cut-off embedded in Bedrock consisting of either a Secant Pile Wall, or O-piles.

Table 2 provides a summary of the comparison that was undertaken for the boulder zone treatment options based on various design, engineering and stability considerations, relative cost, and risk to project schedule.

Based on the comparison conducted, the chosen method of foundation treatment was the installation of an O-pile cut-off wall as it presented the lowest risk to the project schedule and would allow the centerline of the new Dike 1 to remain the same as the original design and best achieve the design objectives as per the original design (Wood 2018).

Table 2: Seepage cut-off treatment options

Option	Treatment goal achievable?	Design, engineering, and stability considerations	Relative cost	Risk to project schedule
Excavation and Replacement	Yes	• Relies on dewatering being successful. • Does not maintain original design alignment - would require about a 12 m step out of Dike 1 centerline for excavation slope stability. • Existing Dike 1 stability and groundwater control a concern at deepest part of excavation	Lowest	High
Jet Grouting	Uncertain	• Difficult to achieve and verify continuous cut-off (shadowing effects around boulders and lack of quality control (QC))	Moderate to High	High

O-pile	Yes	• Need to ensure adequate tie-ins to competent bedrock, Dike 1 core, and competent till / bedrock. • Some form of permeability testing required pre- and post-installation to confirm design criteria achieved	High	Moderate
Secant Pile Wall	Yes	• Similar considerations to O-pile wall, though 2 to 3 overlapping rows required as opposed to one row of O-piles. • Risks of damage due to pile interlocking • Slower construction compared O-pile installation	High	High

O-pile design and installation

Figure 8 provides typical shop drawing plan view and cross-section details for the O-piles as provided by the subcontractor.

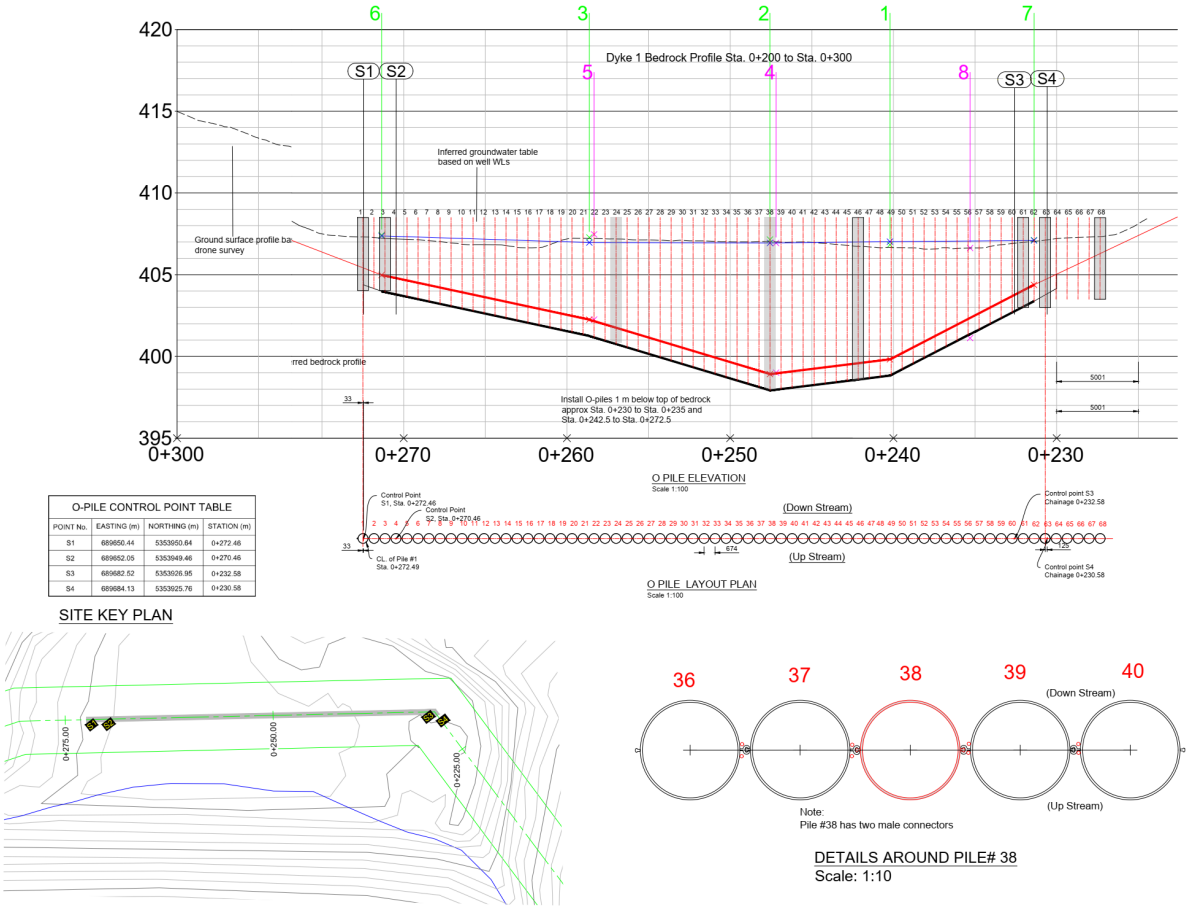

Figure 8: O-pile plan, profile, and cross-section views

The O-piles consist of an inner diameter of 600 mm that is installed via a percussive rotary drill rig. The O-piles connect to each other via an interlocking C-section as shown in detail 4 in Figure 9, with a sealant installed inside the female end of the connector. Upon completion of the installation, grout is injected through the bottom 0.6 m of the pile to encase it within the bedrock. The remainder of the O-pile length is then backfilled with earthfill material to serve as ballast.

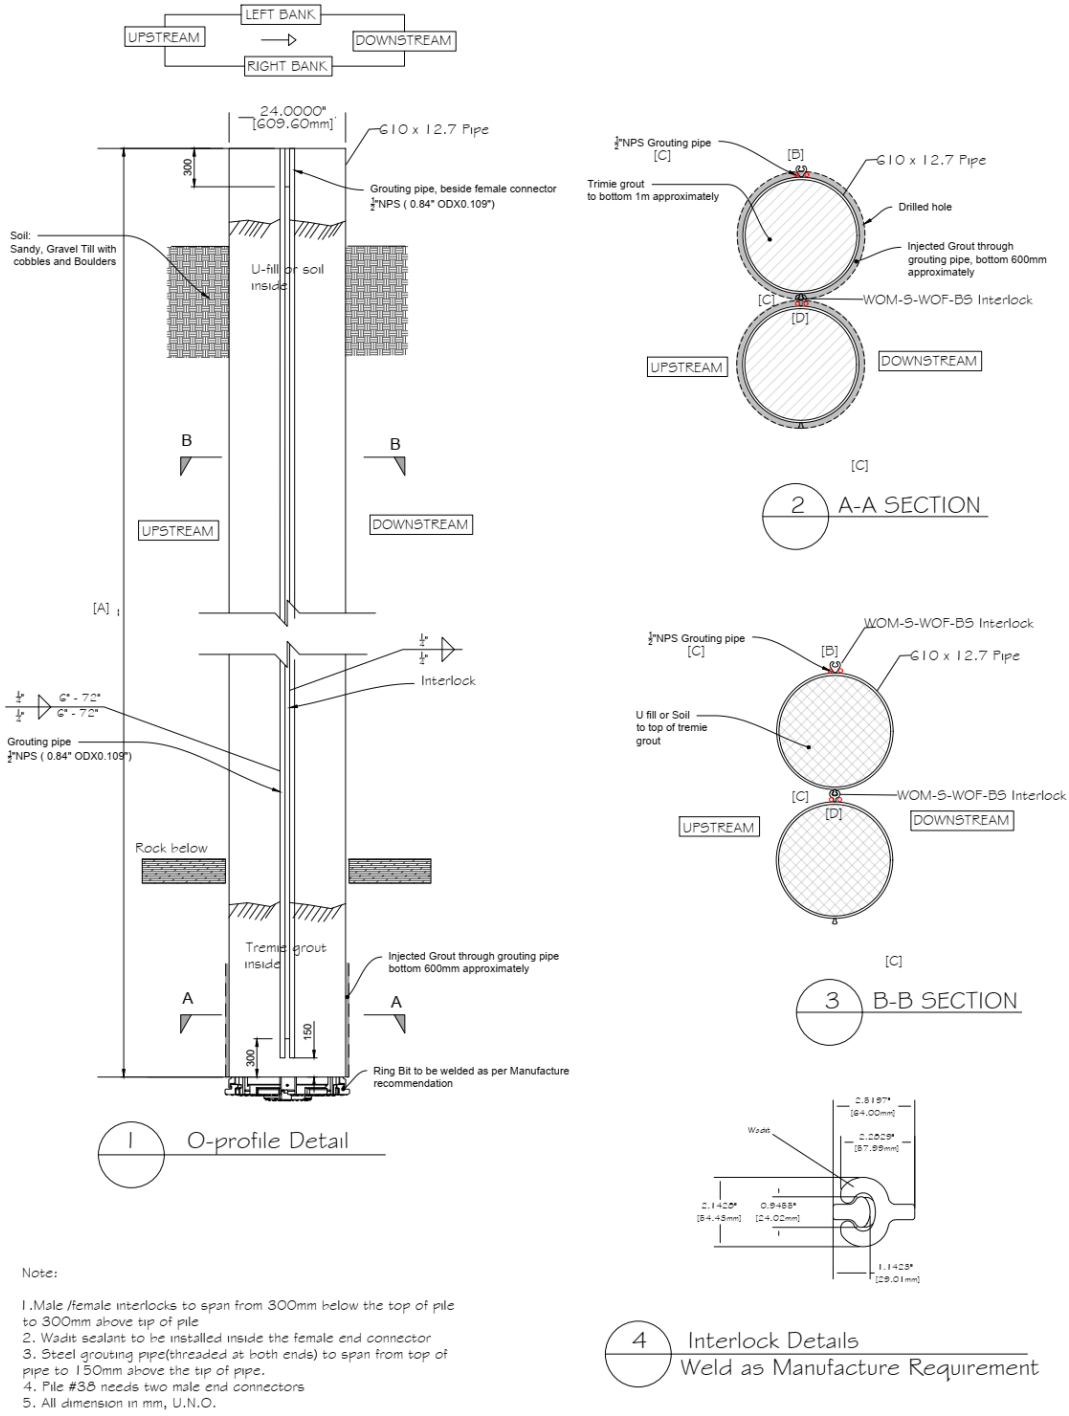

Figure 9: O-pile installation details

Figure 10 provides the as-built profile for the O-pile wall. The O-pile wall was constructed from about Sta. 0+227.5 m to Sta. 0+272.5 m to allow for adequate tie-in to the till core and bedrock abutments at the north and south ends of the excavation, with a minimum 2.0 m overlap between the O-pile wall and the till core, a minimum 1.0 m embedment of the top of the O-pile into the till core above the subgrade elevation, and a minimum 1.0 m embedment into competent bedrock. A provision was made for additional jet grouting between the O-pile connections if damage or verticality issues were noted in the connections during installation, however this was not required based on QC data collected during the installation.

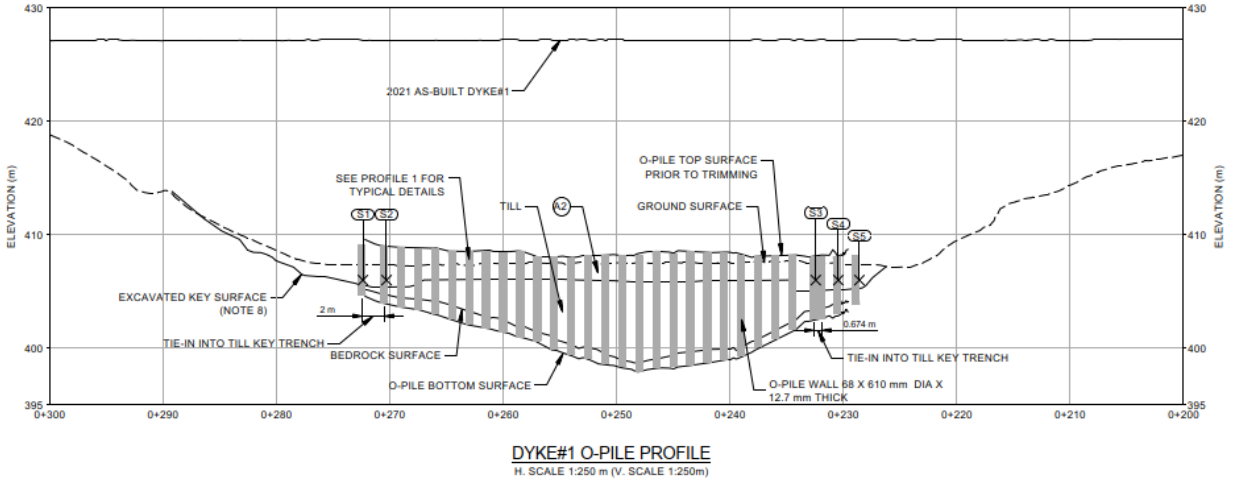

Figure 10: As-built profile of O-pile wall

Pre-/post-installation monitoring and dike performance

Pump tests

Pumping tests to monitor the drawdown cone of a suction pump (Pentair STA-RITE SNE-L 1 hp) were conducted prior to and following the installation of the O-Piles in order to ascertain the hydraulic conductivity of the Dike 1 foundation.

Drawdown data from the pump well both during the pre-O-pile installation test and the post O-pile installation test showed that the bulk hydraulic conductivity of the till in the immediate vicinity around the O-pile was about 2 x 10^{-5} m/s. This is consistent with original assumptions for the hydraulic conductivity of the till formation in the seepage analyses conducted, though did not necessarily reflect potential local hydraulic conductivity values in areas of higher boulder presence, which was believed to be higher.

Total drawdown of the upstream wells over time between the pre-test and the post-test were similar, however the response time (i.e., lag in time between when the pump well flow rate reached steady state and when the upstream wells began to first show a decrease in water table elevation) was slower for the post-test by a factor of 4 across all wells that were instrumented with level loggers. These results show that the

O-pile wall had an effect in the transmissivity rate between upstream and downstream ends. However, trying to quantify how that translated to a change in hydraulic conductivity is complex due to the increased seepage rate / pathway around and below the O-pile wall (Golder, 2020).

Dike instrumentation and seepage pump-back rates

Additional evidence on the effectiveness of the O-pile wall was gathered in the form of vibrating wire piezometer (VWP) data from instruments installed upstream and downstream of the dike as well as seepage pump back rates from the seepage collection pump back station located downstream of the dike. Figure 11 provides a summary of the VWP data collected from the time of the installation of the VWPs until the end of 2023.

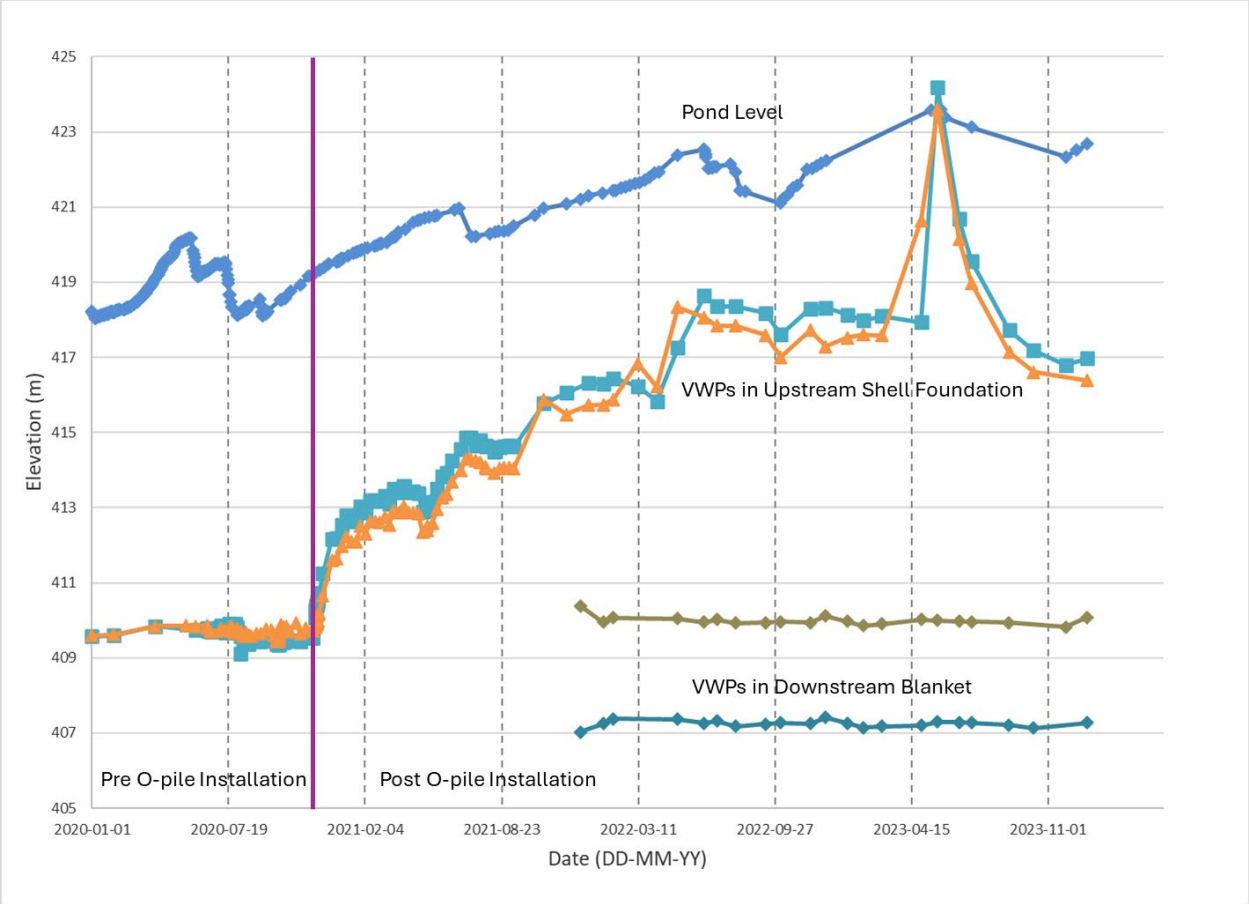

Figure 11: Dike 1 vibrating wire piezometer data compared with primary pond water level

The data indicated an increase in the phreatic surface upstream of the dike immediately after installation of the O-piles, with the trend continuing in subsequent years until the piezometric levels in the instrument begin to mimic that of the pond level fluctuation of the tailings pond. Data from the downstream VWPs show little to no change over time and is consistent with background groundwater levels, indicating that the phreatic surface through the Dike 1 core is decreasing as intended (WSP, 2024). Seepage pump-

back rates have typically ranged on average between 300 m^3/day to 500 m^3/day since the installation of the O-pile wall, which is consistent with the seepage analysis estimate prepared for the design and provided in Figure 7 for a "treated boulder zone".

Conclusion

During the construction of a tailings dam, unexpected foundation conditions may arise that necessitate the collection of additional geotechnical information within a relatively short period of time to modify the design and/or update construction methodology approaches so as to safely execute the work, while maintaining the design intent of the facility. In this instance, the discovery of a boulder field within the foundation glacial till deposit required additional test pitting, monitoring of well installations, and testing of the pump to characterize the subsurface conditions and inform the best foundation preparation approach for seepage control beneath Dike 1. Based on stability and seepage assessments, combined with a comparison of constructability considerations, the O-pile wall approach was decided to likely be the most feasible and effective solution that could be completed within the proposed construction time window. Post construction monitoring of the phreatic surface within Dike 1 as well as downstream seepage pump-back data indicated that the installed O-pile wall appeared to be functioning as intended, ultimately demonstrating that an O-pile cut off wall can be an effective solution for seepage control on par with traditional sheet-pile or grout curtain cut-off wall methods through boulder filled glacial till deposits.

Abstract

The mining industry has significantly impacted our economies and infrastructures, leaving behind environmental concerns such as abandoned mines that require careful monitoring and remediation. Seismic imaging techniques offer non-intrusive solutions for mapping underground mine workings and estimating subsurface material properties. This includes non-invasive solutions to challenges in monitoring for potential environmental catastrophes and remediation efforts. This study overviews existing seismic techniques and proposes unique geophysical solutions to mine closure and remediation efforts.

Introduction

Mine closure, as the final phase of the mining cycle, has gained attention due to environmental impacts. Unplanned closures lead to issues such as toxic material release and soil degradation. Due to the importance of this matter, the US Congress has established CERCLA to address contaminated sites since 1980. Often, project management teams use data from invasive and non-invasive techniques to plan closures and rely on various geophysical methods for subsurface characterization. Non-invasive techniques are based on geophysical methods and should be chosen based on specific project requirements.

Gravity-based techniques use gravitational fields to associate variations in the Earth's gravity measurements with differences in rock densities. They are ideal for covering large areas and can delineate volumes of material with anomalously low and high gravity values (Tuckwell et al., 2008; Ibrahim and Lat, 2004). Magnetic methods measure the magnetic field to locate concentrations of magnetic materials or determine depths to the basement. They are suitable for mapping large geological structures and characterizing bedrock in land-based and aerial applications (Thompson et al., 1980; Naghibian et al., 2005).

Electrical methods use electric fields generated by currents in the ground to study earth resistivity. These methods involve various measurements to analyze current flow, electric potential, and electromagnetic fields within the subsurface material to gather information about the underlying soil and rock. Essential methods include DC resistivity (Binley and Kemna, 2005), induced polarization (Sumner, 2012), self-potential (Panthulu et al., 2001), electromagnetic (Xue et al., 2019), and magnetotelluric (Chave and Jones, 2012).

Seismic methods are used to determine subsurface properties. Active methods include multichannel analysis of surface waves (Park et al., 1999), seismic refraction tomography (White, 1989; Guedes et al., 2022), and full-waveform inversion (Mirzanejad and Tran, 2019; Tran et al., 2019). Passive methods include MAPS (Baglari et al., 2018), ReMi (Louie, 2001), and HVSR curve analysis (Bignardi et al., 2018). Active methods offer higher resolution but are not always feasible. This paper presents two case studies using active source FWI and passive microtremor HVSR to detect legacy mine adits and assist with slope stability analysis of an abandoned coal mine.

Methodology and implementation

Seismic methods for near-surface characterization utilize various information embedded in the recorded seismic waves. For instance, multichannel analysis of surface waves (MASW) uses information in the recorded data dispersion characteristic to estimate shear-wave (Vs) variation; seismic refraction tomography (SRT) uses first arrival travel times to estimate P-wave velocity (Vp) variation; and full waveform inversion (FWI) uses information embedded in the entire seismic waveform to estimate Vp and Vs in the subsurface soil and rock volume. The following provides a brief methodology of each of these techniques. The interested reader is referred to the sources mentioned in the previous section for a more thorough discussion.

Full waveform inversion (FWI)

Full-waveform inversion (FWI) is a non-linear data-fitting procedure aiming at obtaining detailed estimates of subsurface properties from seismic data, which can result from either passive or active seismic experiments. Given an initial guess of the subsurface parameters (a model), the data are predicted by solving a wave equation. The model is then updated to reduce the misfit between the observed and predicted data. This is repeated iteratively until the data misfit is sufficiently small. The FWI can be performed using surface-based and downhole source configurations with nodes on the surface or inside boreholes for deeper characterization. The maximum characterization depth is a function of the wavelength of the propagating wave and is usually approximately one-half the length of maximum coverage area on the surface. The FWI method does not have the limitations of the more traditional seismic techniques such as MASW and ReMi

and is suited to detecting inverse profiles as well as voids and tunnels. See Tran et al., 2019 for a complete discussion of the methodology.

Multichannel analysis of surface waves (MASW)

The MASW imaging method employed in these case studies is based on the dispersion curve inversion using a constrained ensemble Kalman-filtering method introduced by Albers et al. (2019) and demonstrated in an inversion problem by Seylabi et al. (2022). The generation of the dispersion curve was based on the phase shift method by Park et al. (1999). The MASW technique is useful for providing a quick understanding of subsurface layering and shear-wave velocity structure and is often used to generate initial models for a more thorough analysis using FWI.

Horizontal-to-vertical spectral ratio (HVSR)

The HVSR method calculates the HVSR curve used in earthquake hazard assessment. It predicts depth to bedrock and site amplification response. The produced curve can generate a shear wave velocity profile and is based on single three-component node data. The analysis herein is performed using the OpenHVSR software (Bignardi et al., 2018), known for its capabilities in obtaining and inverting the HVSR curve. The HVSR technique is more suitable for determining the depth of bedrock and is not as useful in finding accurate velocity values due to the non-uniqueness of the amplitude of the fundamental and higher modes. For more details, refer to the paper by Bignardi et al. (2018).

Case studies

The following two case studies of mine closure and remediation projects are discussed to highlight the utility of these surface-based seismic methods:

Case study I: Seismic evaluation of an abandoned mine adit

The case study presents the findings of a 3D seismic evaluation and near-surface characterization at the Silver Dyke Mine in Montana. The goal was to locate an abandoned adit, identify drilling targets, and aid in site remediation. Seismic data were collected from 63 receivers and 105 source locations (Figure 1), and a 3D full-waveform tomography analysis was performed over the abandoned adit. The Carpenter Snow Creek Mining District site spanned 9,000 acres in the Little Belt Mountains of southern Cascade County, Montana. It included mine tailings, waste rock, and mine-influenced waters from numerous inactive and abandoned mines. The EPA identified about 96 abandoned mines at the site, with at least 21 being probable contamination sources. Historic mining operations caused soil, groundwater, surface water, and sediment contamination with metals and hazardous chemicals. The Silver Dyke Mining Complex was the largest

mine in the district, featuring the Silver Dyke Glory Hole, associated underground workings, mill facilities, and eroded tailings in Carpenter Creek's floodplain areas.

The field crew collected data over a 36,382 square feet 3D survey area using 63 wireless seismic nodes and 105 source locations. The nodes were positioned with a receiver spacing of 10×20 feet using GPS coordinates and survey tapes. After installation, the nodes conducted self-diagnostic routines and recorded GPS positions for efficient data processing. A manual slide hammer with a timestamp trigger recording device was used to generate seismic signals. The ground under the hammer was struck at least five times at each source location to improve the signal-to-noise ratio. The data were collected, combined, and filtered to remove noise. Faulty channels were identified and removed. The filtered data were used for FWI analysis along with an initial MASW model. Model parameters were updated iteratively to match the seismic response to field data. The resulting Vs and Vp parameters were used to detect subsurface anomalies.

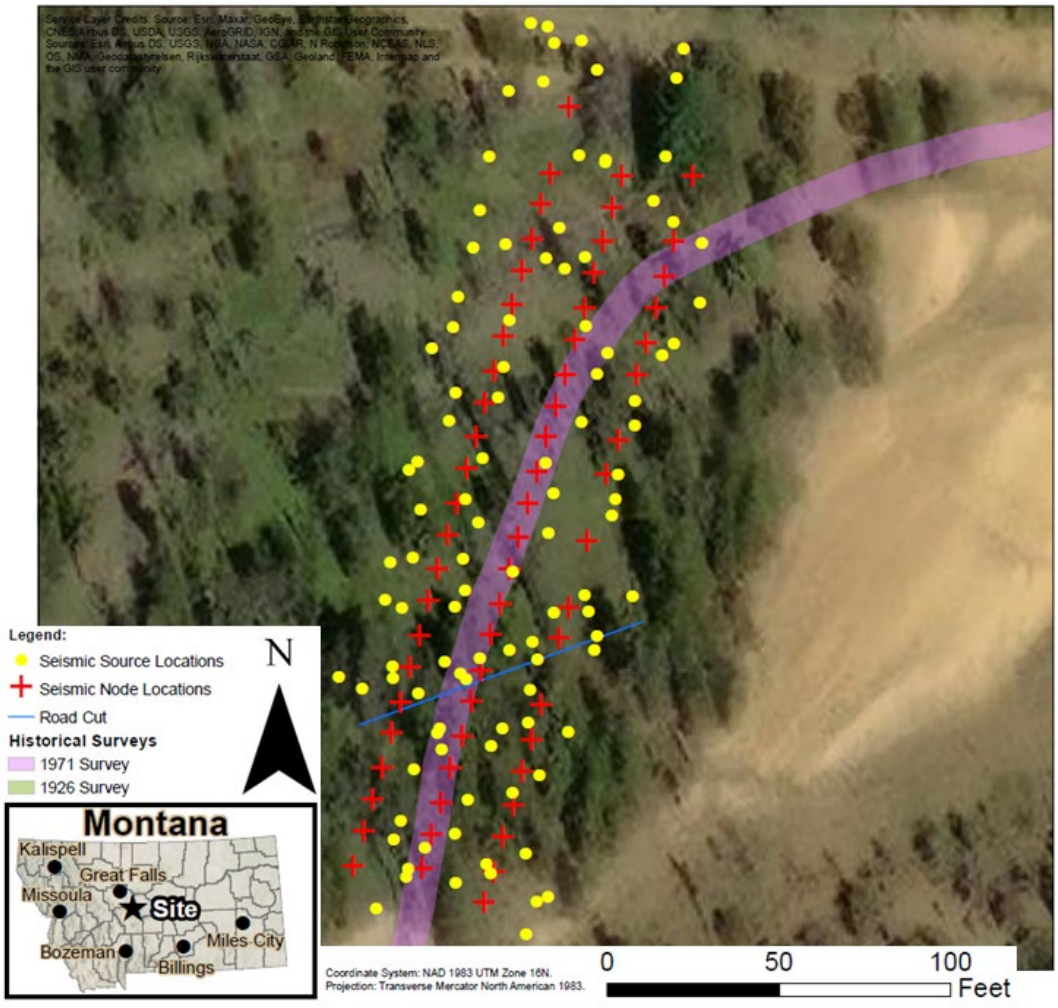

Figure 1: Silver Dyke Mine seismic survey overview

Figure 2 shows a vertical slice view of the final inverted shear-wave velocity 3D volume. There is a clear indication of various anomalies through individual slices. In particular, the anomaly shown by T1 in Figure 2a corresponded to the location of the mining adit that was expected to exist at the site from the project records. We note that the actual as-built location was not known, and the geophysics investigation was used to facilitate its finding. This adit was oriented in the southwest to northeast direction with a depth of around 45 ft from the ground surface southwest to about 60 ft towards the northeast of the survey volume. The second feature of interest is anomaly T2, shown in Figure 2b, which shows contrasting shear-wave velocity values compared to the adjacent material located at a deeper depth of about 90 ft to 100 ft from the surface and oriented west to east of the survey volume. The shear-wave velocities at the location of the T2 anomaly have not been reduced as much as the T1 anomaly during the inversion process due to it being deeper, or possibly due to being filled with a material other than air or water. There was no record of a second adit, and this anomaly was only detected through seismic testing.

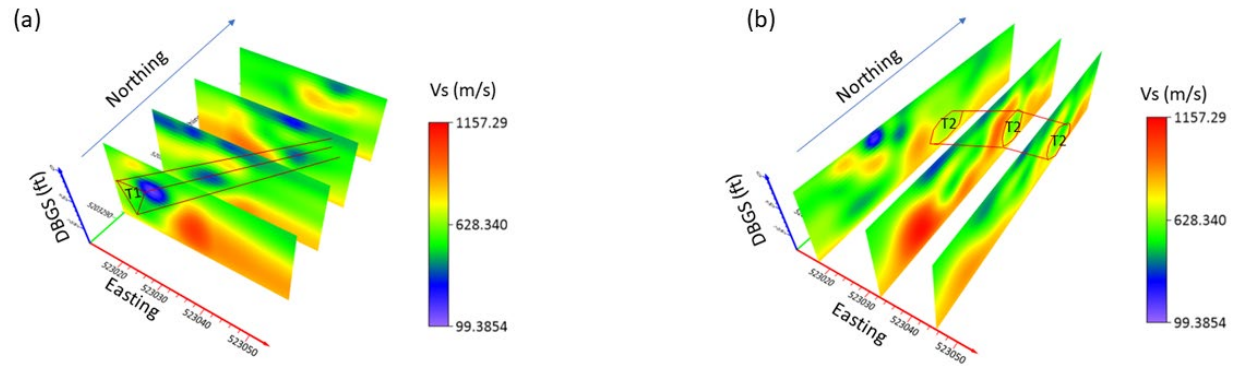

Figure 2: Vertical slices through the inverted shear-wave velocity 3D volume showing features of the mining adits and other subsurface anomalies. The vertical axis shows depth below the ground surface (DBGS) in feet, and the horizontal axis shows easting and northing UTM coordinates in meters

Figure 3 shows sample horizontal slices through the shear-wave velocity 3D volume overlay on the Google Earth satellite imagery base map of the site. The expected path of the mining adit from ground surveys and historical data is also shown, spanning from the southwest towards the glory hole (not shown) located to the northeast of the survey area. There is a concentration of low-velocity anomalies in the 10-ft slice shown in Figure 3a along the expected path of the adit because of less stiff or loose soil and overburden material at those locations.

The T1 and T2 anomalies are shown in panels (b) and (c) of Figure 3, corresponding to vertical slices at 60 ft and 90 ft depths, respectively. The directions of both anomalies are in good agreement with the expected direction of the adit, with the shallower T1 anomaly oriented slightly to the south of the expected orientation.

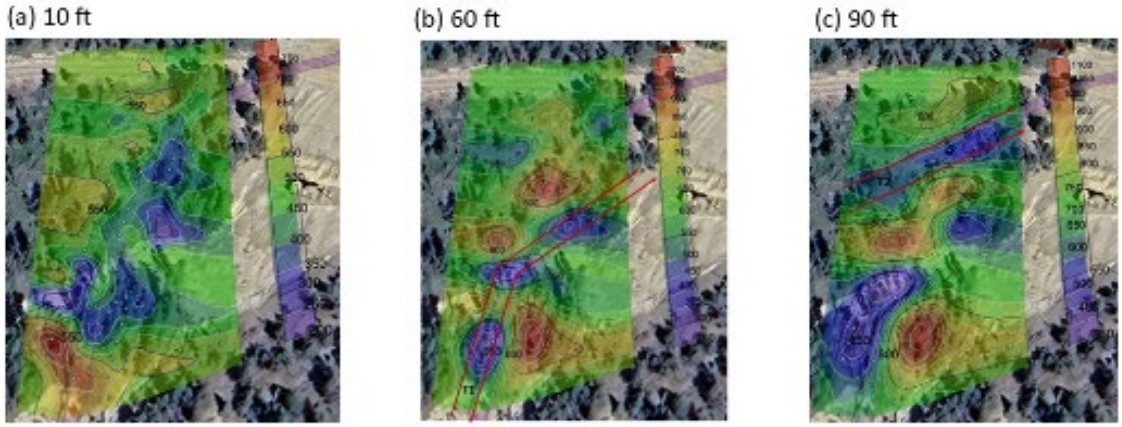

Figure 3: Horizontal slices through the inverted shear-wave velocity volume at depths of 10, 60, and 90 ft below ground surface. The extent of anomalies T1 and T2 are shown in panels (b) and (c) for the 60 ft and 90 ft depths, respectively

Case study II: Estimating shear wave velocities and slope stability analysis at an abandoned coal mine

This study was conducted to assess subsurface conditions and slope stability at the Wise Hill Reclamation Site in Craig, Colorado. The main objective was to measure shear-wave velocities across the slope to support the slope stability assessment. The borehole data was only obtained at the top of the slope with no data at the toe to support a well-informed slope stability analysis due to permitting issues at the time of drilling operations, and the HVSR technique was used to fill this data gap. The site was located on an abandoned coal mine with multiple unknown access tunnels over 200 feet deep. Borehole thermocouple measurements revealed temperatures exceeding 300°F, indicating the presence of coal mine fires across the site. Visual inspections of the slope showed open chimneys and surface cracks, with visible smoke and water vapor emanating from subsurface coal fires.

A microtremor HVSR survey was conducted using sixteen nodes along four lines, as shown in Figure 4. Seismic data were recorded using three-component seismic nodes connected to a digitizer and powered by an external battery. After recording ambient noise data, approximately 5 GB of three-component seismic data were extracted and converted to SEG-Y format for processing. The data were divided into 1-hour segments for HVSR analysis. HVSR curves were compared across the recorded time to ensure they represented subsurface properties and were not influenced by industrial noise.

Figure 5 displays the final horizontal-to-vertical spectral ratio (HVSR) curves for specific sample node locations. The fundamental frequency on these curves represents the depth to the bedrock across the site. Various regression techniques are available to determine the depth of bedrock based on the fundamental frequency shown in Figure 6 (Ibs-von Seht and Wohlenberg, 1999; Parolai et al., 2002). Comparing the fundamental frequency values with the regression lines shows upper and lower limits of

depth to bedrock, as shown in Table 1. Based on these regressions, the average depth to bedrock is 23 feet across all the channels, with variations along different inlines and crosslines, ranging from 5 to 36 feet.

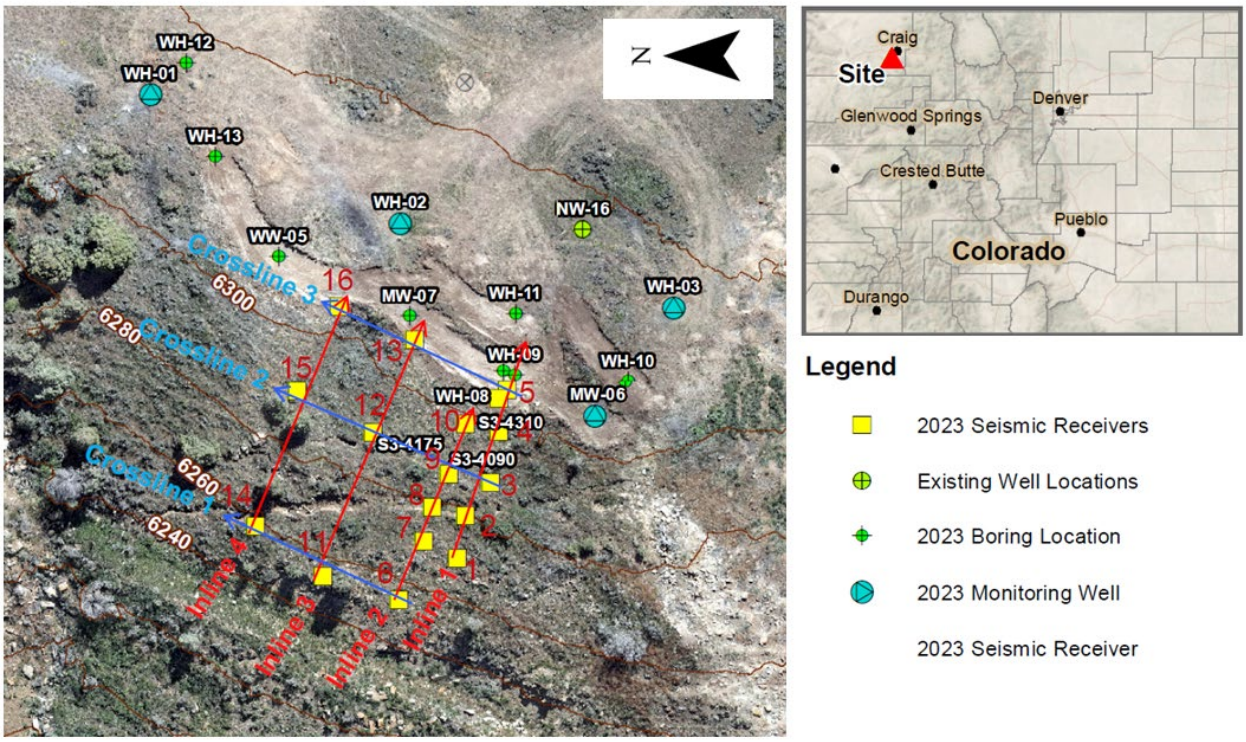

Figure 4: Wise Hill seismic survey overview

To further quantify and visualize velocity variations across the site, the produced HVSR curves were used in a Monte Carlo-based inversion method to match the amplitude and slope of the HVSR curve to that of a theoretical curve. The process perturbed various parameters, including P-wave velocity (Vp), layer thickness (H), viscoelastic medium parameters (QS, QP), density (ρ), and shear-wave velocity (Vs) to generate the best match of the theoretical and experimental HVSR curve that was obtained from the field. Generating many trial models using the Monte Carlo approach allows for exploring the parameter space while looking for new and better-fitting models.

Figure 7 shows velocity variations across sample seismic in-lines and crosslines using a Kriging interpolation method with the 1D velocity profiles from HVSR analysis as input. Based on information from MASW analysis and available drilling logs close to the survey lines, contour lines of 1,500 ft/s to 2,500 ft/s best delineate the range of elevations corresponding to the sandstone bedrock. Based on these results and Table 1, a shallower depth to the bedrock existed downslope of the survey area (nodes 1, 2, 6, 7, 11, and 14), which intercepted deeper slip surfaces and may prevent catastrophic slope failure. We note

that the velocities obtained from HVSR inversion are not unique and require a secondary geophysics method such as MASW, or drilling data to tie with the subsurface geology.

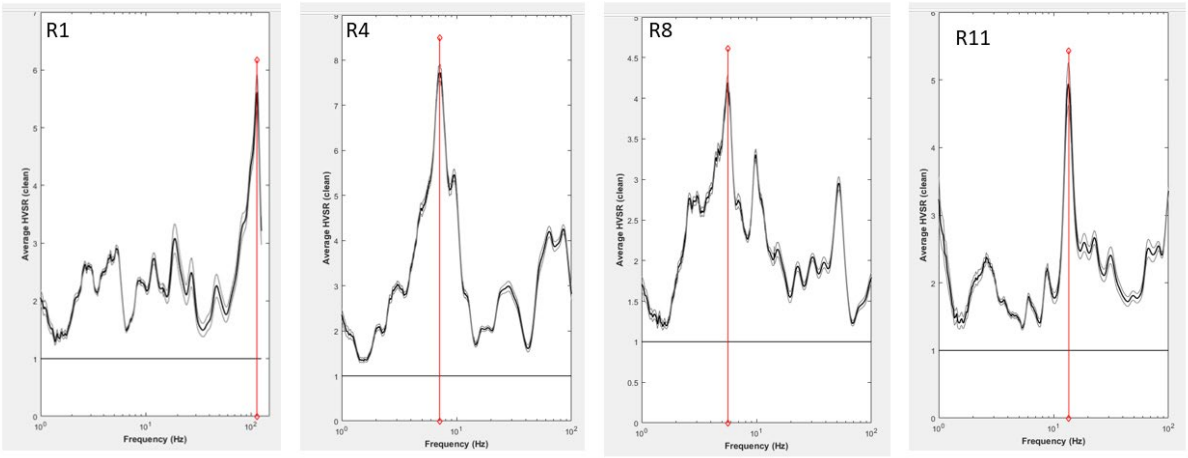

Figure 5: Sample HVSR curves

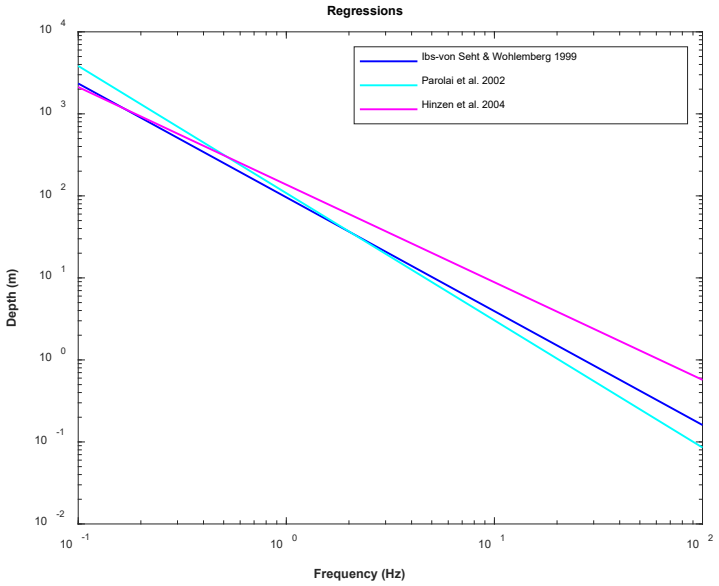

Figure 6: Depth-to-bedrock regression curves

Figures 8 and 9 show the results of a slope stability analysis based on the shear-wave velocity profiles (Figure 7) and Table 1 from the seismic survey for the minimum and maximum estimates of depth to bedrock along crosslines 1, 2, and 3. The slope stability analysis is based on the limit equilibrium formulation and the method of slices for force and moment equilibrium (Zhu et al., 2003). The outputs shown are factors of safety for several potential failure surfaces with the smaller factor of safety outlined. In this context, the factor of safety is defined as the factor by which the soil strength must be reduced so

that the potential sliding mass is at the point of limiting equilibrium. Typically, a critical factor of safety larger than 1.3 is good to ensure that the slope will be stable, with 1.5 preferred for long-term stability. The most comprehensive method implemented in the limit equilibrium formulation is the Morgenstern-Price or the Spencer method (Duncan and Wright, 1980), which provides the most accurate force closure diagram on the slices and is used in this analysis. A Mohr-Coulomb material model is employed with the shear strength parameters defined as tau=C+sigma*tan(ϕ), where C is inherent shear strength, also known as cohesion (can be assumed zero for most critical conditions), ϕ is the angle of internal friction, and sigma is the normal stress. Sigma is obtained from geometry and layering thickness and estimated based on the material unit weight.

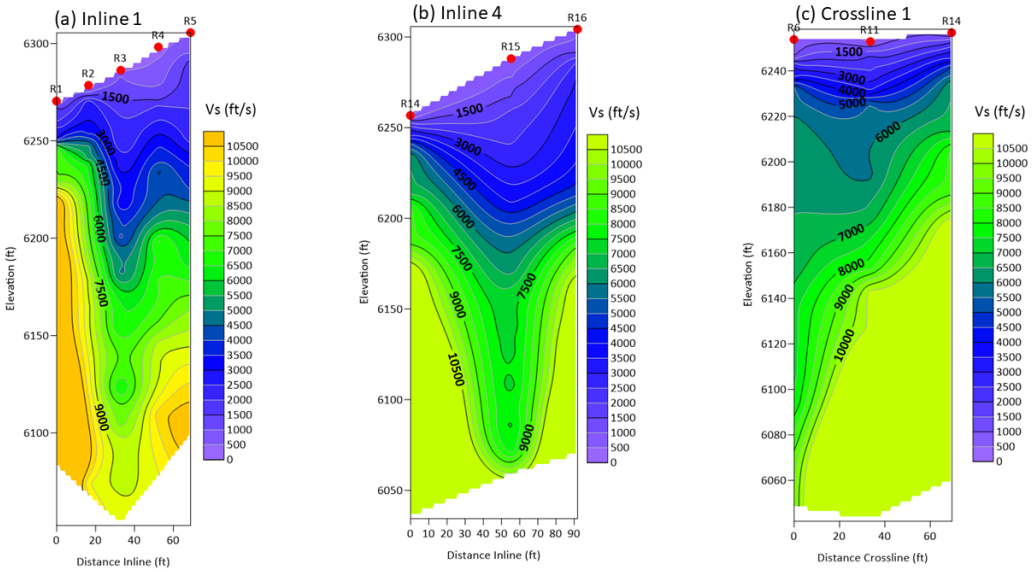

Figure 7: Sample inline and crossline interpolated shear-wave velocity profiles

Based on the performed analysis, the most critical factor of safety for the profile with the lowest estimate of depth to bedrock (Figure 8) is 1.356 for the limiting case of zero cohesion or inherent shear strength, which is an idealized case and may occur as a result of lack of moisture, lack of vegetation or lack of fine grain material or a combination of all these factors. This safety factor for the most optimistic estimate of depth to bedrock is higher than the 1.3 required for short-term stable slope conditions.

Similarly, the most critical safety factor for the profile with the highest estimate of depth to bedrock across crosslines (Figure 9) is 1.175 for the limiting case of zero cohesion, which is lower than the 1.3 value required for the short-term stable slope conditions. The shallow bedrock, as suggested by the HVSR analyses, minimizes the size of the slipping material volume. However, it does not prevent slope failure or possible movement of material onto the road downslope of the analyzed domain. We note that zero cohesion is very unlikely to occur in a real-world case scenario and was used here due to a lack of more accurate

geotechnical data and to show-case variations in the effect of depth to bedrock suggested from the HVSR analysis on the slope stability.

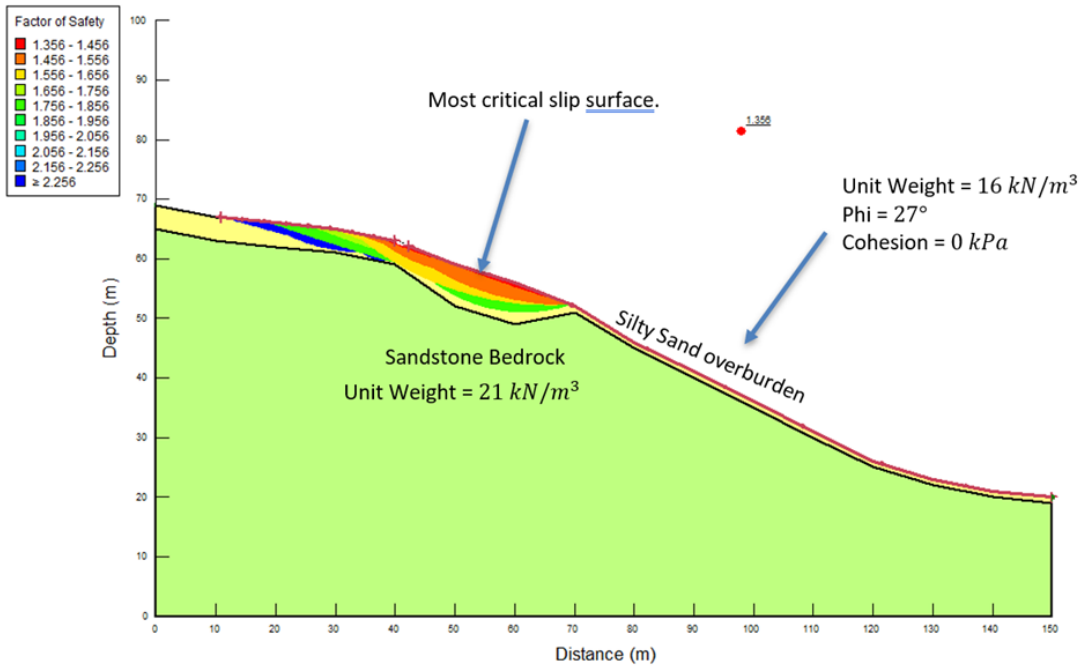

Figure 8: Slope stability analysis showing a probable range of failure surfaces based on the most optimistic estimate of depth to bedrock variation from Table 1

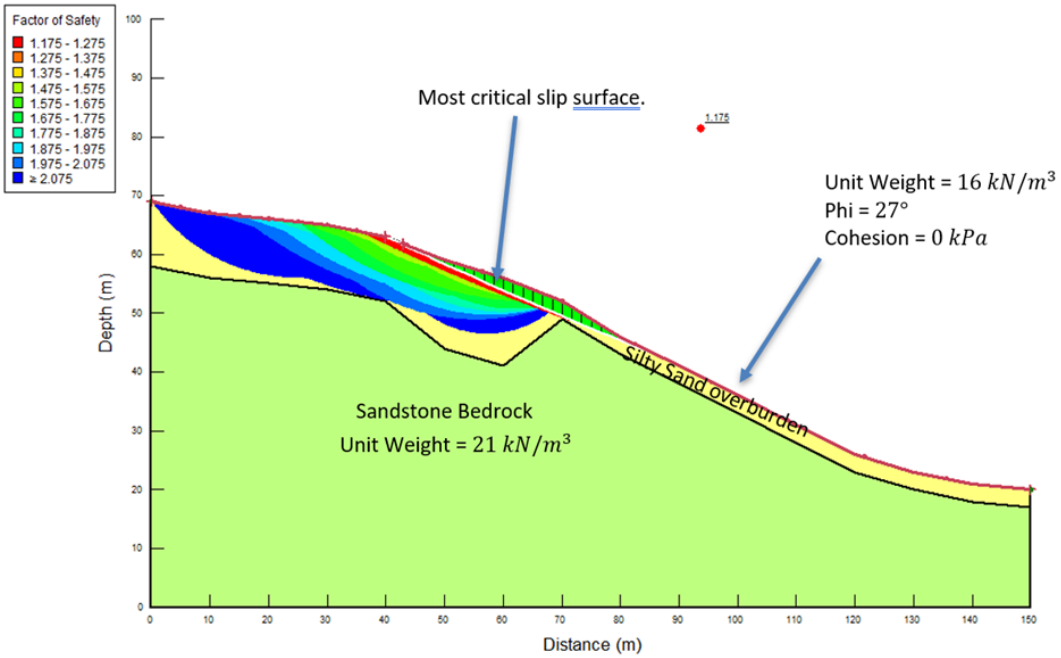

Figure 9: Slope stability analysis showing a probable range of failure surfaces based on the most conservative estimate of depth to bedrock variation from Table 1

Table 1: Estimated depth to bedrock range using HVSR curves

Conclusion

Two case studies demonstrated the effectiveness of active and passive seismic techniques in mine closure and remediation planning. The first study used the active source FWI technique to locate an abandoned mine adit and identify drill targets. The second study used microtremor HVSR analysis to estimate shear wave velocities for slope stability analysis at an abandoned coal mine. The findings indicated the utility of seismic techniques in reducing uncertainty in the mine closure and remediation planning process and reducing the gaps in the data from invasive testing methods.

Tailings Risk Mitigations at Hudbay Flin Flon: Prioritization Approach and Implementation of Multiple Mitigation Measures

Brad Russell, BGC Engineering Inc., Canada
Trevor Ross, Hudbay Minerals Inc., Canada
Matt Dugie, BGC Engineering Inc., Canada
Matthew Schafer, BGC Engineering Inc., Canada
Ed Carey, BGC Engineering Inc., Canada

Abstract

Review of foundation conditions of legacy dams and liquefaction susceptibility assessment at the Flin Flon Tailings Impoundment System identified that several perimeter embankments at the facility were not meeting target safety factors for undrained peak and post-liquefaction loading conditions. It was recognized that remediation of these dams would require extensive investigation and engineering and a thoughtful construction approach on sensitive foundations; a process that would require multiple years to complete.

Several risk reduction measures were identified that could be implemented at the facility. In a phased approach, the project was advanced in a prioritized manner based on the assessed level of risk associated with the various structures, consideration for impacts to operations, as well as practical limitations. The prioritization and sequencing of mitigation measures were based on a qualitative assessment with risk reduction measures ranging from simple measures that could be adopted within a matter of days to complex engineered solutions that required several years to implement, all while monitoring performance.

These measures included: changes in tailings deposition strategy and location; construction of open channel spillways to improve water management and reduce ponding water levels in the TSF; upgrades to the monitoring program and emergency response plans to enable improved identification and response to adverse dam performance including installation of a novel fiber optic cable monitoring system intended to identify large displacement events; control berms to isolate the community from the tailings facility; and dam upgrades that primarily consisted of toe berms to provide buttressing weight on the downstream side of the structures.

This paper describes the means of prioritizing risks, where several hazards were identified with conflicting considerations. The prioritization method enabled practical sequencing and successful

implementation of risk mitigation measures. The designs of key features are described, along with identification of some of the main design constraints and how these were addressed.

Introduction

The Flin Flon Tailings Impoundment System (FFTIS), shown in Figure 1, is a part of the Flin Flon Metallurgical Complex (FFMC). The FFTIS was commissioned in the early 1930s when Hudson Bay Mining & Smelting Co., Limited (HBM&S), which later became Hudbay Minerals Inc. (Hudbay), began depositing tailings in the natural water body that was Flin Flon Lake. As storage capacity requirements increased, containment structures were constructed on an as-needed basis. As a result of the depositional history of tailings and construction practices at the FFTIS, many of the containment structures are founded on hydraulically placed tailings and constructed in an upstream orientation.

Following the catastrophic tailings flow liquefaction failures of the Fundão Dam at the Samarco Mine and the Feijão Dam at Brumadinho in Brazil in 2015 and 2019, respectively, a review of tailings dam safety was initiated by the mining industry. The focus of the review was mainly on tailings dams constructed in the upstream manner, and more specifically, tailings dams that have brittle contractive materials providing a portion of the support or foundation. Further, the incidents prompted updates to design standards and guidelines, including the design approach that if potentially liquefiable materials exist in an embankment or foundation, then the design should progress based on the assumption that liquefaction will occur and use post-liquefaction strengths in stability analysis (Morgenstern, 2018) with an appropriate target factor of safety (FOS).

In 2016, based on screening-level assessment of historical cone penetration test (CPT) data, it was identified that potentially liquefiable tailings existed within the foundations of several dams at the FFTIS. Detailed investigations began in 2017 to assess the liquefaction susceptibility of foundation materials within a critical state soil mechanics framework, characterize undrained peak and post-liquefaction (residual) shear strengths for liquefiable materials, and evaluate the FOS for the FFTIS dam structures based on two-dimensional limit equilibrium analyses. Field work included seismic refraction (SR) and multichannel analysis of surface waves (MASW), geophysical, seismic CPT with pore pressure measurement (SCPTu), and geotechnical drilling with in-situ standard rate and variable rate shear vane testing (VST) and fixed-piston Shelby tube sampling. Laboratory work included index and advanced testing, including triaxial testing following the methods detailed by Jefferies and Been (2016) to support defining critical state soil properties.

Several structures, with a combined length of over 9 km, were identified that did not meet the target FOS criteria developed for the site based on industry guidelines (1.5 for peak undrained strength and 1.1

for post-liquefaction strength loading conditions). In response to the findings, Hudbay initiated a phased approach for upgrades to the facility, referred to as the Legacy Dam Upgrades (LDU) project.

Figure 1: Overview of FFTIS (2018 image). Structures included within LDU project colored orange

Site description

The FFMC is located west of the City of Flin Flon, Manitoba and immediately north of the Town of Creighton, Saskatchewan. The FFTIS generally consists of separate impoundments for each of the mill tailings, zinc pressure leach (ZPL) tailings, and zinc oxide residue. Impoundments for each of the ZPL tailings and zinc oxide residue were constructed immediately adjacent to structures that were constructed at earlier stages in site development to contain mill tailings. Tailings production and deposition at the facility ceased in July 2022 and the facility is currently in a care and maintenance phase. The site is separated into several discrete ponds which served to manage the different tailings streams during operations, as well as surface water management and treatment which continues in the care and maintenance phase.

The site is an undulating landscape typical of the Canadian Shield with elevated bedrock outcrops and a typical lithological sequence in depressions consisting of peat, fine grained glaciolacustrine soils and/or glaciofluvial sand, and glacial till overlying bedrock. The glaciolacustrine clay is typically normally consolidated; however, in many areas an overconsolidated upper layer (crust) is present. The site is located within a relatively low seismicity part of central Canada.

Approach to prioritization sequencing

Several risk mitigation measures were identified that could be implemented at the facility. In a phased approach, the LDU project was advanced in a prioritized manner based on the assessed level of risk associated with the various structures, consideration for impacts to operations, as well as practical limitations. It was recognized that efforts should be made to minimize potential adverse changes in loading conditions at any of the structures not meeting target FOS, and to the extent possible, reduce loading. It was also recognized that stability upgrade construction itself was capable of triggering liquefaction and the assessment of foundation conditions, design, and construction approach would require consideration of this potential.

The prioritization and sequencing of mitigation measures were based on a qualitative assessment that generally considered the following:

1. Existence of a population at risk (PAR) in the downstream area.
2. Effectiveness of the mitigation measure(s) to reduce impact to PAR (consequence reduction).
3. Effectiveness of the mitigation measure(s) to reduce probability of failure (PoF).
4. Requirements for mitigation measure implementation to support continued operations (deposition location or crest raise requirement).
5. Effectiveness of the mitigation measure(s) to reduce risks from multiple hazard sources.
6. The relative timeline required for assessment, engineering, and construction to implement the mitigation measure.
7. The relative cost and resource requirement to complete the mitigation measure.

Based on these considerations, project phasing was developed as described below, along with the related rationale:

- Phase 1: included mitigation measures that could be implemented with relatively minimal investigation and analysis and would have relatively immediate benefit to either reduce potential consequence or PoF (selected initial mitigation measures are described below), including stability upgrades required to support continued tailings deposition of ZPL tailings (i.e. East ZPL Dam toe berm and South ZPL Dam toe berm). A focus of this phase was also to reduce potential impacts (consequence) to the adjacent community of Creighton (i.e. Environmental Control Berms, described below). Through this phase, the necessary investigation, analyses, and engineering for the stability upgrades planned for the subsequent phases was undertaken.
- Phase 2: focused on stability upgrades to reduce potential impact to the highway located adjacent to the facility.

- Phase 3: the early portion of this phase focused on stability upgrades that would reduce potential impacts to the downstream community of Flin Flon (located further downstream compared to Creighton). The balance of this phase was for stability upgrades to structures that had potential impacts that were expected to remain within the limits of the site.

Initial mitigation measures

The initial mitigation measures, shown in Figure 2, were implemented at the site including:

1. Relocation of tailings deposition away from dams with FOS below target
2. Construction of the Oxide Pond Dam (OPD) Spillway; to reduce likelihood of high pond levels (and large pond volumes stored) against the OPD
3. Construction of the South Causeway Spillway; to reduce likelihood of high pond levels (and large pond volumes stored) against several dams
4. Construction of the SZPL Spillway; to reduce likelihood of high pond levels (and large pond volumes stored) against the EZPL Dam and SZPL Dam.

Further, measures were taken to improve monitoring and emergency response capabilities at the facility, including a revision of the emergency preparedness and response plans. Monitoring upgrades included installation of additional conventional geotechnical instruments including piezometers, slope inclinometers, shape arrays, survey prisms, and settlement pins; the instruments were enabled with near real-time data acquisition and upload via cellular network to a data storage and viewing platform.

A significant initial upgrade included installation of a continuous fiber optic cable across the crest of approximately 6 km of tailings dam structures at the facility (Forbes et al., 2021). The purpose of the fiber optic cable was to provide near real-time monitoring (i.e., detection) of a dam failure event and be capable of configuration to an external alarm system. The fiber optic cable, and associated system, was not intended to provide an early warning of a developing dam failure, given the rapid nature and minimal precursor indicators of a potential flow liquefaction-type failure. An interrogation unit, and related processing equipment, monitored the fiber alignment at a sampling rate of at least 1 kHz (i.e., 1,000 cycles per second) with a 10 m channel spacing (i.e., a measurement every 10 m along the alignment). Two types of alarm thresholds were configured to detect potential dam breach scenarios: 1) a Fiber Break Alarm and 2) a Near Fiber Break Alarm. A near real-time notification system was configured to send alerts in the event of a triggered alarm; test alarm scenarios indicated that the system could detect an alarm exceedance and provide the location of the alarm along the fiber optic cable (georeferenced location along the tailings dam) within seconds of the test.

Figure 2: Overview of FFTIS (2019 image). Initial mitigation measures highlighted green

Environmental control berms

As an early consequence reduction measure, Hudbay took an innovative approach to build Environmental Control Berms (ECBs) to isolate the neighboring community from the tailings facility and reduce the potential risk of a dam breach to the nearby population.

A tailings dam breach assessment was performed to inform selection of the alignments and crest elevations. A broad spatial distribution of potential breach locations within the south end of the FFTIS were assessed and extreme breach scenarios were also evaluated in consideration of the potential for an extensive flow liquefaction slope failure, with a wider than typical breach width, such as that which occurred at the Feijão Dam at Brumadinho.

The ECBs (Berm 1, Berm 2, and Berm 3) were designed to span three topographic lows as rockfill embankments, with 6 m wide crests, 1.5H:1V north slopes, and 3H:1V south slopes facing the neighboring community to allow for revegetation. The approximate berm dimensions are as follows: Berm 1 – 5 m high and 130 m long, Berm 2 – 14 m high and 370 m long, and Berm 3 – 6 m high and 60 m long. The berm designs included provisions to maintain drainage through the structures. A simplified design cross-section is shown in Figure 3 while Figure 4 provides an overview photo of the completed structures.

Toe berm design and engineering assessments

Engineering assessments

Between 2017 and 2022, 104 CPTs and 105 drill holes were completed on the site, along with two instrumented test fills, a test excavation, and two dewatering/pumping tests as means to better characterize the materials and the foundation conditions, and plan construction implementation.

Engineering analyses included CPT-based liquefaction susceptibility assessment using methods including Plewes et al. (1992), Robertson (2016), and the CPT-inversion approach of Jefferies and Been (2016). Undrained peak and post-liquefaction (residual) shear strengths were developed based on in-situ variable rate vane shear tests as well as laboratory and case-history based methods available in literature including Olson and Stark (2003), Sadrekarimi (2014), Robertson (2022), and Jefferies and Been (2016).

Stability analyses included primarily two-dimensional limit equilibrium analyses along with selected finite element analyses with the Norsand critical state constitutive model.

The design process considered a number of stability upgrade alternatives including toe berms, de-watering, and ground improvement; details of the options considered are summarized in Table 1.

Table 1: Summary of stability upgrade alternatives considered.

Stability Upgrade Category	Description	Option
Increasing the resistance force	Can be done by adding weight at the toe of the dam or reducing the pore water pressures. Both options result in an increase in effective stress of the soil, and consequently increase in undrained strength leading to increase in FOS	Building a toe berm Dewatering wells
Decreasing the driving force	The general way to decrease the driving force is to remove weight from the upstream of the failure surface	Crest and slope cut
In situ ground improvement	This option is used to increase the shear strength of the soil usually by adding cementitious material into the soil or densifying the soil	Cutter soil mixing Large diameter soil mixing Trench cutting and soil mixing Jet grouting Compaction grouting Vibro compaction Dynamic compaction
Soil replacement	Replacing the weak stratum with well compacted granular soil, crushed stones, or concrete columns in order to increase the shear strength and consequently, FOS values.	Rigid inclusions Stone columns Granular shear keys
Structural reinforcement	Adding structural elements to the slope or foundation soil to stop or increase the resistance along the path of failure planes.	Sheet piles Bored piles Retaining structure

Shear resistance alternatives were evaluated as the most feasible solution to provide the required stability upgrades at the structures considering: 1) toe berms and shear keys are conventional dam stability upgrade approaches with past precedence at the site; 2) toe berm construction would progressively increase the FOS; and 3) toe berms and shear keys would require relatively less engineering effort and time compared to ground improvement options. Further, additional project benefits could be realized by utilizing local contractors with extensive site experience. The stability upgrade design also incorporated removal (borrow) of historical tailings deposits and dams as both a source of toe berm fill but also as a means of reducing driving forces where possible and assist in the overall upgrade strategy. Shear keys, excavated to bedrock, were incorporated into the toe berm designs where practical and/or where site constraints required

a composite design solution. Surface water features and site drainage channels were realigned and upgraded to account for the toe berm footprints and to better align with long-term closure objectives for the site.

Details of the dam stability upgrade designs for select structures, the South Weir Dam (SWD) and Southeast Dam (SED), are provided in the subsequent sections.

South Weir Dam stability upgrade

The original starter dam construction at the SWD began in the 1940s to span across a topographic low between bedrock ridges where the historical Flin Flon Lake narrowed to approximately 50 m wide. The dam fills comprise compacted tailings and waste rock fill with smaller amounts of slag fill and natural sand and gravel for drains and filter layers; it was generally raised in an upstream direction. The Clarification Pond is situated immediately downstream of the structure with a typical water level of El. 318 m; the pond is used primarily for polishing of effluent quality. During early periods of operation, tailings migrated hydraulically from the southern discharge and had dispersed throughout the footprint of the proposed SWD toe berm.

The SWD toe berm, shown in Figure 5, was designed to provide buttressing weight (resistance to driving forces) at the SWD toe and downstream area. The toe berm foundation stratigraphy was dominated by a relatively narrow bedrock topographic low that extends upstream to downstream underlying the Clarification Pond. The topographic low gradually widens in the downstream direction and was infilled with natural sediments including peat several meters thick and glaciolacustrine clay up to approximately 15 m in thickness. The bedrock elevation within the low ranges from El. 285 m to 295 m (approximately 23 m to 33 m below Clarification Pond level).

The toe berm was designed to span between the shorelines of the Clarification Pond to form a "working platform" at El. 319.5 m. This fill was to be placed subaqueously and compacted in a manner to displace the Clarification Pond sludge material in a downstream direction and penetrate the underlying tailings material. A "mud wave" of displaced sludge was expected to form downstream of the placed fills; the material was excavated and hauled away to avoid restricting the penetration of the rockfill. The design included two benches over the working platform, to El. 322.5 m over a 170 m width and El. 324 m over a 60 m width, which was constructed of rockfill in compacted lifts. A simplified design cross-section is shown in Figure 6.

As construction progressed, a total of 14 SCPTu's and seven drill holes were completed within the toe berm footprint as part of design confirmation with the intent: 1) to confirm toe berm fill and foundation stratigraphy including the bottom of rockfill elevation target at El. 314 m was being achieved, 2) to investigate the foundation soils using CPT and VST to confirm selected design inputs, 3) to install instrumentation to support both short-term construction monitoring and long-term performance monitoring

of the toe berm. The drilling was completed in three phases during construction to allow stratigraphy (including bottom of rockfill) to be confirmed as working pad construction progressed. It also allowed instrumentation including piezometers, settlement plates, and slope inclinometers to be installed and thus, monitored relatively close to the leading slope of the working pad over the duration of the work to help promote worker and dam safety. The encountered toe berm fill and foundation stratigraphy were generally in agreement with the SWD toe berm design inputs and generally confirmed the design basis. Localized areas of thicker peat and glaciolacustrine clay were encountered at some locations within the topographic low underlying the toe berm. At one location, measured PWP conditions following working pad construction were higher than design expectations. In this area, a test fill was completed to confirm the understanding of the PWP conditions prior to completing Stage 2 toe berm construction above El. 319.5 m.

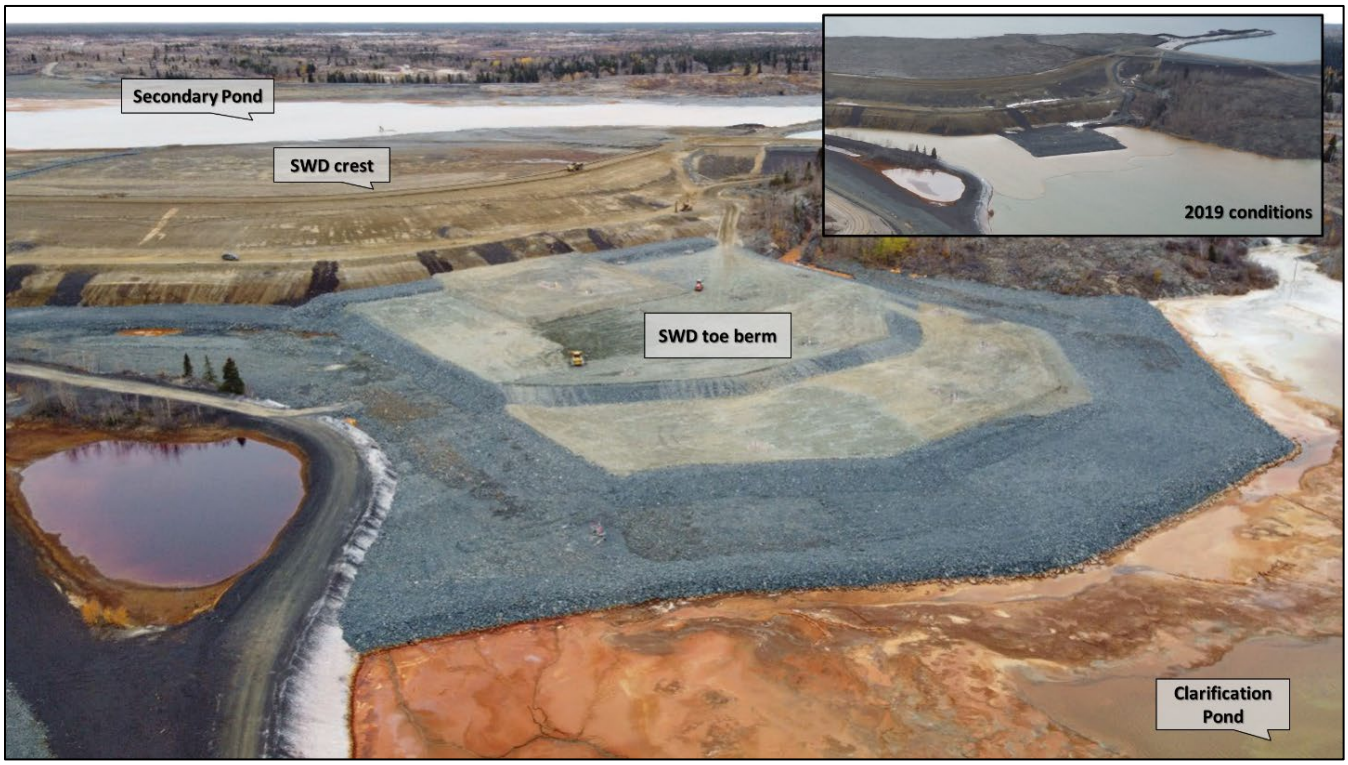

Figure 5: SWD toe berm construction; nearing completion and initial conditions (inset)

Southeast Dam stability upgrade

The Southeast Dam is one of the oldest structures within the Flin Flon Tailings Impoundment System. Construction activities began in 1927. The original starter dam was constructed across historical Flin Flon Lake between bedrock highs where the lake narrowed to approximately 125 m. The starter dam was generally founded on soft to firm normally consolidated glaciolacustrine clay up to approximately 6 m in thickness. The dam was raised in an upstream direction as required, using waste rock, slag, and compacted tailings. The dam comprises several terraces where previous construction included set-backs to reduce the

seepage gradient through the structure. The terraces were constructed over existing tailings beaches up to approximately 40 m in thickness beneath the structure.

The SED stability upgrade design involved the combination of a toe berm and shear key. Inclusion of the shear key was necessary due to constraints imposed by surface water management infrastructure (the Lake Bottom Sump) located at the downstream toe of the structure. Prior to the start of construction, a shear key field excavation trial was constructed over a plan area of approximately 25 m by 5 m. The trial work confirmed that shear key construction in a series of overlapping panels was feasible. The shear key design and construction involved the excavation of glaciolacustrine soil to bedrock over the design footprint and backfilling with compacted rockfill. A sand and gravel filter was placed along the upstream perimeter of the shear key to limit the potential of internal erosion of the foundation soil into the rockfill.

The toe berm at the lower terrace consisted of a single 85 m wide bench graded between El. 321 m to El. 319 m with perimeter slopes of 1.5H:1V. The toe berm is comprised of three primary material zones (from downstream to upstream): 1) a 3.8 m wide zone of coarse rockfill for erosion protection; 2) a 15 m wide zone of compacted rockfill; and 3) a 0 m to 30 m wide zone of compacted tailings. The toe berm included an internal drainage system that comprised three finger drains that tied into the existing slag downstream slope and a toe drain connecting the finger drains. The toe berm included benches in the upper portion of the structure; each of these were primarily constructed of compacted tailings with a 0.5 m thick layer of rockfill erosion protection. A simplified design cross-section is shown in Figure 7.

Monitoring and performance

The LDU project relied on an extensive network of instrumentation monitoring soil behavior. Over 200 automated piezometers, two automated shape arrays, 13 slope inclinometers (read daily), and 60 survey prisms (read daily) supported the evaluation of measured soil behavior versus expected performance. Further, the fiber optic detection system was monitored throughout the work and offered insight during quarry blasting activities and the subsequent assessment and field inspections to permit resumption of activities.

A construction monitoring and emergency preparedness plan was developed and updated throughout the project. The plan included the responsibilities of various parties involved in the construction works, site specific emergency response procedures, and dam safety monitoring requirements, including instrumentation reading frequencies and trigger levels for action.

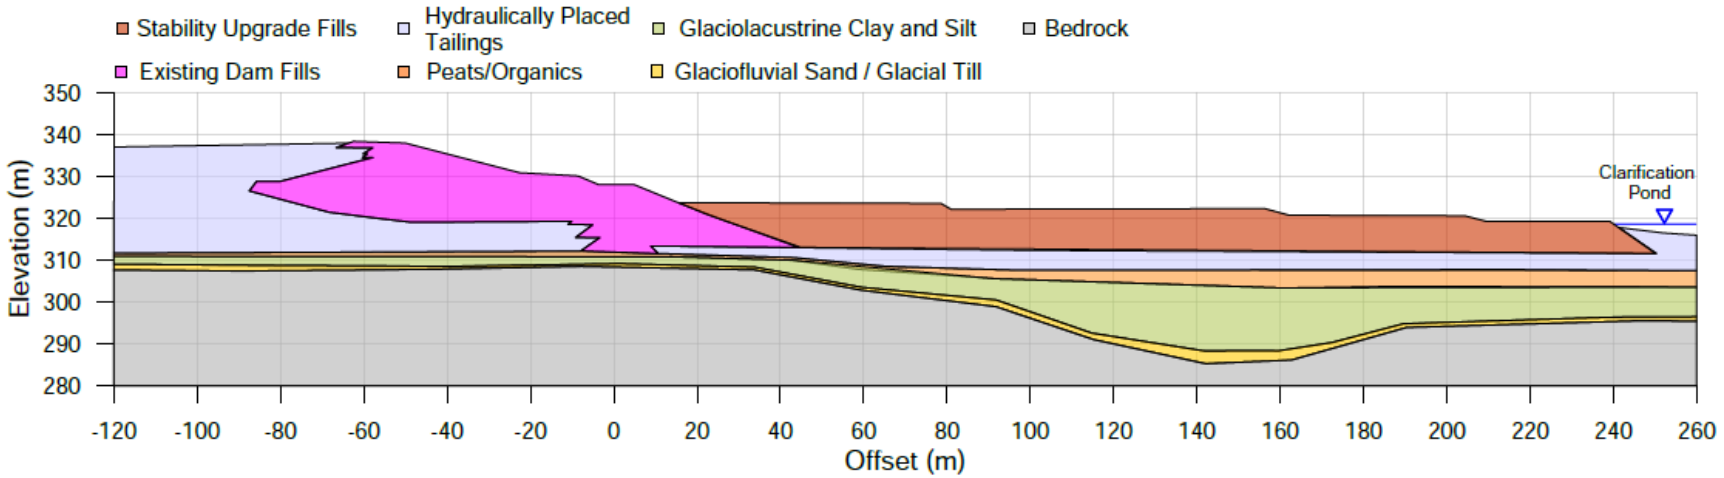

Figure 6: SWD stability upgrade design cross-section

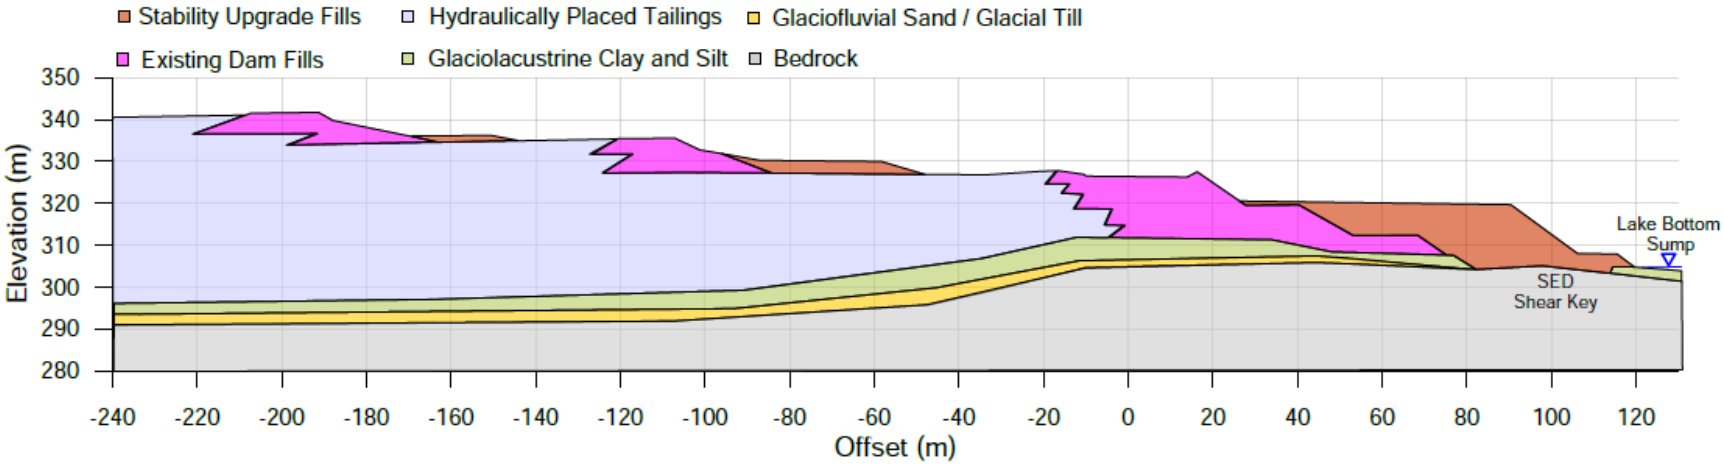

Figure 7: SED stability upgrade design cross-section

Conclusion

The LDU project at the FFTIS included approximately 1.5 million m^3 of fill placed, which significantly transformed the overall landscape of the facility and improved conditions towards being a long-term stable landform. The project represented a significant reduction in risk of a legacy tailings facility in close proximity to a population area.

This paper describes the means of prioritizing risk reduction measures where several hazards were identified with conflicting considerations. The prioritization method enabled practical sequencing and successful implementation of risk mitigation measures. The project encountered design constraints and varied conditions that required a balance of novel techniques and assessments, along with conventional methods, to achieve the project objectives.

Abstract

This paper presents a case study of efforts by Freeport-McMoRan Bagdad Inc. (FMBI) to optimize the design of a filter zone for a rockfill embankment that provides containment of a tailings storage facility (TSF). The efforts included large-scale trials to optimize placement requirements and demonstrate acceptable self-healing performance of a proposed filter material with relatively high fines content.

Large-scale testing procedures to evaluate the placement and performance of the proposed filter are described, including lessons learned. The case study highlights the performance of a filter material with higher fines content than typical filters, describes the methods used to optimize filter placement, and demonstrates acceptable self-healing behavior of the proposed filter material to mitigate construction defects and cracks in the filter.

Site and TSF overview

Freeport-McMoRan Bagdad Inc. (FMBI) is an open-pit copper and molybdenum mining, milling, and leaching operation in Arizona. The mine operates at a variable production rate, depending on the rock type being milled, with an annual average of approximately 77,000 tons per day. Tailings from the mill are thickened and pumped to the mine's Upper Mammoth TSF through two tailings delivery pipelines for deposition via on-dam cyclones, single-point discharge, and perimeter spigots.

The centerline underflow sand embankment is constructed using on-dam cyclones placed at 50-foot intervals along a structural steel jacking header system. Approximately 100 cyclones are currently installed, and operators typically run 60 cyclones at a time during active deposition.

The Upper Mammoth Secondary Dam (UMSD) is a continuation of the Upper Mammoth TSF embankment. The UMSD is the right abutment for the underflow sand embankment and provides impoundment containment on the northern and eastern extents of the TSF up to the design elevation. The design for the UMSD includes six 50-foot-high centerline rockfill raises. Each raise is constructed using run-of-mine rockfill from the open pit. The upstream slope of each raise includes a two-stage filter zone to prevent migration of tailings into the rockfill. Whole tailings are deposited upstream of the UMSD, using spigots. A typical section is shown in Figure 1.

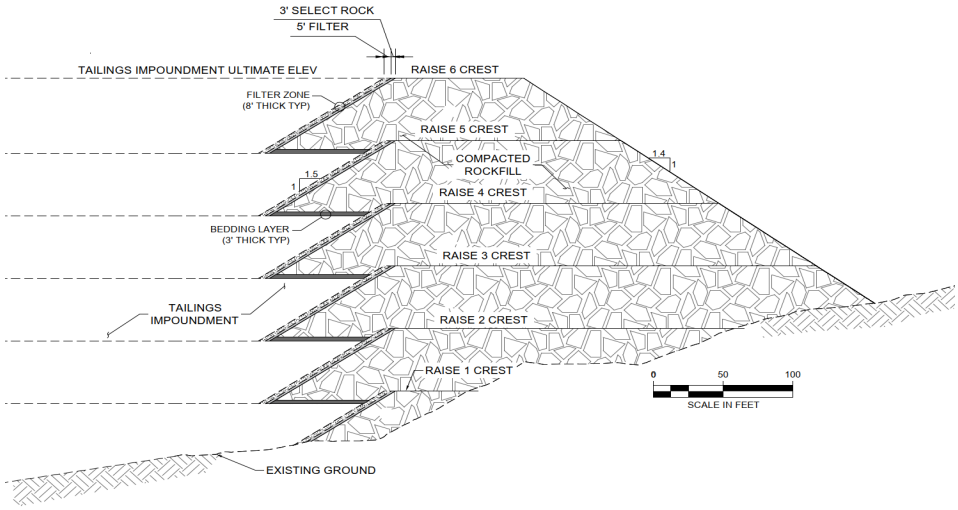

Figure 1: Typical Upper Mammoth Secondary Dam section

Introduction

During early design phases of the Upper Mammoth TSF project, a run-of-mine rockfill test fill program and filter compatibility evaluations indicated the need for a filter zone between the rockfill and the spigotted whole tailings. Filter zone gradations were developed using the Natural Resources Conservation Service (NRCS) filter design criteria outlined in Part 633 of the National Engineering Handbook (NRCS, 1994). The NRCS filter design criteria include requirements for filter compatibility and permeability that are reflected in the design procedure. Filter erosion boundary criteria developed by Foster and Fell (2001) were also considered to evaluate material susceptibility to erosion and optimize the design. These filter criteria were developed for earthen water-retaining structures, which are typically subject to the relatively high seepage gradients that are inherent in such structures. The primary function of the filter zone at the Upper Mammoth TSF was to provide separation and filter compatibility between the rockfill and the whole tailings to prevent erosion, piping, and sinkholes. Permeability of the materials was not a driving factor because of the arid climate of the site and because the reclaim pond was to be managed thousands of feet from the crest of the UMSD, resulting in seepage gradients lower than those at most water-retaining structures.

The filter zone was designed with an overall thickness of 8 feet, to balance constructability, technical requirements, and economy. The filter zone, which overlies the rockfill upstream slope, was designed with 3 feet of Select Rock and 5 feet of Filter measured horizontally. Figure 2 shows the materials used in the construction of the UMSD, from left to right; Rockfill, Select Rock, and Filter respectively.

Figure 2: Rockfill, select rock, and filter (shown left to right)

At the time of the study, FMBI operated a small crusher on-site to produce stemming material for blast holes in the open pit. The small crusher was operated near the location of the UMSD and was identified as the preferred source for the generation of the filter zone materials. The stemming material gradation is finer than the Rockfill and coarser than the initial filter design gradation and was adopted as Select Rock without modification. The byproduct of stemming material production is similar to the initial filter design gradation bands, except that the byproduct has higher fines (5 percent to 15 percent) and more fine sand. Modifications to the crusher to produce a byproduct with lower fines content and less fine sand were evaluated; however, the fines content could not be reduced to the target of 5 percent or less without the additional effort and cost of washing the material.

Given that the primary purpose of the filter zone is to provide separation and prevent migration of material between the Rockfill and whole tailings, the potential for reduced construction cost, and the opportunity for reduced environmental impacts, the stemming byproduct was proposed as filter for the project without modification. However, compaction of a filter with relatively high fines content had the potential to result in a stiff material with more potential to hold a crack or defect.

AECOM performed seepage and slope stability analyses to evaluate the geotechnical impacts of potential cracks, erosion, and piping of material into the pore spaces of the Rockfill, which could potentially result in an elevated phreatic surface or reduced shear strength in the rockfill. Based on the geotechnical analyses performed, cracks and erosion of the proposed filter material would have minimal impacts on the UMSD's performance. FMBI and AECOM, with input from the Independent Technical Review Board, decided that the proposed filter should be evaluated for erodibility, self-healing, and dispersivity.

Laboratory testing demonstrated non-dispersive behavior of all samples tested, and a procedure was developed to evaluate the self-healing behavior of the proposed filter material.

Filter erodibility test procedures

A literature review did not identify a standardized method for filter erodibility testing, so a testing procedure was developed as described herein. The purpose of the filter erodibility testing was to evaluate the ability of the proposed filter to self-heal under different placement and compaction techniques in the event of the formation of a crack or presence of a construction defect.

A total of 15 filter erodibility tests were performed by AECOM and FMBI. The first nine tests were used to refine the setup and testing procedure and are excluded from discussion in this paper for brevity. The procedure used for the last six filter erodibility tests is summarized below:

1. Test pads were constructed with a 1- to 2-foot-thick graded and compacted Select Rock layer overlain by 1 to 2 feet of filter material, as shown in Figure 3. The test pads were graded to a flat working surface.

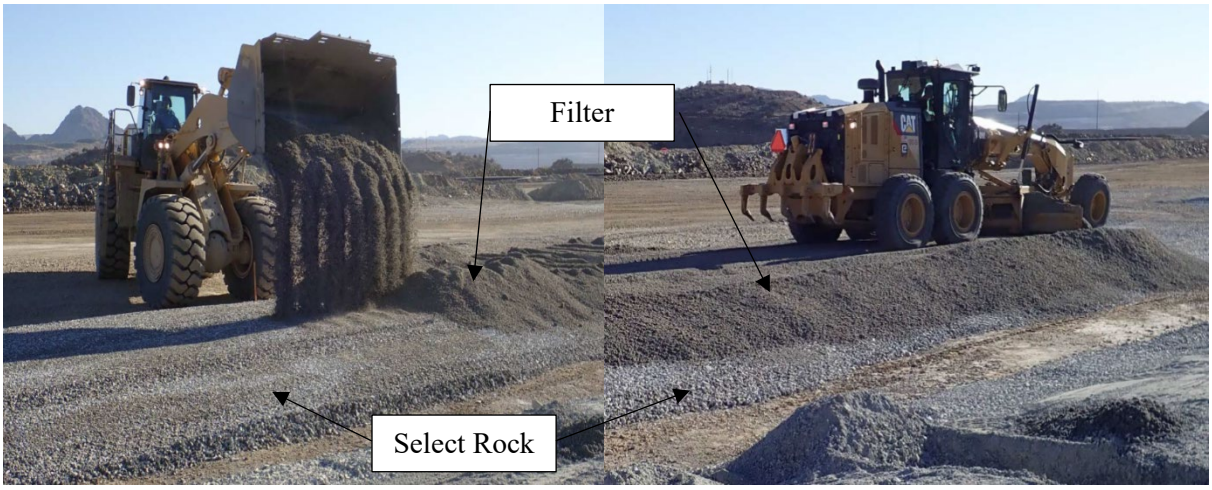

Figure 3: Test pad filter placement (left) and grading (right)

2. A trench was then excavated within the filter material down to the contact at the top of the Select Rock. Two steel plates were used for the various tests: one of the plates was 1 foot high by 2 feet long and the other was 2 feet high by 3 feet long. Both plates were ¼ inch in thickness. The plate was inserted vertically into the trench until it made contact with the Select Rock. Filter material was backfilled and compacted around the plate, using variable compactive methods (backhoe tamping or two to eight passes of a vibratory smooth drum roller). Steel plate placement is shown in Figure 4.

3. For three of the tests (up to 6 inches of underflow sand were placed on top of the filter material to simulate interaction of the underflow sand with the proposed filter and Select Rock. The underflow sand provided some surficial support and reduced the applied water stress on the crack, with the result that its self-healing ability could be better assessed.
4. Approximately 10 gallons of water were slowly added to the surface, near the plate, to moisten the materials and to minimize absorption of water during the test. Once all the water had infiltrated into the filter material, a minimum of four nuclear density gauge tests were performed to measure the density and moisture content of the compacted filter material.
5. A rubber-tire backhoe used a rope strap to remove the plate and simulate a crack in the filter material. The boom of the backhoe was used to pull the steel plate up vertically to minimize lateral disturbance of the filter material and underflow sand (if used). The steel plate just prior to removal is shown in Figure 4 (right photograph).

Figure 4: Backfilling of steel plate (left) and compacted surface prior to removal (right)

6. Orange surveyors paint was used to mark the crack location and help identify the migration of filter and underflow sand (if used). A photograph of the setup just prior to adding water to the simulated crack is shown in Figure 5.
7. Water was then poured from a 5-gallon bucket at a controlled rate across the filter material or underflow sand surface (if used) toward the crack. When the crack was visibly closed at the surface and water was observed to pond, water application was stopped, and the amount of water used was noted. Once the ponded water had infiltrated into the filter, additional water was poured, and that process was repeated until the planned quantity of water had been added to the test area.

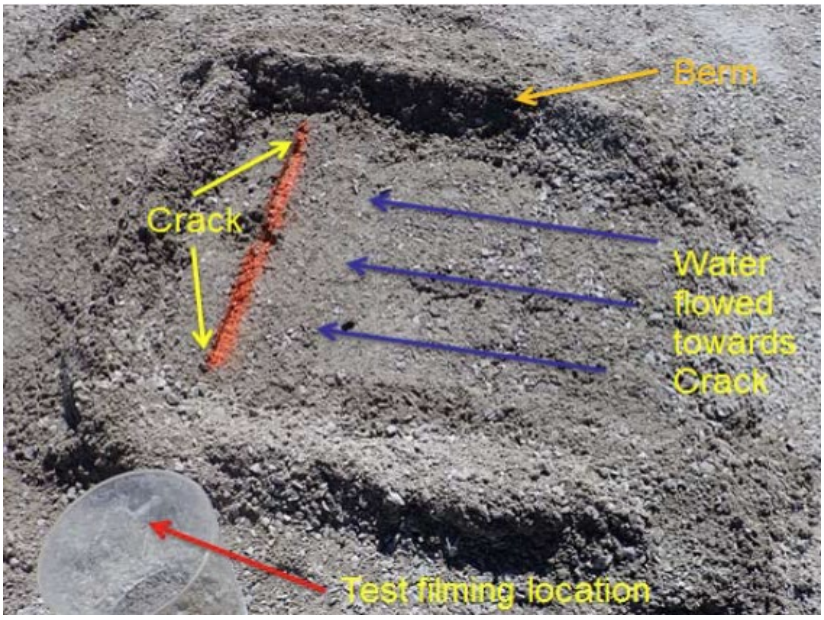

Figure 5: Simulated crack prior to adding water

8. After all the water had infiltrated, a vertical excavation within the filter material was performed at the location of the simulated crack. Visual observations were made by AECOM staff to document whether the crack had self-healed and whether the filter material had migrated into the Select Rock among other notable observations. A typical photograph of the vertical excavation is shown in Figure 6.

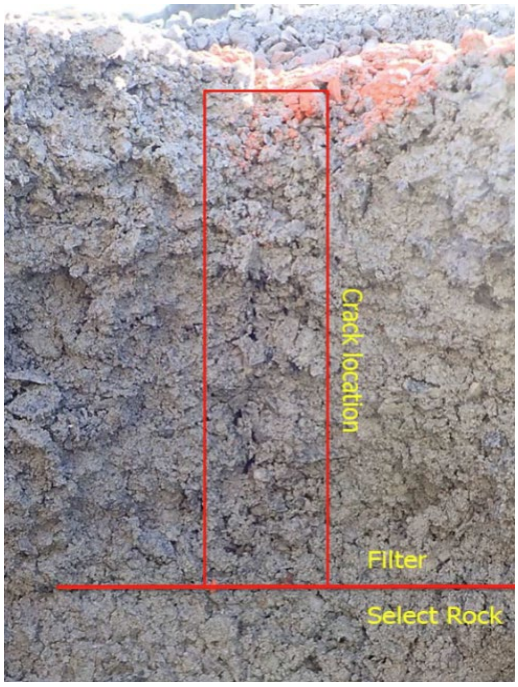

Figure 6: Vertical excavation of simulated crack

9. Samples of the filter material and Select Rock from each test were collected for particle size analysis, Atterberg limits, and dispersion testing.

Detailed observation logs noting the compaction method, crack size (steel plate), water application rate, and presence of underflow sand were kept. The observation logs also recorded how many gallons of water flowed into the crack before it started to heal, and they included numerous photographs and videos.

Filter erodibility test results

Laboratory testing performed on samples collected during the filter erodibility test identified the material as a clean to clayey fine gravel (GP-GC, GC) or clean to clayey fine gravel/sand (SP-SC) with fines ranging from 9.1 to 14 percent. The plasticity index ranged from 7 percent to 15 percent, depending on the source rock.

Two photographs identified as representative of good self-healing tests have been included in Figures 7 and 8. Figure 7 includes a photograph from Test 11 showing the simulated crack prior to plate removal and after the test and excavation to show the degree of self-healing in cross-section. This test did not include underflow sand on top of the filter material.

Figure 7: Simulated crack for Test 11 with no underflow tailings on top

Figure 8 includes a photograph from Test 13, which had 6 inches of tailings placed on top of the filter material, showing the simulated crack and the degree of self-healing in cross-section. The underflow sand entered the crack; however, the underflow sand did not reach the Select Rock. Underflow sand entering the crack is not surprising, as water flowed over the underflow sand (which easily erodes) before entering the crack. In both photographs, the orange paint applied to the surface of the crack was visible at the top of the Select Rock, indicating a crack through the material was successfully created. The distribution of orange paint within the crack illustrates the self-healing of the crack.

Figure 8: Simulated crack for Test 13 with underflow tailings on top

Test 10 through Test 15 are described in detail in Table 1, and the results of these tests, which are presented as dry density versus volume of water applied until surface ponding occurred, are shown in Figure 9. The following comments and conclusions were made based on the final six tests.

- The tests performed with less compactive effort (looser with lower dry density and void ratio) demonstrated faster self-healing performance, with just a few gallons of water flowing over the surface before the water started to pond. Minimal compactive effort (light tamping) was included in the revised project specifications based on this observation.
- From Figure 9, we can observe that while the general conclusion of lower density results in better self-healing, it is apparent that the addition of underflow to the filter surface slowed the self-healing process. The authors believe the self-healing process slowed because less sheet flow erosion was occurring at the filter surface (due to support provided by the underflow), requiring more inflow to self-heal, and

this likely better represents in-situ conditions. Thus, the authors feel large-scale tests should include representative base materials on top of the filter.

- From Figure 9 and Table 1, it can be concluded that Test 12 is an outlier, requiring about 15 gallons to self-heal and begin ponding versus 5 gallons for a similar test setup and density. Based on index property testing, the filter material requiring more water to self-heal had a slightly higher plasticity, enabling it to sustain a crack longer before eventually self-healing. Limits on plasticity were included in the project specifications based on this observation.

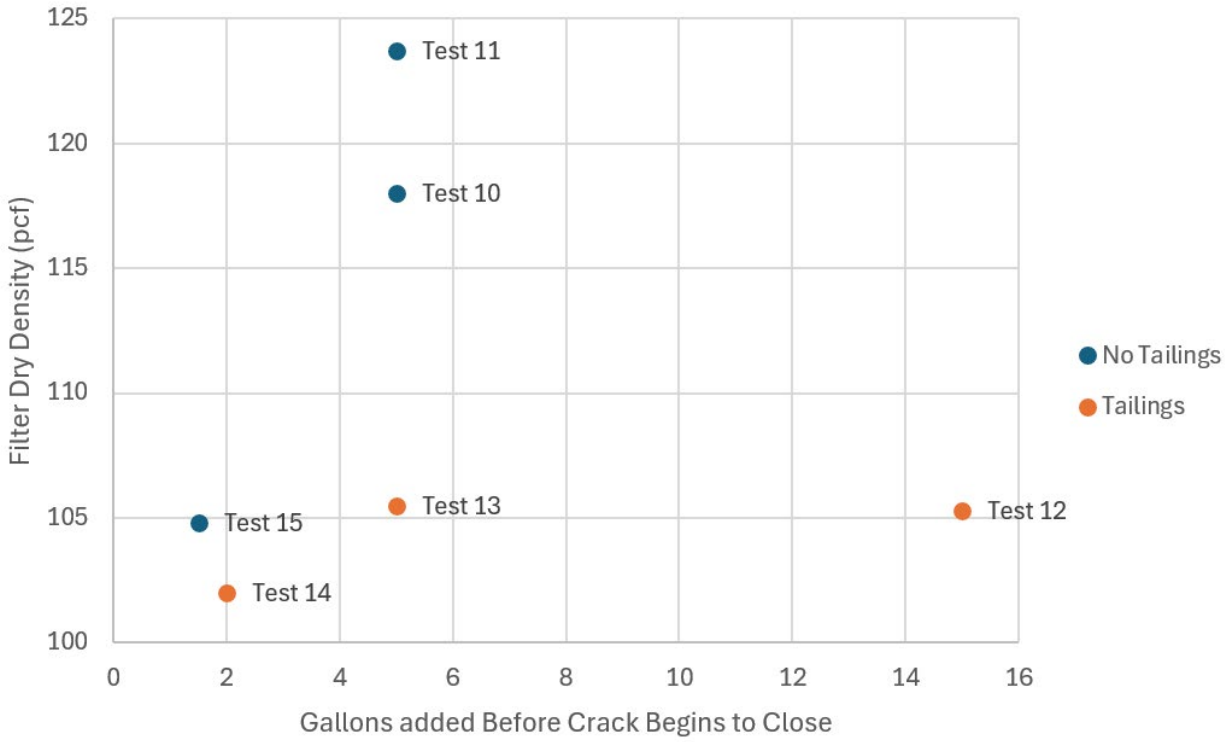

Figure 9: Summary of results from Tests 10 through 15

Table 1: Large-scale filter erodibility testing summary

Test No	Compaction Method	Depth of Tailings Placed (in)	Steel Plate Size	Water Application Rate	Water Applied Before Crack Starts to Close (gal)	Filter Dry Density (pcf)	Notes
10	2 passes vibratory compaction	0	1'x2'x¼'	15 gal/2 min	5	118.0	Crack visible at surface when plate removed. First 5 gallons flowed into crack and then began to pond at the surface. Ponding slowly dissipated into the crack area. Crack location visible in excavation down to Select Rock, but not open; had "healed" filter material.
11	8 passes vibratory compaction	0	1'x2'x¼'	15 gal/2 min	5	123.7	Crack visible at surface when plate removed, with some surface disturbance as filter material stuck to plate. First 5 gallons flowed into crack and then began to pond at the surface. Ponding slowly dissipated into the crack area. Visible surface settlement at crack location. Crack visible but mostly self-healed with filter material.
15	Surface tamped with backhoe	0	1'x2'x¼'	15 gal/2.5 min	1.5	104.8	Water flowed into crack freely for several seconds until edge of filter broke/caved off and started to plug filter. Additional 2.5 gallons of water added; minor seepage preference to crack, but flow backed up quickly. Line of crack clearly visible, minor voids present between bridging locations, small amount of paint down to surface of Select Rock.
12	Surface tamped with backhoe	6	2'x3'x¼'	35 gal/10 min	15	105.3	Underflow sand removed around plate prior to removal to prevent collapse. Crack visible when plate was removed. 15 gallons flowed into crack before it began to close. After 30 gallons, layer of fine-grained underflow sand formed covering the crack. Orange paint observed at Select Rock contact and crack self-healed and partially filled with tailings.
13	Surface tamped with backhoe	6	1'x2'x¼'	15 gal/5.5 min	5	105.5	Underflow sand removed around plate prior to removal to prevent collapse. Crack visible when plate was removed. 1-2 gallons flowed into crack before it began to pond. Orange paint observed at Select Rock contact and crack self-healed and partially filled with underflow where inflow was observed.
14	Surface tamped with backhoe	6	2'x3'x¼'	15 gal/8 min	2	102.0	Underflow sand removed around plate prior to removal to prevent collapse. Crack visible when plate was removed. 1 to 2 gallons flowed into crack before it began to pond. Crack self-healed minor infilling of underflow where inflow was observed.

Conclusion

This paper presented a large-scale field-testing procedure to evaluate the self-healing potential of filter material potentially susceptible to cracking due to relatively high fines content under various compactive efforts. AECOM and FMBI developed the testing program because a standardized method for filter erodibility testing was not identified in the literature. The procedure was useful in evaluating the self-healing potential of the proposed filter and optimizing placement requirements. By documenting and sharing our program, it is hoped that this procedure can be further refined and used as a starting point for other projects. The large-scale testing procedure evolved during the field trial and the key takeaways we wish to highlight are listed below.

- Filter material should be moistened to minimize absorption of water during the test prior to removing the steel plate.
- Surficial painting of the crack provides an insightful method to track water progression and self-healing.
- Detailed documentation of compacted filter density, applied water, and post-test excavation photographs were critical to assessing and interpreting test results.
- Water application during the test should be performed in a controlled and repeatable manner.
- Filter density versus volume of water required to self-heal (as inferred from ponding at the surface) was a useful metric for comparing tests.

The results of the case study highlight the following conclusions.

- The primary function of the filter zone at the Upper Mammoth TSF was to provide separation and filter compatibility between the rockfill and the whole tailings to prevent erosion, piping, and sinkholes. The permeability of the materials was not a driving factor because of the arid climate of the site and because the reclaim pond was to be managed thousands of feet from the upstream crest of the UMSD, creating seepage gradients lower than those at most water-retaining structures. Therefore, materials with higher fines content than typical filters can be considered for use as filter, provided the proposed materials meet the compatibility requirements for no erosion, demonstrate self-healing behavior, and provided that geotechnical seepage and stability impacts are minimized.
- Large-scale tests demonstrate that filter placement with minimal compactive effort resulted in the fastest self-healing. This finding was incorporated into the updated project specifications.
- Filter material with higher plasticity was observed to self-heal more slowly than filter material with lower plasticity. This finding was incorporated into the updated project specifications.

- The results of this case study were used by FMBI to optimize the design and operational life-cycle stages of a UMSD filter zone at the Upper Mammoth TSF. The proposed filter material was used for construction of the UMSD filter zone after appropriate modifications to the design, project specifications, and monitoring requirements. These changes resulted in reductions in construction costs and the environmental impacts associated with producing typical filter materials.

Abstract

Introducing vibration energy to tailings often induces liquefaction (release of water) and/or a thixotropic response (shear thinning). Performing filtration simultaneously delivers game-changing filtration performance.

This is the basis of Viper, the vibration-enhanced vacuum belt filtration technology that continuously produces filtered tailings with desirable moisture content at high production rates. This paper introduces the technology and shares case study data from various projects around the world, including pilot plant and industrial equipment – answering the question "how much difference can vibration make?"

The conclusion contemplates the resultant filtration plant, explaining how Viper unlocks a step change reduction in cost and complexity as well as delivering operational and maintenance advantages relative to competing technologies. It is for these reasons that Viper is enjoying interest, investigation, and implementation from a number of the world's leading mining and minerals organizations.

Introduction

Awareness, investigation and implementation of Viper filtration technology continues to grow, fueled by the enduring demand for technology for large-scale tailings filtration and encouraged by significant investments by modern miners.

Viper is a differentiated technology, leveraging vibration and vacuum for superior dewatering performance, while also facilitating a step-change simplification of the operational and maintenance requirements (relative to currently available technology). The game-changing technology is being operated and maintained at throughputs up to and exceeding 50,000 tpd, with future applications above 100,000 tpd currently under investigation.

This paper explains the fundamentals of the technology and provides relevant examples of successful application at various stages of project lifecycle, before closing with the value proposition of overcoming the cost and scalability deterrents inherent to filtered tailings.

Seven years since the 2017 report commissioned by the Mine Environment Neutral Drainage (MEND) Project Secretariat Study of Tailings Management Technologies identified that "cost and scalability of filtered tailings is one of the deterrents for mining companies," most other major filtration equipment companies continue to develop incremental improvements to existing technology. This approach may not deliver the step-change required.

Viper technology

Introducing vibration energy to tailings often induces liquefaction (release of water) and/or a thixotropic response (shear thinning). Performing filtration simultaneously delivers game-changing filtration performance.

This is the basis of Viper, the vibration-enhanced vacuum belt filtration technology which continuously produces filtered tailings with desirable moisture content at high production rates. A process description summary is included as an appendix.

The 3D model screenshot in Figure 1 illustrates a Viper vacuum belt filter. Note the green Viper modules; these are the additions to the Jord OEM conventional vacuum belt filter.

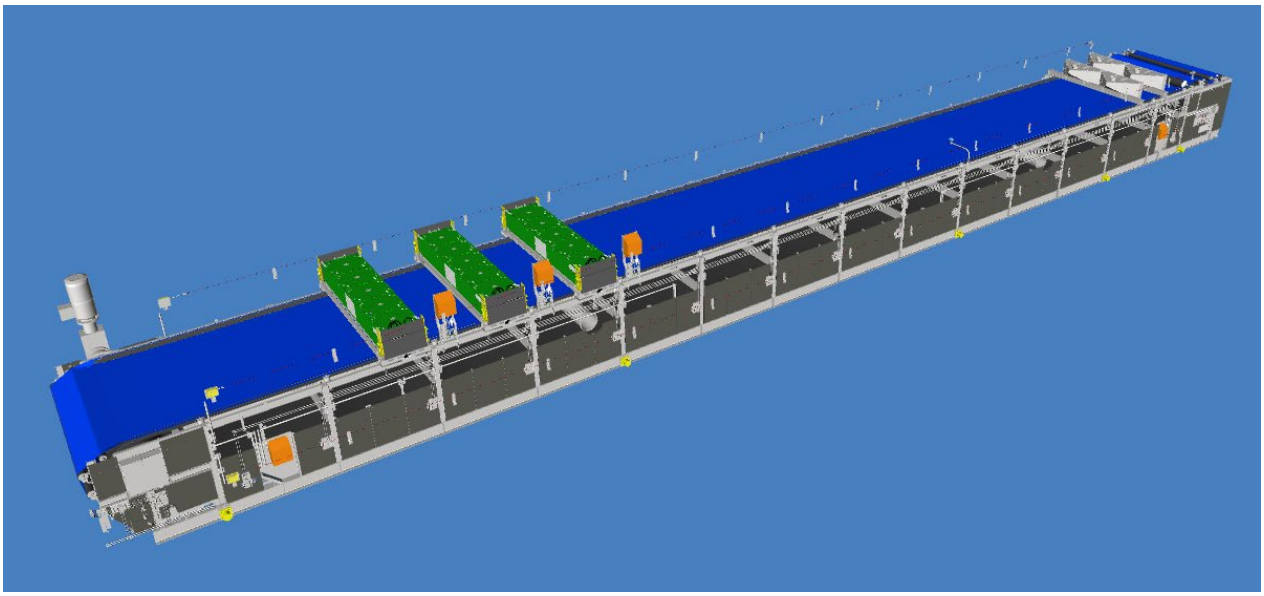

Figure 1: Viper vacuum belt filter

Critically, despite the addition of Viper modules, all fundamentals of vacuum belt filter plant design, operational and maintenance practices, which are generally well understood by the mining industry, remain valid. These include:

- Continuous process.
- Robust and reliable with high equipment availability.
- Simple, scalable technology with more than 30 years of operational history in the industry.
- Operates with a single filter cloth with typical lifetime 6 months.
- No operator intervention for cake discharge.
- Cake (from one or multiple filters) can be discharged directly to overland conveyor.
- Minimized civil and structural costs, often installed low to the ground and outside without cover (climate permitting).
- Low supporting infrastructure costs and complexity.

In many cases, including case one and case two below, the overall Viper solution is providing such an exceptional value proposition that it was selected over alternative, conventional filtration solutions despite the early stage of technology maturity at the time.

Full-scale operational plants

Figure 2: Viper technology in operation

Although Viper is a relatively young technology, numerous references exist in both the Americas and in Australia. Three of these applications are discussed below.

In combination, an industry significant, large-scale operation, at 60,000 tpd capacity (see case one), numerous gold tailings applications, including one with fine grind (see case two) and one at 4,000 masl elevation (see case three), provide compelling evidence to demonstrate industry confidence and the proven ability to unlock filtered tailings by applying the Viper technology to their process.

Future customers are in the enviable position of being "first to be second."

Case one

Through 2024, operational ramp up continues on the 60,000 tpd Viper vacuum belt filter plant in Western Australia for fine magnetite concentrate. This plant, complete with eight (8) 158m^2 filters is shown in Figure 3. The process plant produces 20 million tonnes per annum of concentrate via a proprietary process flow sheet. The process plant produces 100% of its production as slurry concentrate which is filtered below the transportable moisture limit (TML) of approximately 10%w/w.

Figure 3: 60,000 tpd Viper vacuum belt filter plant during ramp-up

Case two

In 2017, a conventional vacuum belt filter was installed to wash (i.e., remove cyanide) and filter deslimed tailings from a conventional carbon-in-pulp (CIP) processing plant. Subsequently, the tailings specification was changed which eliminated the desliming process and sent full-stream tailings (with a finer particle size distribution (PSD) of solids) to the filter, which could not be effectively dewatered at the required rate from the existing vacuum belt filter.

A paper was published in *Proceedings of Tailings and Mine Waste 2020,* "Enhancing vacuum belt filter dewatering to adapt to finer tailings grind – a case study" (Whatnall et al., 2020). This paper indicated the suitability of Viper in this application. The following year, the first full-scale commercial Viper system was commissioned filtering the full stream tailings.

Figure 4 compares the performance (production rate and cake moisture) of the conventional vacuum belt filter with the performance of the Viper vacuum belt filter over a 48-hour period during commissioning in August 2021. When operating with the Viper vacuum belt filter, the cake moisture is approximately 4 points lower and the throughput rate is increased by 35%.

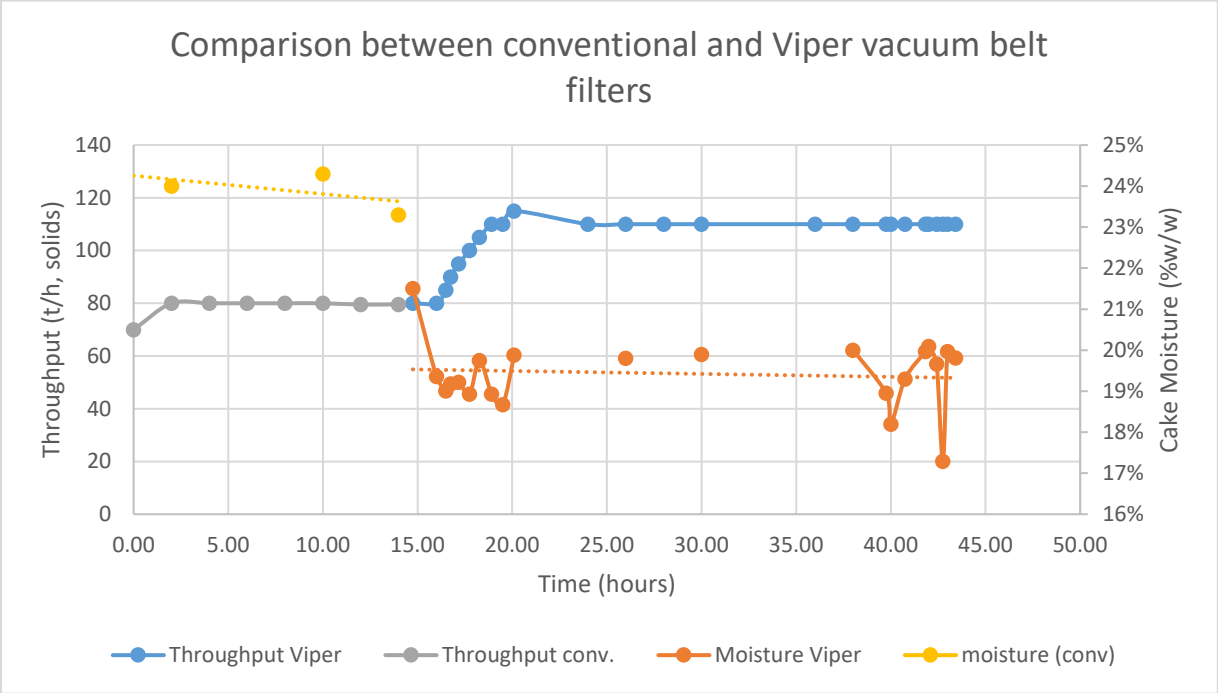

Figure 4: Comparison between conventional and Viper vacuum belt filters

Over the subsequent twelve months through 2022, a summary of weekly metallurgist notes confirm production priorities changed to preference throughput over final moisture resulting in:

- Throughput rates of 110–130 tph.
- Cake moisture content of 20–21% w/w.

Case three

One of the early adopters of filtered tailings in the 1990's, at an altitude of 4,000 masl, a Chilean precious metal miner operates a Meryl Crowe process plant with a fleet of vacuum belt filters for tailings.

This site has maintained interest in Viper technology for many years, and in 2022 engaged in a test work program to investigate the opportunity is to reduce cake moisture and increase production rate from their existing tailings belts filters by retrofitting them with Viper and reduce (or eliminate) the bottleneck for production when processing future tailings.

Work published by (2023) provided a summary of results. Fast-forward to Q1 2024, and Viper equipment has been retrofitted on one of their vacuum belt filters. See Figure 5 below, which is a snapshot taken during initial operation.

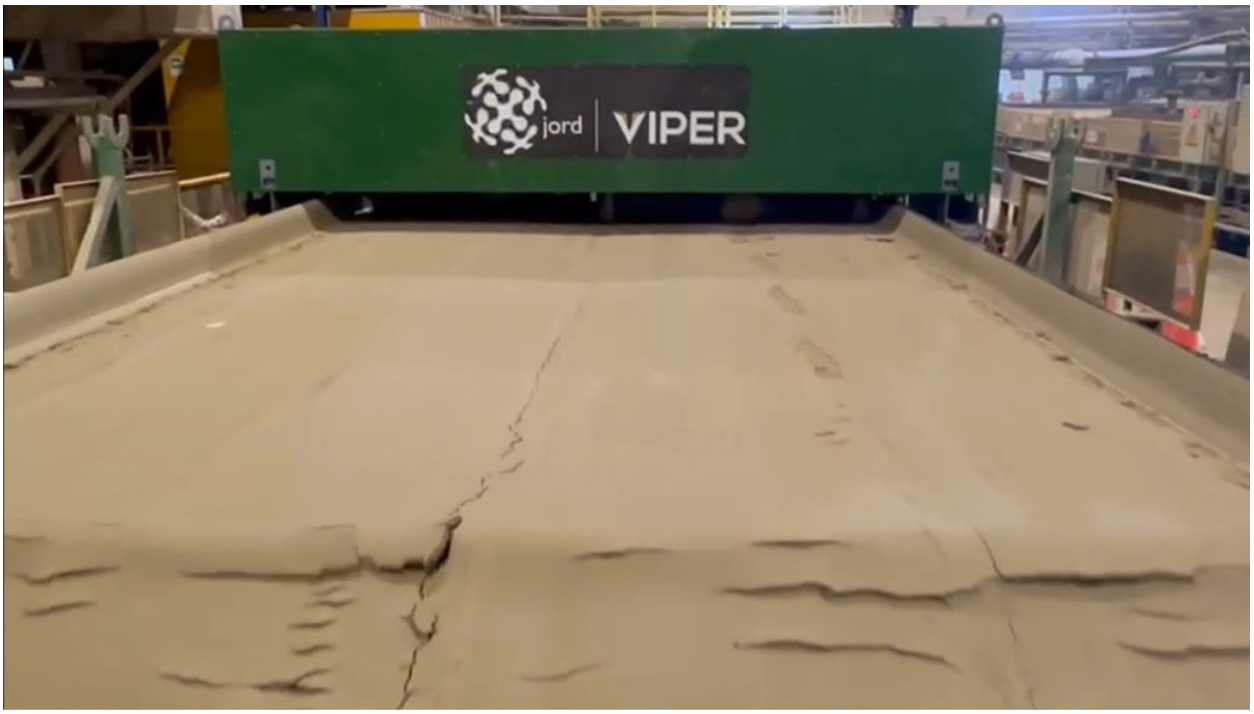

Figure 5: Initial operation of Viper retrofit

Initial results have been encouraging, with a typical moisture reduction, compared to no Viper, of ~1 point when operating one Viper module and 3-5 points when operating two Viper modules in series. Refer Figure 6 below. Work is continuing to optimize the equipment and the process to best meet the needs of the process plant going forward, including to deliver throughput increase in addition to lower cake moisture.

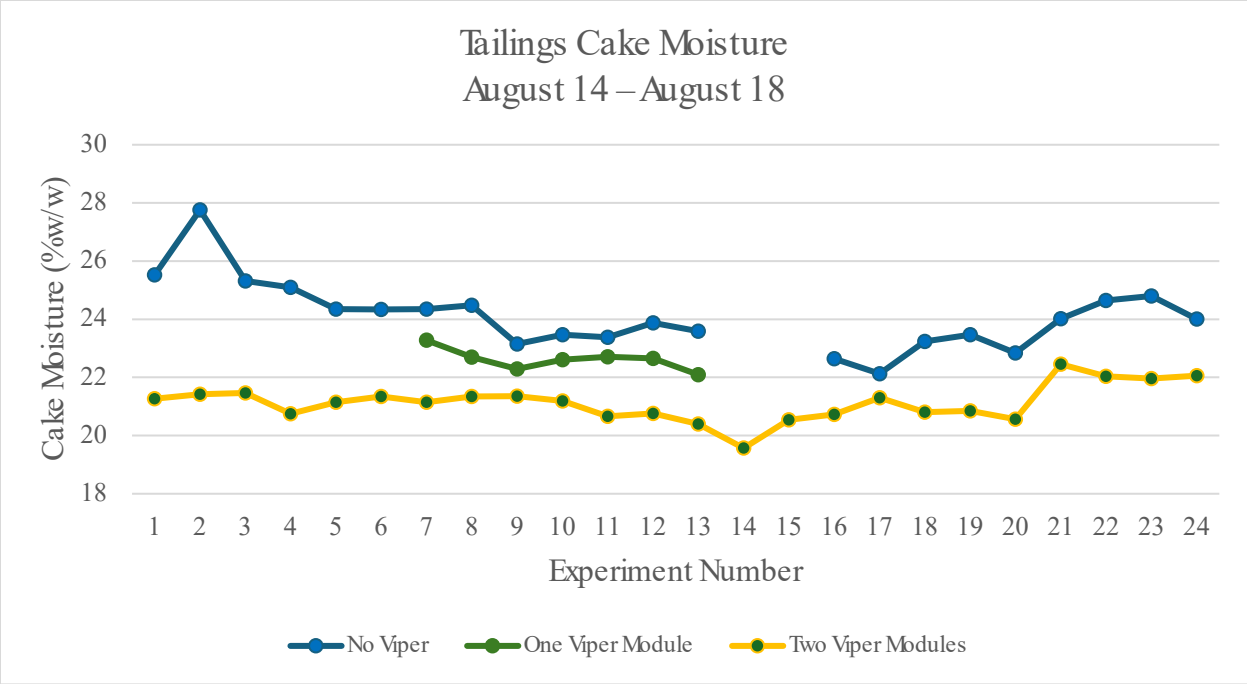

Figure 6: Comparison of cake moisture between Viper and no-Viper operation

Viper investigation examples

The past 12 months have seen significant interest and investigation of Viper technology from operations and projects.

Two further cases are summarized below to provide some examples of the opportunities and potential applications. The cases presented have contracted the supply of pilot Viper equipment to support project design and performance guarantees.

Case four

A large multinational company with operating iron ore mines in Brazil, commissioned test work to determine whether the addition of vibration would make vacuum filtration feasible for their fine iron ore tailings materials. The opportunity is to unlock a cost-effective, manageable filtration plant that would allow their strategic goal for filtered tailings to be realized.

The results from the work were encouraging, indicating that the addition of vibration to the filtration process resulted in acceptable cake moisture (~14%w/w), triggering preparation of a concept plant design (to verify the value proposition) then an agreement to mobilize our pilot plant to the site location for a campaign expected in late 2024.

This project is a useful example of a typical project cycle, investigation with bench test work, concept study then pilot plant campaign. If warranted by results and the project, typical next steps include feasibility study, commencement engineering then project execution with detailed design and equipment/plant supply.

Case five

This case study focusses on the pilot campaign conducted at site, an opportunity in the USA for filtering phosphogypsum slurry, a tailing from fertilizer production.

The pilot plant includes the vacuum belt filter with vibration rollers, filtrate receivers, filtrate pumps, vacuum pump and ancillary equipment, such as the belt conveyors. See Figure 10 for an overview of the equipment arrangement.

The vacuum belt filter has a filtration area of up to 17ft^2 (15" wide × 157" long), the effective length can be reduced if required to reduce the capacity of the system. Installed on to the vacuum belt filter are up to four vibration roller assemblies. The overall system was designed and operated at a throughput rate approximately 1 tph solids.

The objective of the pilot campaign was twofold. Firstly, to generate a large stockpile of filtered cake to verify the materials handling characteristics of the produced and secondly to verify the process performance of the Viper filter to allow detailed design and for the purposes of performance guarantees.

Initially work focused on the production of a large stockpile of filter cake, the target was a 10′ high stack. Figure 7 shows the initial production to allow the increase in the angle of the discharge conveyor, Figure 8 shows the resultant 10′ high stockpile.

Figure 7: Stockpile generation

Figure 8: 10' high filter cake stockpile

Once the stockpile was complete, the filter cake was removed for materials handling testing and analysis (by others). The focus was shifted to process performance of the filtration. The key outcomes from the testing were:

- Vibration helps produce lower cake moisture, the more vibration iterations, the lower the cake moisture.
    - No vibration = moisture 35+% w/w.
    - 4 vibration rollers = moisture typically 26-27%w/w as low as 25%w/w.
    - 3 vibration rollers = moisture 27-29%w/w.
    - 2 vibration rollers = moisture ~30% w/w.
    - 1 vibration roller = moisture >30% w/w.
- Thinner cake helps produce lower cake moisture.
    - ½" cakes = moisture ~26% w/w.
    - 5/8" cakes = moisture ~27% w/w.
    - 5/8" – ¾" cakes = moisture ~28% w/w.
    - ¾" – 1" cakes, no data.
    - 1" or thicker cakes = moisture ≥ 30% w/w.
- Consistency of sampling is critical for reliable data. As per Figure 9, the stockpile was visibly "steaming," it was necessary to attempt to quantify the impact for a given time period of

atmospheric exposure. Zero minutes (i.e., immediate sealing) and 10 minutes atmospheric exposure were chosen, and the summarized data is presented below.

- Cool evening (30°F), no wind = average 1.7 points moisture reduction.
- Midafternoon (50°F), no wind = average 1.9 points moisture reduction.
- Midafternoon (50°F), wind ~10 mph = average 2.6 points moisture reduction.

Figure 9: "Steaming" stockpile

At the time of publishing, work is continuing to document and analyze the generated data to meet the objectives of the pilot plant campaign.

State of practice

Supported by the growth and projected demand for the Viper technology, additional resources have been established in strategic locations to provide support from project identification, project development and delivery through to aftermarket.

Critical to the uptake of the Viper technology is the opportunity to test and demonstrate the performance and operability of the technology. To this end, various options are available for consideration:

- Laboratory-scale testing, providing qualitative process performance results. This requires a relatively small sample size and facilitates a rapid assessment of the suitability for a given application.
- Pilot-scale testing (see container mounted equipment in Figure 10), providing quantitative process performance results and exposure to technology operability and maintenance. Pilot-scale testing requires larger sample size, in the order of 5-20 tpd (instantaneous rate).

- Demonstration-scale testing, a single-train full-scale Viper vacuum belt filter system (see Figure 11) providing industrial-scale performance results and operation and maintenance experience. Production rate in the order of 5,000 to 10,000 tpd for one individual filter.

Figure 10: Viper pilot plant

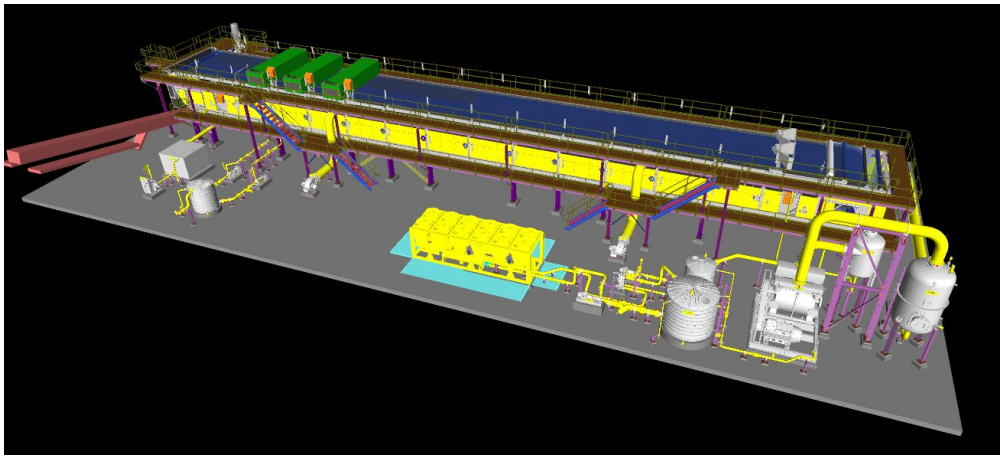

Figure 11: Viper demonstration plant

For Viper retrofit scenarios (i.e. existing conventional vacuum belt filter plants), a fourth option is leasing full-scale Viper modules to be installed onto the existing equipment providing a fast, cost-effective path to determine performance prior to roll out across the entire plant. A range of hire equipment is readily available to suit standard conventional belt filter sizes or site-specific equipment can be provided on this basis.

Conclusion

This paper explores Viper as a desirable technology solution to overcome the well-known cost and scalability challenges of tailings filtration.

The Viper technology enhances filtration performance through the addition of vibration to the process of conventional vacuum belt filtration. Critically, the addition of Viper modules changes none of the fundamentals of vacuum belt filter plant design, operational and maintenance practices, which are generally well understood by the mining industry remain valid.

In 2021, the first full-scale commercial Viper system was commissioned on tailings and shortly afterwards a 60,000 tpd Viper filtration plant was commissioned. Uptake and investigation are growing, supported by a range of testing capabilities. This includes both bench, pilot and demonstration plant options. The project cycle from investigation through study, design, delivery, installation, commissioning and on-going aftermarket services is supported by relevant technical experts.

Appendix

Viper vacuum belt filter process description

Viper vacuum belt filters are continuous production machines, often numerous machines are operated in parallel, however, single filter operations are common.

Slurry is fed into the feed pipe manifold at low pressure suitable for an open pipe discharge. The feed pipe manifold distributes the slurry evenly to each of the feed slurry inlets of the feed box located at the tail end of the belt filter. The feed box distributes the feed slurry evenly across the width of the moving filter cloth.

The filter cloth is the filter media, it is supported on the rubber carrier belt. The carrier belt has recessed grooves cut into it, across its width, and holes along its centerline. Under the holes, the carrier belt passes across the vacuum box. The water/liquor in the feed slurry is drawn by vacuum through the solids and the filter cloth as filtrate. The filtrate is channeled along the carrier belt drainage grooves and through the filtrate holes into the vacuum box. Air from atmosphere is also drawn via the vacuum through the filter cake and follows the same path as the filtrate into the vacuum box. Filtrate and air are drawn from the vacuum box via filtrate hoses to the filtrate manifold to the terminal point. Piping connects the filtrate manifold to the filtrate receiver which is ultimately connected to a vacuum pump creating vacuum in the system. Once the filtrate enters the filtrate receiver, the liquid is separated from the air flow and falls to the bottom of the receiver where it is pumped away via a filtrate pump.

The carrier belt is supported on cushions of air above perforated air tables each side of the vacuum box. A high volume blower fan supplies air which is ducted to the underside of the air tables.

Sealing the stationary vacuum box against the moving carrier belt are two wear belts traveling in recessed channels of guide plates which straddle the open top of the vacuum box. Clean water is supplied to the wear belt, guide plate, carrier belt interface to cool, lubricate and provide a vacuum seal.

The drive motor and gearbox turn the filter's head pulley which drives the carrier belt. The speed of the carrier belt can be adjusted via a VSD to suit the filter feed rate and optimize the filter cake thickness. Cake thickness can be automatically controlled by varying the belt speed with reference to radar cake thickness monitors installed on the filter.

The carrier belt, filter cloth and filter cake move together from the tail end towards the head end of the filter.

Viper modules are installed at one or more locations along the top of the belt filter. Each Viper module consists of two vibrating roller assemblies (cartridges) housed within an enclosure. When engaged, both cartridges lower a roller down into the filter cake passing below. Vibration passes from the roller into the cake enhancing the dewatering performance. The roller is driven by the cake with adhesion reduced through use of low surface energy materials and high vibration frequencies.

Vibration speed is VSD controlled to optimize process and mechanical performance. Vibration amplitude can be changed by manual adjustment of the internal exciter mechanism, typically done during commissioning.

The weight of Viper cartridges on the filter cake is controlled by a "Preload System." The preload system uses a pressure control valve to inflate rubber air bellows which lift the roller. Preload is controlled by a radar level sensor directly in front of each roller. If the roller sinks into the filter cake pressure is increased. If the roller floats over the cake pressure is reduced.

Each Viper is also equipped with a set of lift bellows which raise and lower the entire module. When turned on the bellows lower the Viper on to the belt filter. When turned off the bellows lift the Viper away from the filter.

Following the last Viper, the carrier belt, filter cloth and filter cake continue down the belt filter. At the discharge end the carrier belt turns down around the head pulley while the filter cloth and filter cake travel forward over a final cake cracking roller. Finaly the cloth turns down dropping the broken cake into the discharge chute.

The carrier belt and filter cloth, now on the return side of the filter, pass through a series of spray bars which clean the cloth from both sides and remove any solids from the grooves of the carrier belt. The returning wash water, including solids, is collected in the wash return hopper and discharged.

The clean filter cloth and carrier belt are supported by separate rubber lined return rollers as they return to the tail end of the filter. A tension roller rests on top of the cloth using gravity to maintain the correct tension. If the tension roller drops too low, indicating a loose cloth, a proximity sensor will alert the operator. Cloth tracking is maintained by a pair of pneumatic valves actuated by the edge of the filter cloth. These valves control the angle of the pneumatically driven cloth tracking roller which steers the cloth back to center. Should the carrier belt or the filter cloth track outside allowable limits drift switches at the head and tail of the filter trigger and the filter is stopped to prevent damage.

Once at the tail the cloth is directed up to the top of the filter, under a bowed roller to reduce creasing, and over an idler roller, before rejoining the carrier belt under the dam roller in preparation for feed slurry.

Characterizing Creep Behavior of a Fine-grained Zinc Pressure Leach Tailings

Jade Chung, BGC Engineering Inc., Canada
Adrian Wightman, BGC Engineering Inc., Canada
Stephanie Alexander, Hudbay Minerals Inc., Canada

Abstract

The settlement of mineral tailings is commonly represented with only primary consolidation, as this mechanism is typically considered responsible for most of the decrease in thickness of the tailings deposit. However, materials containing certain hydrated minerals additionally undergo large vertical strains due to secondary compression (creep). The total decrease in thickness caused by creep over the lifespan of some material deposits can be greater than the decrease in thickness resulting from primary consolidation, as evidenced in case history reviews by various authors (Singh and Mitchell, 1968; Mesri, 2003).

In this study, the creep behavior of Zinc Pressure Leach (ZPL) tailings was assessed, using site survey data and results from laboratory testing. Survey data of the tailings beach surface and the upstream-constructed dam surface showed greater rates of settlement continuing over longer time periods than typical for silt-sized mineral tailings particles. Results of laboratory creep testing of the tailings material were consistent with the site survey data and showed elevated rates of vertical deformation beyond the interpreted end of primary consolidation.

Various theoretical, semi-empirical, and empirical models were considered and compared to assess their suitability to represent the consolidation and compression of the ZPL tailings. The outcome of this study was the selection of a combination of semi-empirical (Bjerrum, 1967; Garlanger, 1972) and empirical (Singh and Mitchell, 1969) methods as the basis for analysis of the ZPL tailings compression observed to date and the estimation of settlements projected to occur in the future. The concepts of sets of parallel compression curves (Bjerrum, 1967) and estimation of quasi-preconsolidation stress (Garlanger, 1972) formed the theoretical framework for differentiating the effect of consolidation from the effect of creep. The power law representation of creep strain rates (Singh and Mitchell, 1969) was used to support the analysis of available test data and for comparison to observed in-situ settlements.

Introduction

Zinc Pressure Leach (ZPL) tailings are the residue from a method of processing a finely ground zinc concentrate with sulfuric acid and oxygen in a pressurized multi-compartment autoclave. In this process, iron sulfate, gypsum, jarosite, elemental sulfur, and other precipitates are generated as the residue and the zinc sulfate solution is processed further to recover the economic and precious metals. A result of the ZPL process is that the residue, mixed with water, transported, and placed in the tailings facility.

During zinc processing and active deposition at the ZPL Tailings Facility mine personnel were typically present to observe and monitor the effects of compression of the ZPL tailings over time, such as: development of cracks at the surface of upstream constructed dams, decreased freeboard, or formation of depressions in the ZPL tailings surface. However, active deposition in the facility ended in 2022, and the facility is transitioning to care and maintenance and closure phases. Hudbay Minerals Inc (Hudbay) is intending to develop plans with reduced monitoring effort and progress toward post-closure landforms. Closure options being considered include the placement of cover materials and the effects of this additional load and the long-term compression of ZPL tailings is the premise for this study.

Background

Tailings deposit and facility description

Deposition of ZPL tailings into the ZPLTF commenced in 1992. The ZPL tailings were transported as a slurry of tailings solids and water via a 300 mm (12") diameter pipeline, exiting through a single point outlet at the ZPLTF, the position of which has varied throughout active deposition (1992 to 2022). The ZPL tailings are contained by a series of four perimeter dams (Figure 1): West, North, and East ZPL Dams, which have been incrementally raised in a combination of centerline and upstream configurations over the years; and the South ZPL Dam, which has been raised incrementally in centerline and downstream configurations.

Figure 1: Aerial photograph of ZPL tailings facility in 2022

ZPL tailings description

The ZPL tailings have generally been described as laminated, orangish red, nonplastic silt with trace sand, soft, moist to wet and with a metallic odor. Particles of ZPL tailings have been observed to form very thin, elongated, needle-shaped agglomerations, visible to the naked eye.

The approximate in-pipe gravimetric water content of the ZPL tailings slurry was estimated as 360%, based on volumetric water to solids ratio of 10:1 (as reported by the operator), with an average specific gravity of solids of 2.77. The water content of ZPL tailings samples recovered from ZPL tailings deposits underlying the dam fills ranged from 20% to 70%. The general trend of the water content data was decreasing water content with decreasing elevation (see Figure 2a).

The particle size distribution of ZPL tailings samples typically comprised 100% fines (<0.075 mm), 92% to 95% being silt-sized particles and 5% to 8% being clay-sized particles (Figure 2b). In accordance with the ASTM 4318-17 standard for Atterberg limits testing, the ZPL tailings samples were reported to be "nonplastic." The ZPL tailings samples were classified using the USCS as "Silt," with USCS symbol "ML."

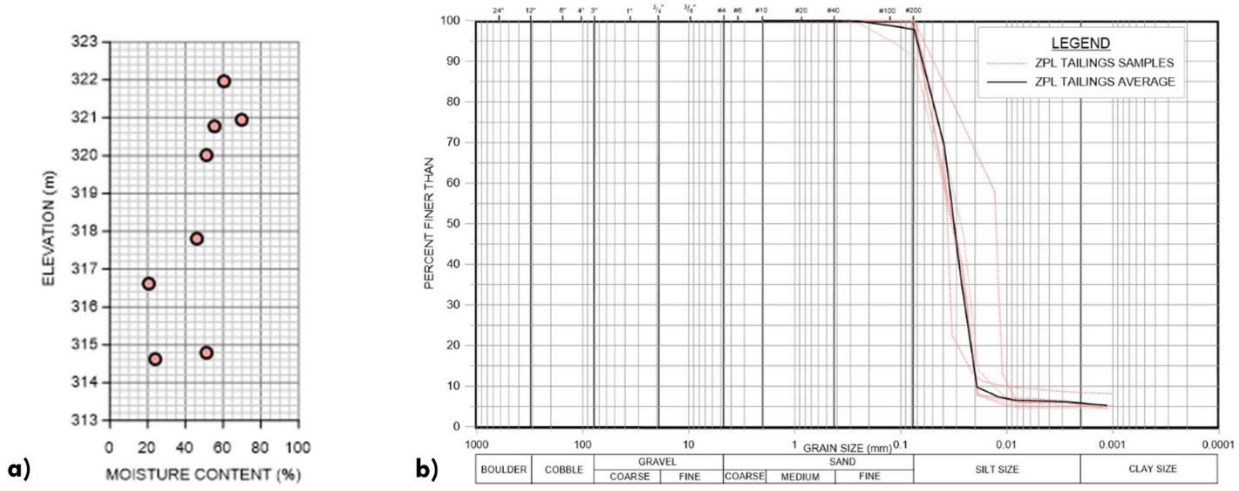

Figure 2: Results of laboratory tests on ZPL tailings samples (a) water content, (b) particle size distribution

The specific gravity of three samples of ZPL tailings solids were tested using the water pycnometer method (ASTM D854-14). The specific gravity of the ZPL tailings samples ranged from 2.6 to 2.9, with an average value of 2.8. The unit weights were assigned based on the measured mass of a known volume of ZPL tailings, which were recovered in thin-walled (Shelby) tubes using fixed piston samplers in conjunction with mud rotary drilling using side-discharge tricone bits. The assigned unit weights of ZPL tailings were as follows:

a. The saturated unit weight was 17.6 kN/m^3.
b. The dry unit weight was 11.4 kN/m^3.

c. The moist unit weight was calculated as 14.5 kN/m^3.

Trace minerals, trace metals, X-ray diffraction, and scanning electron microscopy tests were completed by SGS Canada (Lakefield) on two representative samples of ZPL tailings. The results of the tests indicated that the samples comprised primarily iron sulfates (50% to 55%), gypsum (20% to 30%) and iron oxides (10% to 25%). Gypsum is a hydrated calcium sulfate (CaSO4•2H2O) mineral, that is soluble in water and subject to rheological (flow) behavior that is time, stress, and humidity dependent.

Compression mechanisms in fine grained soil

The decrease in thickness (compression) of a fine-grained mineral soil is conventionally described as resulting from two mechanisms occurring sequentially: primary consolidation, followed by creep. Primary consolidation is the decrease in volume of the fine-grained soil as the excess pore pressures are dissipating, and the effective stress (load exerted on the particle to particle contact area) is increasing. Creep[1] describes the decrease in volume at a constant (macro-scale) effective stress (constant applied load), after excess pore pressures have dissipated.

Primary consolidation

The magnitude of volume decrease occurring in primary consolidation is a function of the magnitude of the stress increase relative to the initial effective stress and the greatest effective stress to which the soil had previously been subjected (preconsolidation stress). The relationship between effective stress and volume decrease of a given material is represented with two parameters:

1. The compression index (C_c) relating the volume (represented as void ratio) decrease to effective stresses exceeding the preconsolidation stress (p_c).
2. The recompression index (C_r) relating the volume decrease (void ratio) to effective stresses exceeding the initial effective stress, yet less than the preconsolidation stress.

The C_c and C_r can be interpreted from laboratory consolidation testing of either remolded/reconstituted samples or intact samples (Schmertmann, 1953). The typical laboratory consolidation test used to define these parameters is one-dimensional loading of the sample in an oedometer, either by:

1. Maintaining a constant rate of strain, by increasing the vertical load at whatever rate is necessary and continuously monitoring/recording the applied load and vertical displacement.
2. Incremental loading, with the duration of each load increment continued until the end of primary consolidation.

[1] Note that the terminology to describe the decrease in volume of a material deposit at a constant applied load or constant macro-scale effective stress is inconsistent in the available references. This behavior has also been referred to as “delayed consolidation,” “secondary consolidation,” “secondary compression,” and “solidification.”

The amount of time required for completion of primary consolidation (dissipation of excess pore pressures) is dependent on the permeability of the fine-grained material, the thickness of the material, and the drainage conditions. The completion of primary consolidation for each load increment in a laboratory consolidation test is interpreted using the logarithm of time method (Casagrande and Fadum, 1940), or the square root of time method (Taylor, 1942). From the assessment of time required for completion of primary consolidation for a given increase in effective stress, the coefficient of consolidation (c_v) can be assessed.

Secondary compression (creep)

The time-dependent decrease in volume of a material that occurs under constant applied load (creep) remains inconsistently defined and variably characterized in industry applications and in peer-reviewed published works. Creep has been described as occurring under either drained or undrained conditions (Mitchell and Soga, 2005); it has also been described as occurring under constant effective stress (Bjerrum, 1967). In recent publications, common terminology describes creep as occurring under a constant applied load, with drainage and pore pressure conditions described on a case-by-case basis (increasing, decreasing, remaining constant, or negligible; Mitchell and Soga, 2005; Terzaghi et al., 1996), rather than integral to the definition of creep.

The mechanisms thought to be responsible for creep are numerous, and include both microscopic and macroscopic behaviors, such as the following:

1. Deformation due to structural viscosity (Terzaghi, 1941; Taylor, 1942; Bjerrum 1967; Fredlund and Rahardjo, 1993) and the water flow from micro-pores to macro-pores (Zeevart, 1986; Navarro and Alonso, 2001; Mitchell and Soga, 2005).
2. Sliding between soil particles (Grim, 1962; Gupta, 1964; Kuhn and Mitchell, 1993).
3. The breakdown of interparticle bonds (Taylor and Merchant, 1940; Terzaghi, 1941; Crooks et al., 1984; Mesri, 2003).
4. Deformation due to "jumping" of bonds/exceedance of activation energy (Mitchell et al., 1968; Kwok and Bolton, 2010).

A commonality between the above listed mechanisms is the co-involvement of water particles and mineral particles. It is the ongoing interaction between the water particles and mineral particles that permits continued volume change. Thus, minerals that contain "bound water" (hydrous materials), such as most clay minerals, gypsum, and some other micaceous minerals, are subject to much greater magnitudes of volume decrease than anhydrous minerals such as quartz.

Mathematical modeling of creep

Many mathematical models have been developed with the goal of quantifying the volume decrease associated with creep. Some of the more common mathematical models used to estimate the volumetric

change due to creep include:

1. Empirical
    a. Semilogarithmic relationship between void ratio (or strain) and logarithm of time (Mesri and Godlewski, 1977; Walker and Raymond, 1968; Yin, 1999).
    b. Power law relationship between strain rate, stress, and time (Singh and Mitchell, 1969; Ting, 1983).
2. Semi-empirical
    a. Semilogarithmic time-dependent compression (Bjerrum, 1967) and quasi-preconsolidation stress (Garlanger, 1972).
    b. Elastic-viscous-plastic logarithmic and power functions (Yin and Graham, 1994).
3. General Stress-Strain-Time/Elastic-viscoplastic Models
    a. Overstress Theory (Adachi et al., 1996; Desai and Zhang, 1987).
    b. Nonstationary flow models (Sekiguchi and Ohta, 1977; Nova, 1982; Matsui and Abe, 1985).

The selected basis for analysis of the ZPL tailings creep behavior is a combination of semi-empirical (Bjerrum, 1967; Garlanger, 1972) and empirical (Singh and Mitchell, 1969) methods. The concepts of sets of parallel compression curves (Bjerrum, 1967) and estimation of quasi-preconsolidation stress (Garlanger, 1972) formed the theoretical framework for differentiating consolidation and creep. The power law representation of creep strain rates (Singh and Mitchell, 1969) provided a mathematical model to interpret creep test data and estimate settlements.

Bjerrum (1967) describes the compression behaviors of clays (fine grained soils) that are subject to delayed or secondary consolidation (creep), as being represented by a system of approximately parallel lines on the void ratio vs. vertical stress (log scale) diagram (see Figure 3a), rather than by a single curve. Each of the lines represents the void ratio – vertical stress relationship for a given duration of sustained loading (Bjerrum, 1967). The load-deformation "path" of soil undergoing compression follows along one of these parallel curves as the effective load increases. When the effective stress stabilizes (constant) the load-deformation path progresses vertically between one compression curve to a parallel compression curve that is characteristic of the duration of the sustained load (Figure 3a). Garlanger (1972) expanded on this parallel compression curve concept, providing a conceptual framework and computational solution for the "quasi" preconsolidation stress, the analogous maximum effective stress with an equivalent effect on void ratio and future loading, resulting from the creep occurring under a sustained lower magnitude vertical effective stress (Figure 3b).

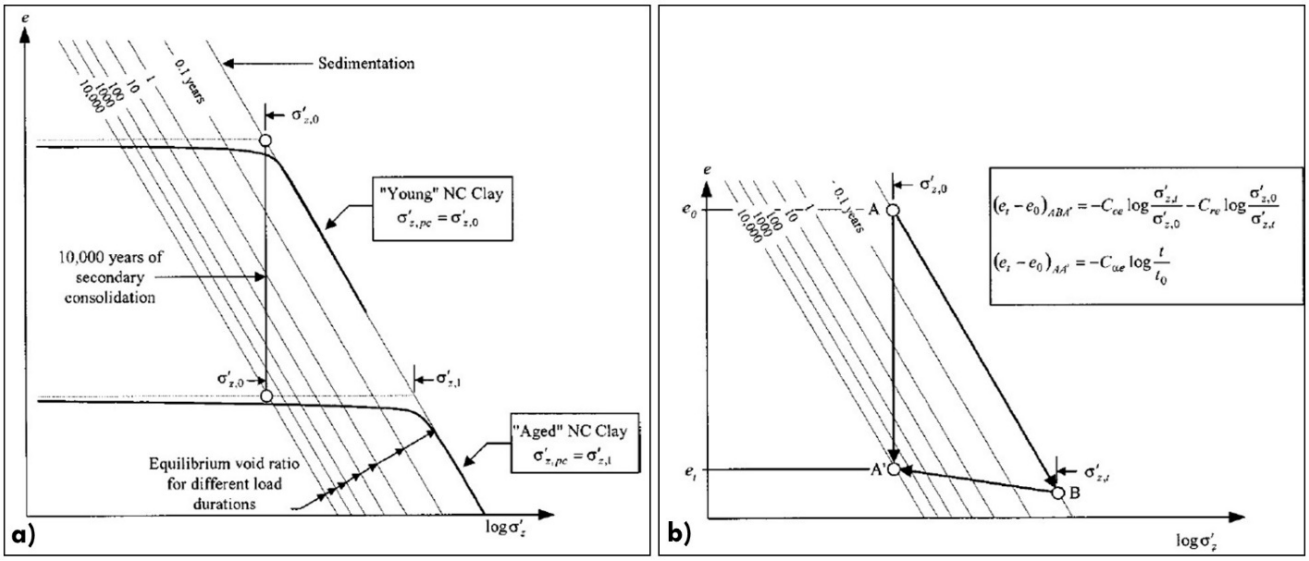

Figure 3: (a) Consolidation curves for loads of varying duration; (b) Quasi-preconsolidation stress resulting from creep (Liingaard et al., 2004, after Bjerrum, 1967)

Singh and Mitchell (1968) proposed a three-parameter power law relationship to represent the strain rate ($\dot{\varepsilon}$) as a function of the applied load (D) and elapsed time after application of load (t), for a selected unit of time (t1). The three parameters, unique to a given soil, being:

1. A = y-intercept of the linear trend of ln $\dot{\varepsilon}$ versus D plot (for unit time t1) (Figure 4a).
2. α = constant slope of the ln $\dot{\varepsilon}$ versus D plot, where all $\dot{\varepsilon}$ interpreted at same elapsed time (Figure 4a).
3. m = constant (negative) slope of the log ε̇ versus log time plot (Figure 4b).

The Singh and Mitchell (1968) strain rate function is shown in Equation 1. By integrating the Singh and Mitchell (1968) strain rate equation with respect to time, the strain accumulated from an initial time (t_0) to a subsequent elapsed time (t_f) is represented using Equation 2.

$$\dot{\varepsilon} = Ae^{\alpha D}\left(\frac{t_1}{t}\right)^m \quad \text{(Equation 1)}$$

$$\varepsilon = \int_{t_0}^{tf} Ae^{\alpha D}\left(\frac{t_1}{t}\right)^m = \frac{Ae^{\alpha D}}{(1-m)}\left[{t_f}^{(1-m)} - {t_0}^{(1-m)}\right] \quad \text{(Equation 2)}$$

Where $t_1 = 1$ (unit time)

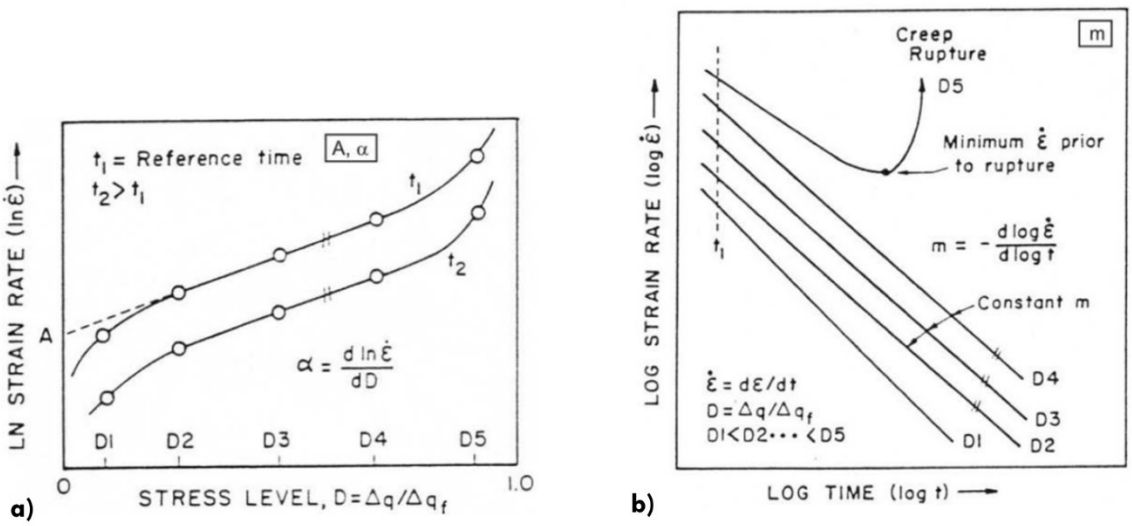

Figure 4: Singh and Mitchell (a) "A" and "α" parameters; (b) "m" parameter (Lacasse and Berre, 2005, after Mitchell, 1976)

Methodology

The compression of the ZPL tailings in-situ, and the resulting effects on tailings surface elevation and dam fill settlement, are controlled by the mechanical behaviors of the ZPL tailings varying with load and duration under a given load. The primary consolidation and secondary compression parameters of ZPL tailings were interpreted from the results of 1D (oedometer) consolidation tests completed at the BGC Advanced Laboratory in Fredericton, NB, Canada, as described in the following sections.

Laboratory test for interpretation of primary consolidation parameters

The compression index (C_c) and coefficient of vertical consolidation (c_v) of the ZPL tailings were interpreted from the results of 1D (oedometer) consolidation testing on specimens prepared using a slurry reconstitution of a ZPL tailings sample recovered in a thin-walled (Shelby) tube using the stationary piston sampling method within a drillhole advanced using mud rotary drilling methods and a baffled tricone bit. The intent of completing a consolidation test on a slurry reconstituted sample was to obtain data that could represent the ZPL tailings slurry consolidation shortly post-deposition, and prior to development of any "quasi" preconsolidation-stress due to creep effects (Figure 3b).

The slurry reconstituted sample was produced from the thin-walled Shelby tube using the following steps:

1. Mixing ZPL tailings from Shelby tube SH-04 (DH-BGC20-39) with ZPL tailings pond water (Figure 5a) to a slurry with water content of approximately 370% (by mass). The water content was selected to be consistent with the estimated in-pipe water to tailings ratio of 10:1 as reported by Hudbay (January 12, 2022).

2. Placing the liquid form slurry into a sedimentation column (Figure 5b) consisting of double porous stones at the base, the oedometer ring, and a membrane-lined extension column (with equal inner diameter as the consolidation ring).
3. Allowing the ZPL tailings to settle out of suspension (sedimentation) into the oedometer ring at the base of the settling column setup. Removing the membrane-lined extension column following the completion of sedimentation of the ZPL tailings solids.
4. Trimming the ZPL tailings sample to the top of the oedometer ring (Figure 5c).
5. Placing only the porous stone and top cap onto the sample as a low "seating load" to maintain a relatively low quasi-preconsolidation stress while promoting the necessary contact between the top cap and sample to promote accurate displacement readings for the test load increments (Figure 5d).
6. Maintaining "moist" conditions using saturated paper towels and plastic coverings for the ZPL tailings specimen during testing (Figure 6a), rather than submerged conditions (due to the high solubility of some compounds in the tailings, particularly when subject to increased pressure).
7. Completing the incremental load consolidation test in general accordance with ASTM International standard D2435M-11 (ASTM, 2020). Each load increment was ended after completion of primary consolidation (as interpreted using the square root of time method [Taylor, 1942]). One offload-reload cycle was completed prior to the final offloading of the sample.

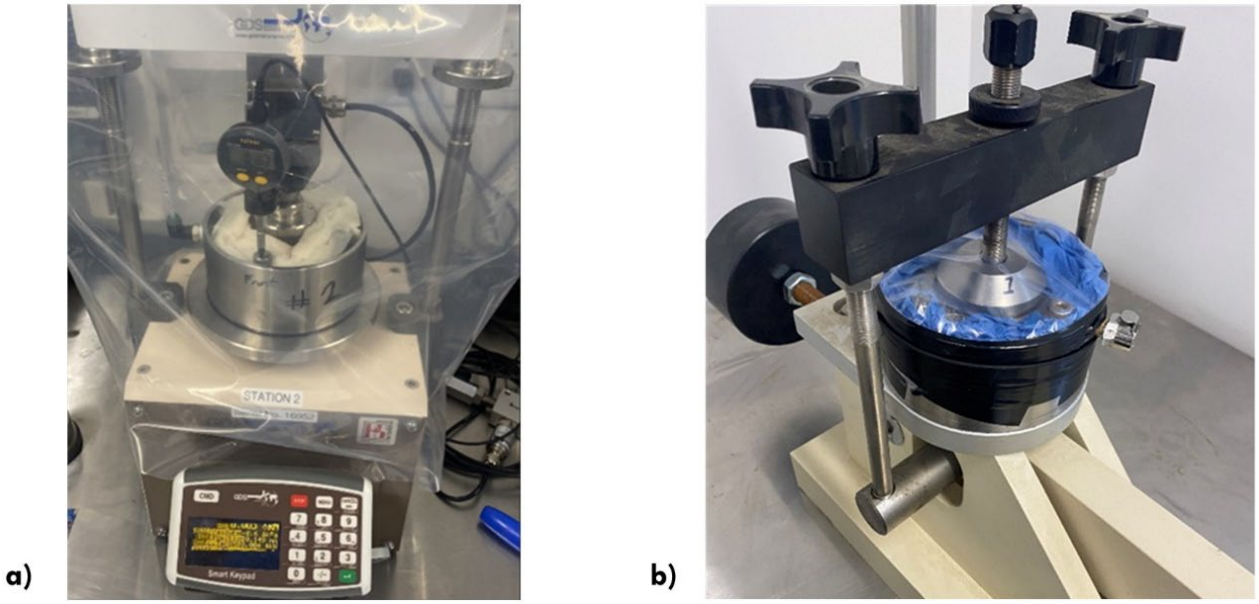

Figure 6: Oedometer equipment and materials set up for moist conditions for: (a) consolidation of slurry reconstituted test specimen; (b) intact

Laboratory test for interpretation of creep parameters

The creep behavior of ZPL tailings was assessed based on results of two long-term creep tests on specimens prepared from intact Shelby tube samples of ZPL tailings recovered using stationary piston methods, from drillholes advanced with mud rotary techniques and a side discharge tricone bit. The creep tests were completed at the BGC advanced soil testing laboratory in Fredericton, NB, Canada, using dead-weight consolidation load frame equipment and mechanical displacement gauges. Manual loading and displacement readings were intentionally selected to exclude issues of data loss that were considered likely with the use of digital systems for test durations exceeding one year.

The creep tests were completed under the one-dimensional (1D) loading conditions of consolidometer (oedometer) equipment. Test specimens were prepared in general accordance with ASTM D2435M-11 (ASTM, 2020). Test specimens were maintained in "moist" conditions during the creep test, using saturated rags and plastic coverings sealed to the cell with electrical tape (Figure 6b).

Loading of the test specimen was applied incrementally (load ratio of 2), up to the target creep loads of 201 kPa (Test C4) and 416 kPa (Test C3). Each load increment below the target creep load was applied for a duration of 24 hours. The creep test loads were applied for durations of 429 days (Test C4) and 416 days (Test C3). Following the creep test load application, incremental load increases were continued to the maximum loads of 2992 kPa (Test C4) and 3273 kPa (Test C3), as limited by the equipment setup. The tests were then completed with incremental offloading, to establish the rebound load-deformation curve.

Data and discussion

Primary consolidation

The consolidation curve (void ratio [e] versus log vertical effective stress plot) for the test on slurry constituted ZPL tailings specimen (C0) is shown in Figure 7. The interpreted C_c value was 0.42 (modified compression index, $C_c' = C_c/(1+e_0) = 0.16$). The interpreted c_v within the stress range of 10 kPa to 400 kPa (representative of typical in-situ conditions) was 1×10^{-5} m^2/s. The consolidation curves for two 1D consolidation tests completed on intact ZPL tailings samples are also shown in Figure 7 for comparison.

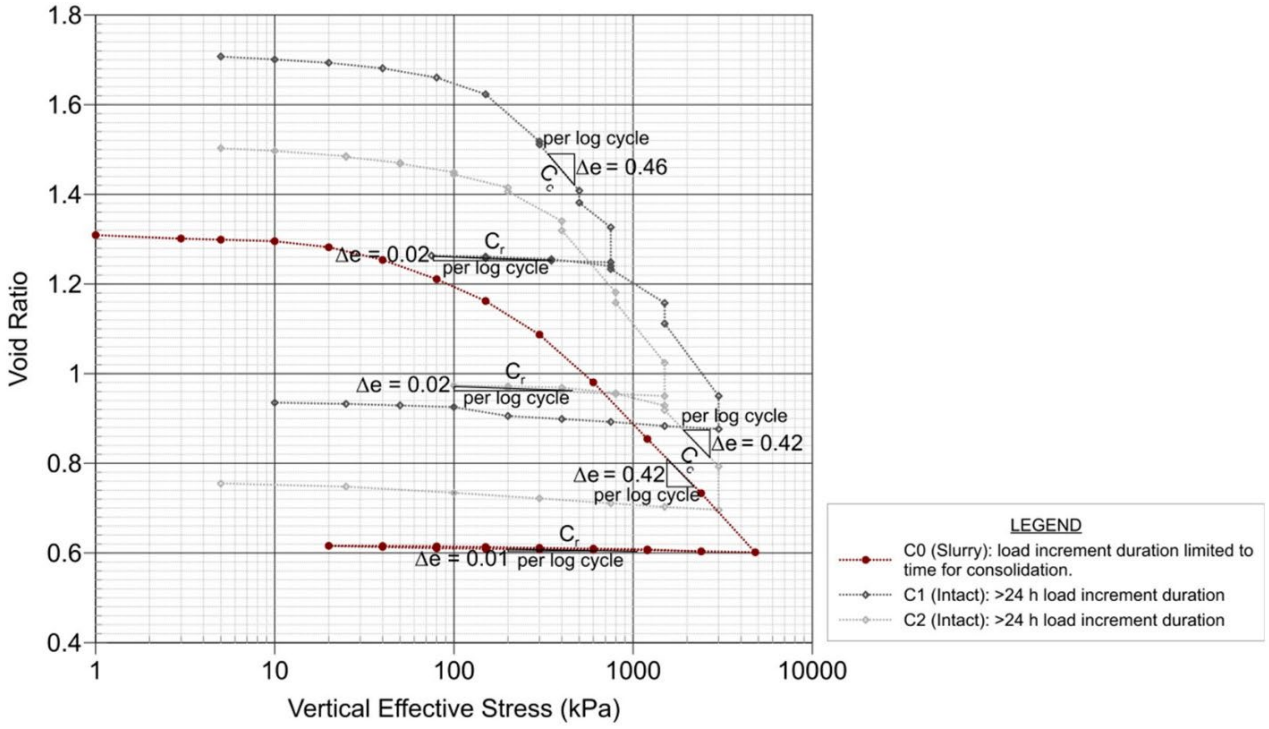

Figure 7: Consolidation of curve of slurry reconstituted and intact ZPL tailings sample

The interpreted recompression index (C_r) value was interpreted from reloading stages of the 1D consolidation test on the slurry reconsolidated specimen, in addition to the reloading stages on four 1D oedometer consolidation tests on intact ZPL tailings specimens (C1, C2, C3, and C4; Table 1). The reconsolidation curves for the test on the slurry reconsolidated specimen (C0) and two of the intact specimens (C1 and C2) are shown in Figure 7. The interpreted C_r values ranged from 0.006 to 0.020, and the assigned representative C_r value was 0.01 (modified recompression index, $C_r' = C_r/(1+e_0) = 0.006$).

Table 1: Results of reloading stages of 1D consolidation test

Depth (m)	Test ID	Test specimen type	Test conditions	Initial void ratio	Initial water content (%)	C_r	C_r' $[C_r/(1+e_0)]$
9.40 to 10.00	C0	Slurry reconstituted	Moist[1]	1.64	75.1	0.006	0.002
13.90 to 14.50	C1	Intact	Submerged[2]	1.71	55.5	0.015	0.006
20.06 to 20.70	C2	Intact	Submerged[2]	1.50	51.3	0.020	0.008
17.00 to 17.60	C3[3]	Intact	Moist[4]	1.25	49.9	0.006	0.003
9.40 to 10.00	C4[3]	Intact	Moist[4]	1.74	74.7	0.011	0.004

Notes:
1. Moist test conditions refer to use of humidification and covered cell conditions, as shown in Figure 6a.
2. Submerged test conditions refer to use of tap water to maintain the submerged condition of the test specimen within the oedometer cell. Crystals were observed to form along the surface of the water bath at the oedometer cell wall during the test. It was inferred that the source of the material forming the crystals was some soluble portion of the sample specimen that dissolved in the (tap) water bath.
3. Creep test completed on this test specimen (C3 creep test at 200 kPa load increment, C4 creep test at 400 kPa load increment).
4. Moist test conditions refer to use of humidification and enclosed cell condition shown in Figure 6b.

There was limited available published data on the consolidation parameters of similar tailings materials. A study on gypsum tailings (from phosphoric acid production [Blight, 1979]) indicated a tailings c_v of 3×10^{-5} m/s. The compression index of a fine iron tailings (Hu et al., 2019), with slightly lower fines content (78%) and void ratio of 1.4, was found to be 0.26. The compression index of a copper-zinc tailings with 90% fines content and void ratio between 1.2 and 1.4 was found to range from 0.24 to 0.30 (Fan and Rowe, 2022). The C_c of ZPL tailings was more similar to $C_c = 0.40$ of coal wash tailings (low plasticity, 66% fines, $e_0 \sim 1.6$) as reported by Qiu and Sego (2001).

Creep parameters

The creep behavior of ZPL tailings was assessed based on the results of two long-term creep tests loads applied for durations of 429 days (Test C4) and 416 days (Test C3). The strain vs. √time and strain vs. log time plots for the creep test load increments of Test C3 and C4 are shown in Figures 8a and 8b, respectively. Data from an ASTM "reference clay" is also plotted for comparison of the non-creep susceptible behavior of the "reference clay" and the ZPL tailings behavior.

The Singh and Mitchell (1969) creep parameters were interpreted from the displacement-time data of the creep load increments, using linear and exponential trendline fitting to plots of the following:

1. Ln strain rate vs. vertical stress (Figure 9a).
2. Log strain rate vs. log time (Figure 9b).

The Singh and Mitchell creep parameters interpreted for the ZPL tailings were as follows:

1. $m = 0.9$.
2. $\alpha = 0.0017$.
3. $A = 0.5$ % per day.

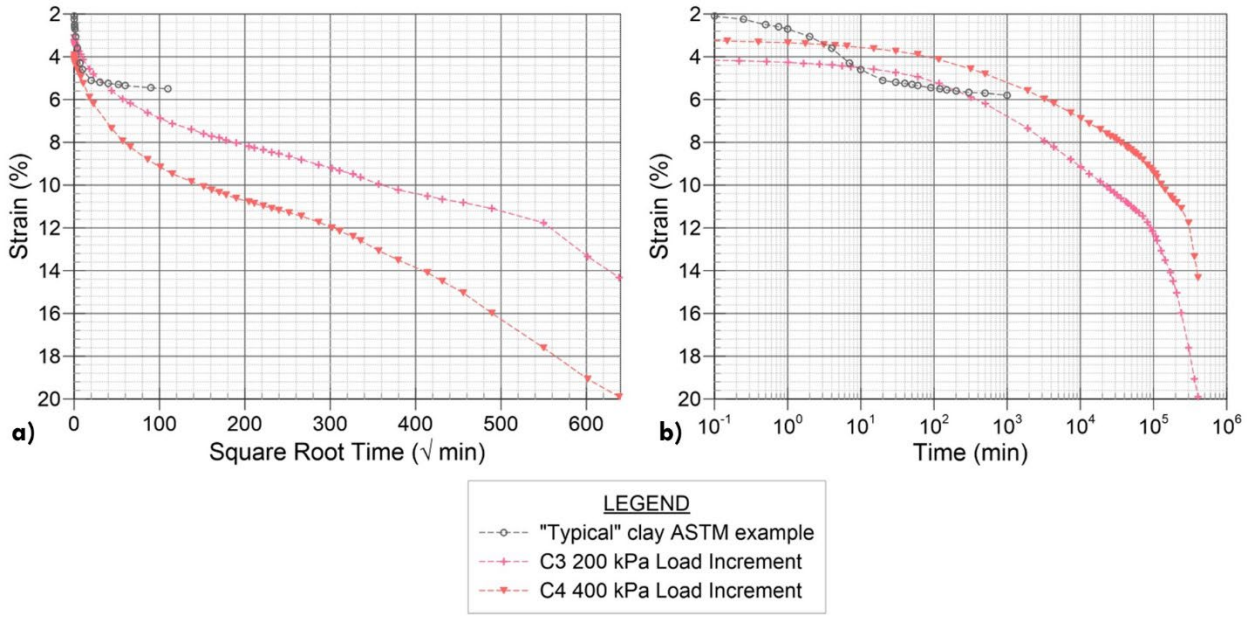

Figure 8: Strain accumulated during creep tests on intact specimens plotted against: (a) square root time; (b) log time

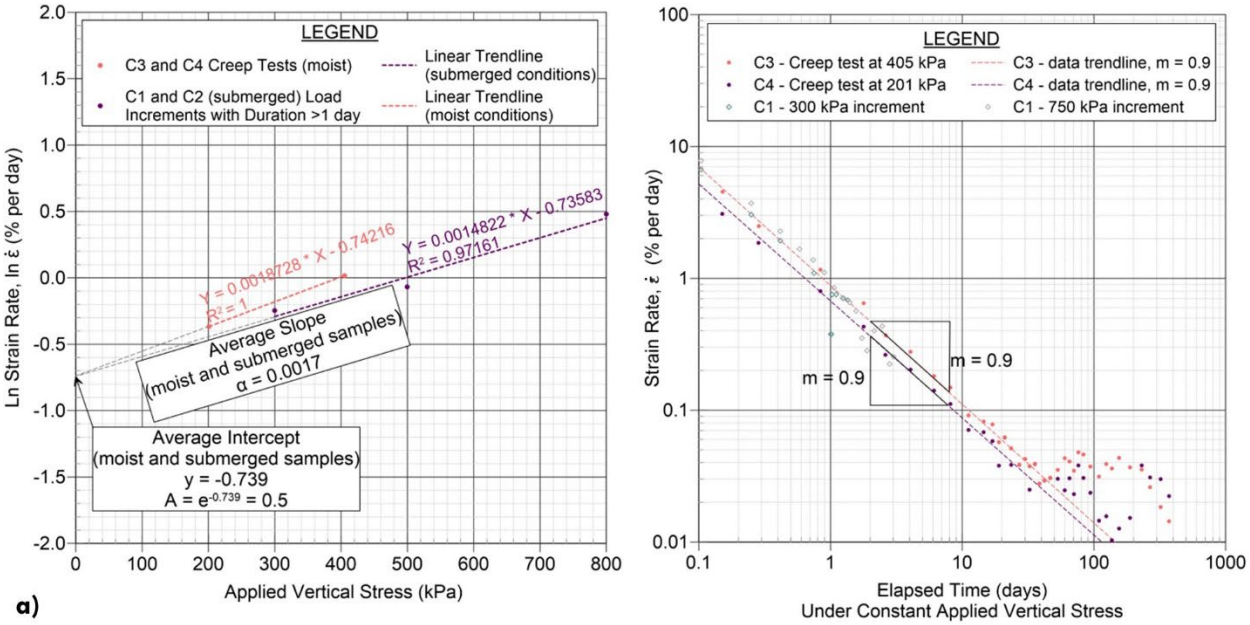

Figure 9: Interpretation of Singh and Mitchell (1969) creep parameters "A," "α," and "m" from (a) Ln strain rate vs. applied vertical stress, and (b) strain rate vs. log time plots

A comparison of the creep deformation modeled using the interpreted parameters and the creep test data is shown in Figure 10.

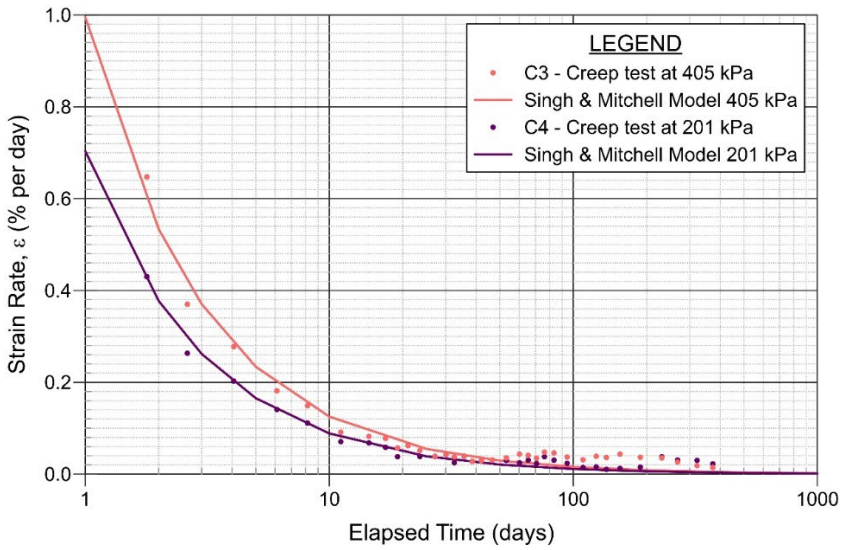

Figure 10: Comparison of laboratory creep test data and modeled creep strain rate using Singh and Mitchell (1969) parameters

Most published case histories of creep behavior describe the compression of organic materials, high plastic clays, or frozen sand units. No case histories of Singh and Mitchell power law modeling of creep in fine grained (mineral) tailings were found during the literature search. Comparison of creep behavior of the ZPL tailings to subaqueous deposits of clay/silty clay may be relevant because of the common (hydrated) mineral-water interaction in both clay minerals and gypsum, and the high water and void content resulting from subaqueous depositional environments. The Singh and Mitchell parameters of two potentially relevant case histories are provided in Table 2. Note the similarity of the "m" parameter relating the change in strain rate over time for the Bohai Bay sediment, San Francisco Bay mud and ZPL tailings.

Table 2: Comparison of Singh and Mitchell creep parameters of mineral soils in published case histories and ZPL tailings

Material	m	A (% per day)	Authors	Notes
Silty Clay Sediment (Bohai Bay Tianjin, China)	[1]0.83	[2]0.22	Li et al. (2019)	1. from 1-m = 0.17 2. from $A^*t_1/[1-m]$ = 0.37%/min 3. $\bar{\alpha}$, not α, was presented in study. $\bar{\alpha}$ correlates a normalized stress value to strain rate.
San Francisco Bay Mud	0.84	0.72	Lacasse and Berre (2005)	Samples tested in anisotropic triaxial compression. $\bar{\alpha}$, not α, was presented in study. $\bar{\alpha}$ correlates a normalized stress value to strain rate.
ZPL Tailings	0.9	0.5	(this study)	Samples tested with 1D loading in oedometer.

Conclusions and limitations

Based on the comparison of the estimated settlements and surveyed data, the selected mathematical model

and input parameters appear to be suitable to represent the compression behavior of the ZPL tailings. The mathematical modeling of the ZPL tailings compression includes assumptions and simplifications that result in inherent limitations of the model. Some of the key assumptions and simplifications applied in the mathematical modeling include:

1. Constant parameter values were interpreted to be generally applicable to ZPL tailings material; there is no accounting for spatial variability of the material parameters.
2. Interpretation of material parameters from one-dimensional loading in the laboratory test (laterally confined conditions in the standard oedometer equipment).

Because these assumptions and simplifications do not fully capture the complexity of the actual load conditions and potential spatial variability of material at the ZPL tailings facility, there is uncertainty to be considered when using the interpreted parameters and power law model for estimating settlements at the facility.

InSAR Study into Pre- and Post-Failure Deformations of the Jagersfontein Tailings Dam

Divya Sekhar Vaka, GEOFEM, Cyprus
Skevi Perdikou, GEOFEM, Cyprus

Abstract

Tailings storage facilities (TSFs) are critical for storing large volumes of flowable material; however, there are potential catastrophic consequences if failures occur. Interferometric Synthetic Aperture Radar (InSAR) has proven cost-effective and efficient for monitoring TSFs. This study focuses on the application of InSAR, particularly the Small Baseline Subset (SBAS) technique, for monitoring the Jagersfontein TSF in South Africa before and after its collapse in September 2022. Historical satellite remote sensing analyses using fifty-one pre-collapse, and fifty post-collapse Sentinel-1 single look complex (SLC) images reveal significant displacement trends. Pre-collapse analysis shows pronounced displacement along TSF edges, with notable subsidence identified over the legacy and reclaimed mine waste stockpiles, and adjacent to the water reservoir. Two uplift zones are observed near the reclaimed mine waste stockpile and at the breach location, possibly indicating horizontal movement of the south wall prior to collapse, as suggested by widened wall observations from optical satellite imagery. Maximum displacements include -57 mm at the eastern point from January 2021 to August 2022, and -114 mm at the northern point from September 2022 to May 2024. Post-collapse analysis confirms intensified displacements along TSF edges, highlighting ongoing instability. The study underscores InSAR's effectiveness in detecting pre-collapse deformation patterns and monitoring post-collapse dynamics, emphasizing the importance of continuous monitoring to mitigate risks associated with TSF failures and to enhance safety protocols globally.

Introduction

Tailing storage facilities (TSFs) store considerable volumes of flowable material, which can result in loss of life and irreparable damage to infrastructure and the environment if accidentally released. Historical TSF failure events underscore the critical importance of implementing proactive monitoring systems at TSF sites to ensure safe performance (Perdikou and Lees, 2023). A key objective in TSF monitoring is to detect potential signs of instability by analyzing spatiotemporal rates of displacement (Rana et al., 2024). Conventional TSF monitoring methods include field observations and in-situ measurements using

inclinometers, extensometers, LiDAR, GPS, and manual settlement plates. However, Interferometric Synthetic Aperture Radar (InSAR) has emerged as a complementary and efficient tool for TSF monitoring due to its cost-effectiveness (Mohamadi, 2024; Sciortino et al., 2021; Thomas et al., 2019).

The availability of extensive both free and commercial synthetic aperture radar (SAR) data with global coverage enables regular, accurate, and simultaneous monitoring of TSFs using various InSAR techniques. One of these, Differential InSAR (DInSAR) measures the phase difference between two SAR images and converts this phase difference into line-of-sight (LOS) displacement. DInSAR is widely used in the mining industry to monitor short-term and rapidly moving displacements. Nevertheless, DInSAR has limitations due to decorrelation and atmospheric variations between two image acquisitions.

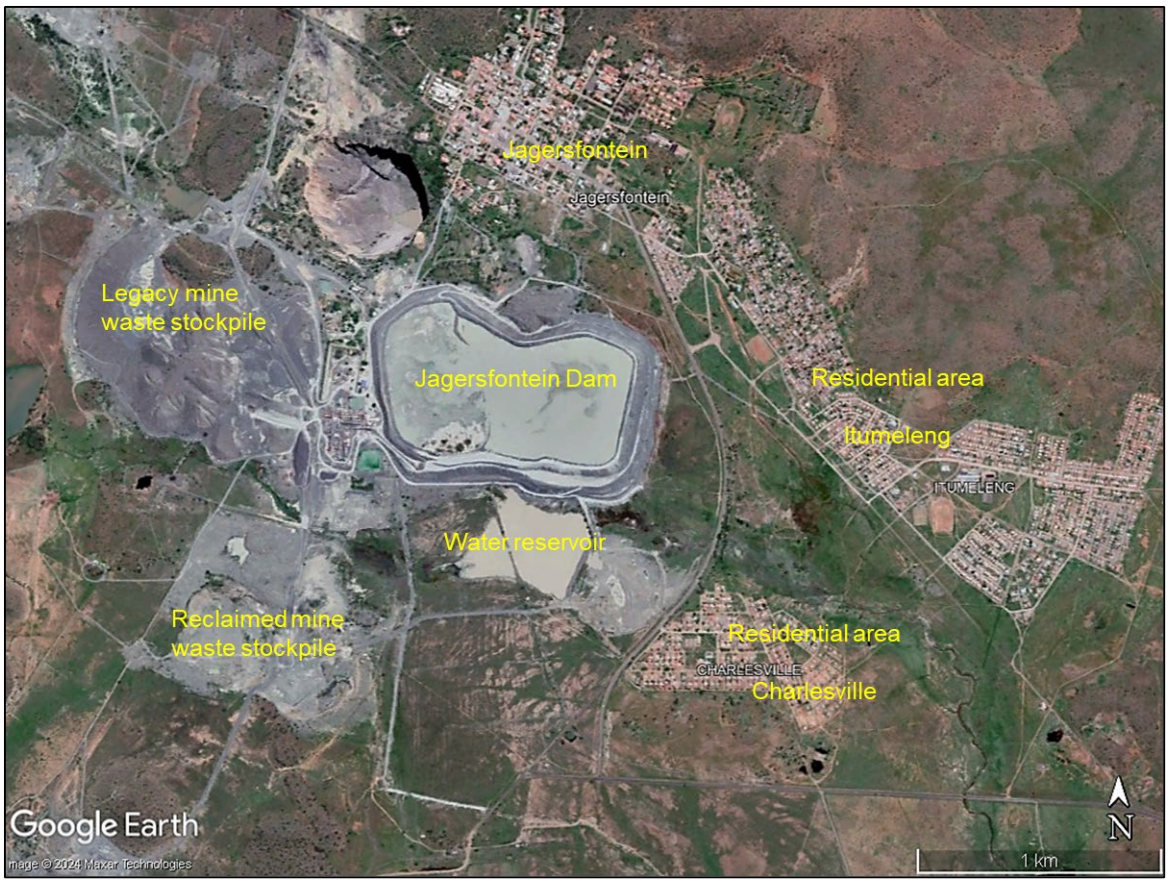

Figure 1: Google Earth imagery of the Jagersfontein Dam in February 2021 (19 months before its collapse). Labels are modified from Torres-Cruz and O'Donovan (2023)

In contrast, time series InSAR can measure millimetric-scale displacements by employing multiple SAR images for displacement monitoring (Hooper et al., 2012). Time series InSAR techniques, such as Persistent Scatterer Interferometry (PSI) and Small Baseline Subset (SBAS), are effective in monitoring TSFs exhibiting slow, long-term deformations. Additionally, time series InSAR techniques overcome the limitations of DInSAR by analyzing a network of interferograms and utilizing filtering operations (Vaka et

al., 2023). Additionally, In SAR monitoring provides a means to detect precursor accelerations that could inform time-to-failure predictions (Rana et al., 2024; Vaka et al., 2023).

On September 11, 2022, a diamond tailings dam in Jagersfontein (see Figure 1) breached, releasing sludge that killed at least one person and damaged numerous houses. The objective of this study was to monitor the Jagersfontein TSF in South Africa using InSAR. Specifically, we utilized SBAS to detect pre-collapse and post-collapse surface displacements of the Jagersfontein TSF. This article focuses on the results of historical satellite remote sensing analyses and the utility of InSAR for pre-collapse and post-collapse monitoring of the Jagersfontein TSF in South Africa.

Study area

The city of Jagersfontein has a long history of mining activities, dating back to the 1870s. In 1931, the De Beers Group acquired the mine and operated it until 1971, when underground ore extraction ceased. The mine changed ownership multiple times: it was sold in 2010 and subsequently sold two more times, with the last sale occurring some months before the dam collapse. The final owner was Jagersfontein Developments, a subsidiary company (Torres-Cruz and O'Donovan, 2023).

On September 11, 2022, the dam collapsed at its southeastern corner in two locations, as visible from Google Earth imagery captured in September 2022 (Figure 2b). A recent study by Torres-Cruz and O'Donovan (2023), using optical satellite image analysis, revealed that in May 2019, erosion gullies had developed on the internal face of the northern wall as well as on the external face of the southeastern wall where the failure occurred. Additionally, Google Earth imagery from May 2019 shows evidence of erosion or instability at the same location where the dam later collapsed (Figure 2a).

Method

For the analysis presented in this paper, fifty-one and fifty images were analyzed using the Small Baseline Subset (SBAS) technique in the pre-collapse and post-collapse periods, respectively. The SBAS technique reconstructs the phase history of a pixel with respect to the first acquisition from a network of interferograms with small temporal and perpendicular baselines, ensuring maximum interferometric coherence (Berardino et al., 2002). Interferograms were generated by setting a temporal baseline threshold of 40 days. The topographic phase was removed using a Shuttle Radar Topography Mission (SRTM) Digital Elevation Model (DEM). The differential interferograms were filtered using a Goldstein filter and multi-looked to form approximately 15 m pixels. An unwrapped coherence threshold of 0.1 was used to mask low coherence areas during phase unwrapping, which was performed using the Minimum Cost Flow (MCF) approach. The unwrapped interferograms are subsequently inverted to generate displacement time series for each pixel. These time series are displayed as points, with their colors indicating velocity: warmer colors

represent subsidence, while cooler colors denote uplift. The entire InSAR processing was carried out using ENVI SARscape.

Figure 2: Google Earth imagery of the Jagersfontein Dam a) showing erosion gullies in May 2019 b) after the breach in September 2022.
The inferred location of the erosion is marked with a red circle

Table 1: Details of the data used for the pre-collapse and post-collapse analysis

Period	Data	No. of images	No. of interferograms
Pre-collapse	02-01-2021 to 25-08-2022	51	111
Post-collapse	18-09-2022 to 22-05-2024	50	133

Results

Pre-collapse InSAR time series displacement

Figure 3 illustrates the surface displacement results from the SBAS analysis in the Jagersfontein area in the pre-collapse period. The analysis reveals significant displacement along the edges of the TSF prior to its collapse. The results are interpreted as follows: subsidence, indicated by warm colors, represents movement away from the radar, while uplift, shown in cool colors, represents movement towards the radar. Besides the TSF edges, the results identify three subsidence locations: over the legacy mine waste stockpile, the reclaimed mine waste stockpile, and to the right of the water reservoir, as shown in Figure 4.

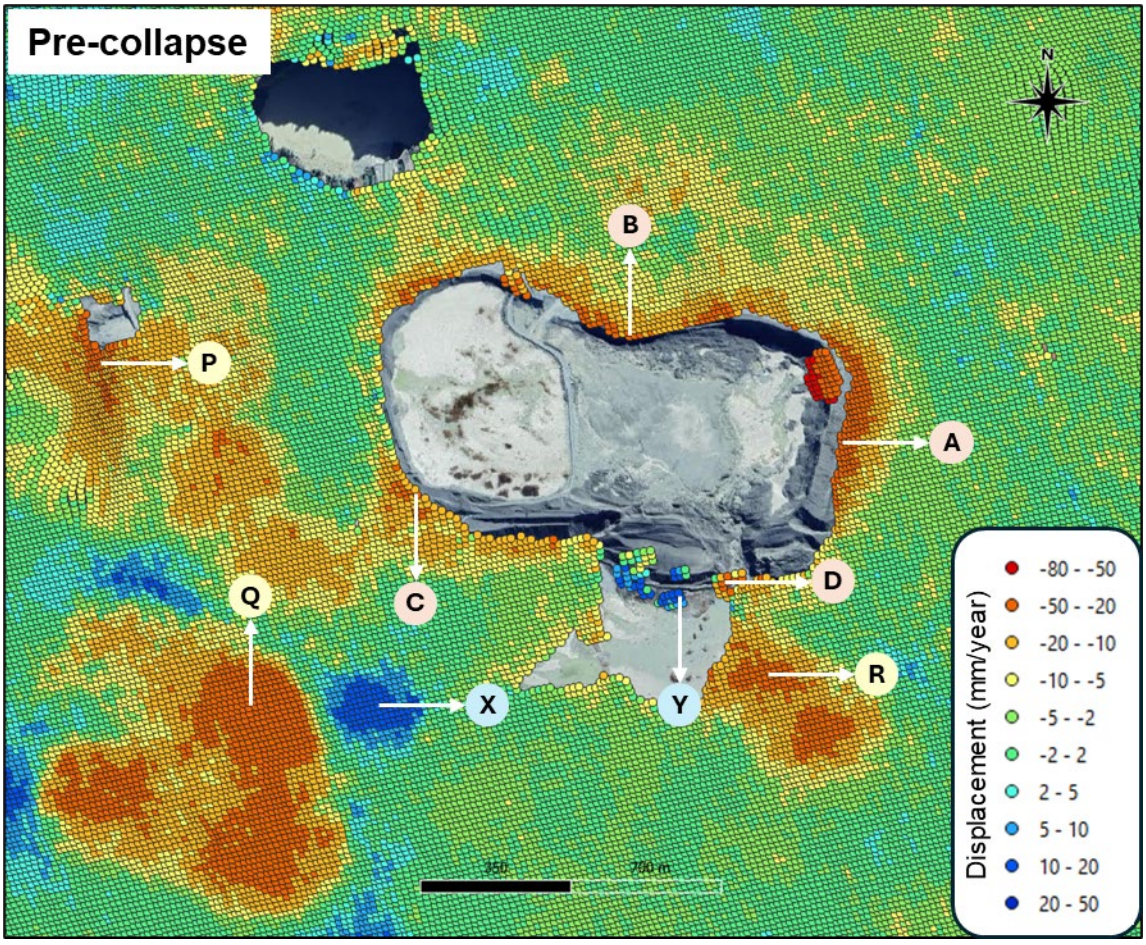

Figure 3: InSAR LOS displacement rate (mm/year) during the pre-collapse period from January 2021 to August 2022.
The subsidence time series is displayed in Figure 4 along the edges of the TSF (points A, B, C, D), at the mine waste piles (points P, Q), and to the right of the water reservoir (point R). The uplift time series is displayed at points X and Y

Additionally, the analysis indicates two uplift locations near the reclaimed mine waste stockpile and at the breach location. The uplift at the breach location may represent horizontal movement towards the

satellite before the collapse, as inferred from optical satellite images that report a widened wall at this location (Torres-Cruz and O'Donovan, 2023). The uplift at the other locations could suggest a new dumping site, warranting further detailed study.

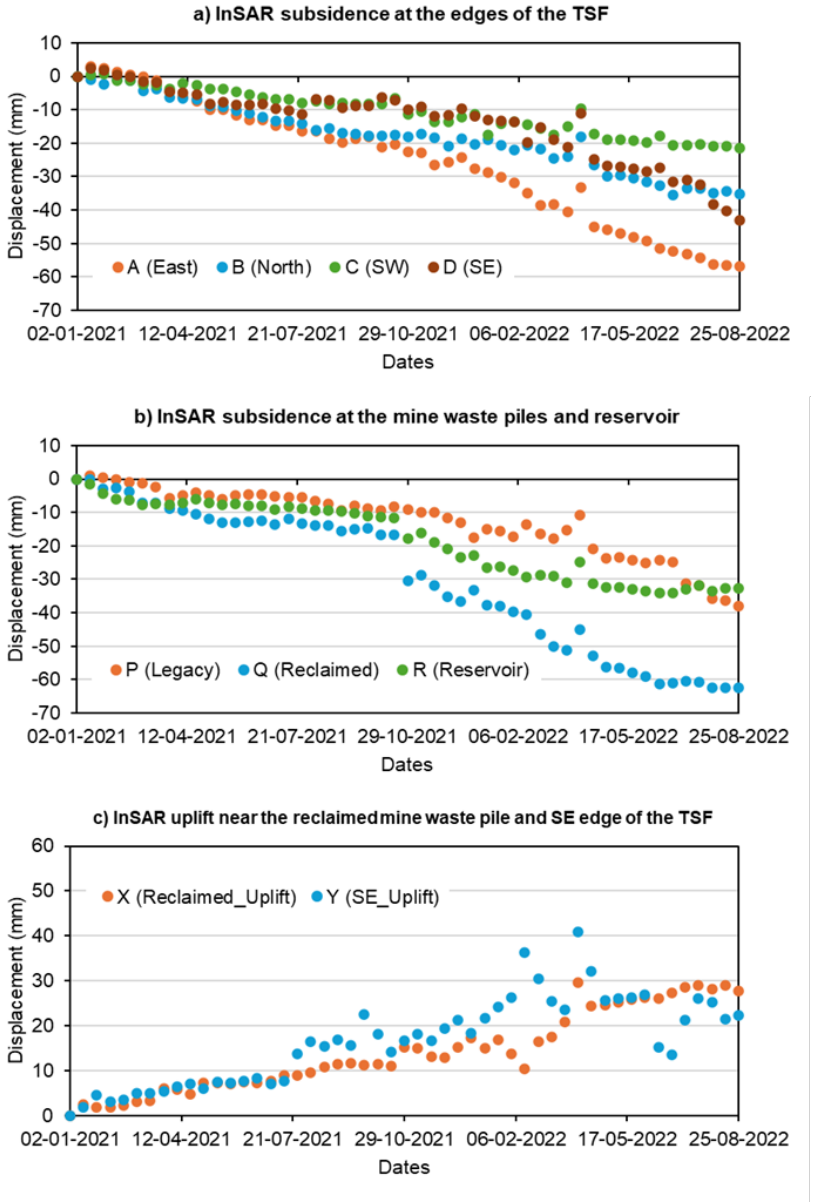

Figure 4: InSAR displacement time series before the collapse a) InSAR subsidence time series at the perimeters of the TSF (points A, B, C, D). b) InSAR subsidence time series at the mine waste stockpiles (points P, Q) and adjacent to the water reservoir (point R). c) InSAR uplift time series at the reclaimed mine waste stockpile and the breach location (points X and Y)

Figure 4 depicts the displacement time series (subsidence and uplift) at various points shown in Figure 3. The eastern point exhibited a maximum displacement of -57 mm from January 2021 to August 2022. Similarly, the northern, southwestern, and southeastern points showed maximum displacements of -35 mm,

-21 mm, and -43 mm, respectively. Notably, the southeastern corner indicated subsidence fluctuations of greater than -4 mm in February, April, June, and August 2022. Overall, significant displacement was observed along the eastern and southeastern walls during the pre-collapse period.

Post-collapse InSAR time series displacement

Figure 5 depicts the surface displacement results obtained from the SBAS analysis conducted in the Jagersfontein area during the post-collapse period. The analysis highlights increased displacement along the edges of the TSF leading in the post-collapse period. Clear subsidence signatures are evident along the TSF boundaries compared to the pre-collapse period. Additionally, three distinct subsidence areas are identified: over the legacy mine waste stockpile, the reclaimed mine waste stockpile, and to the right of the water reservoir, as depicted in Figure 5. Although fewer deformation points are observed at the legacy mine waste stockpile, a discernible subsidence trend is evident.

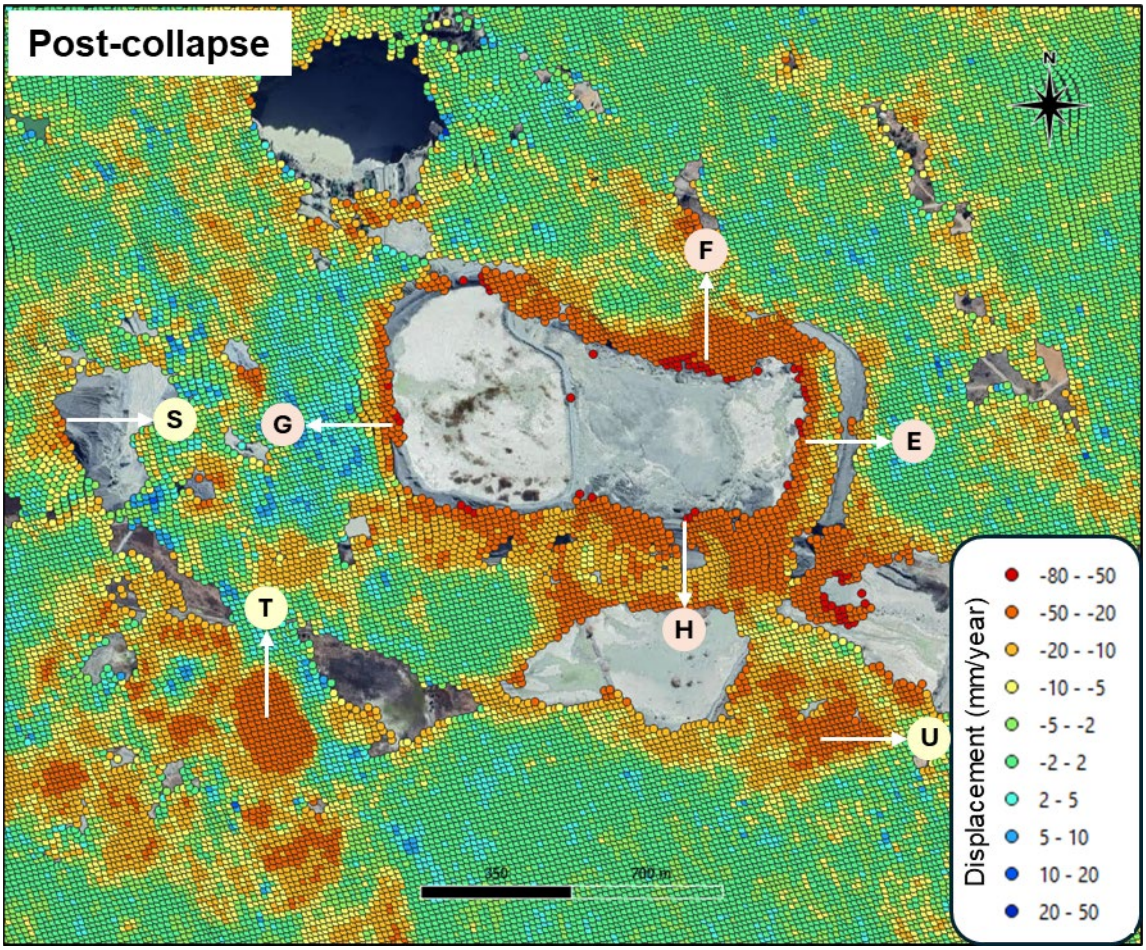

Figure 5: InSAR LOS displacement rate (mm/year) during the post-collapse period from September 2022 to May 2024.
The subsidence time series is displayed in Figure 6 along the edges of the TSF (points E, F, G, H), at the mine waste piles (points S, T), and to the right of the water reservoir (point U)

Notably, the uplift zones observed in the pre-collapse analysis are absent in the post-collapse results. While the absence of the uplift zone near the breach location was anticipated, further investigation is required to understand why the other uplift zone disappeared in the post-collapse analysis.

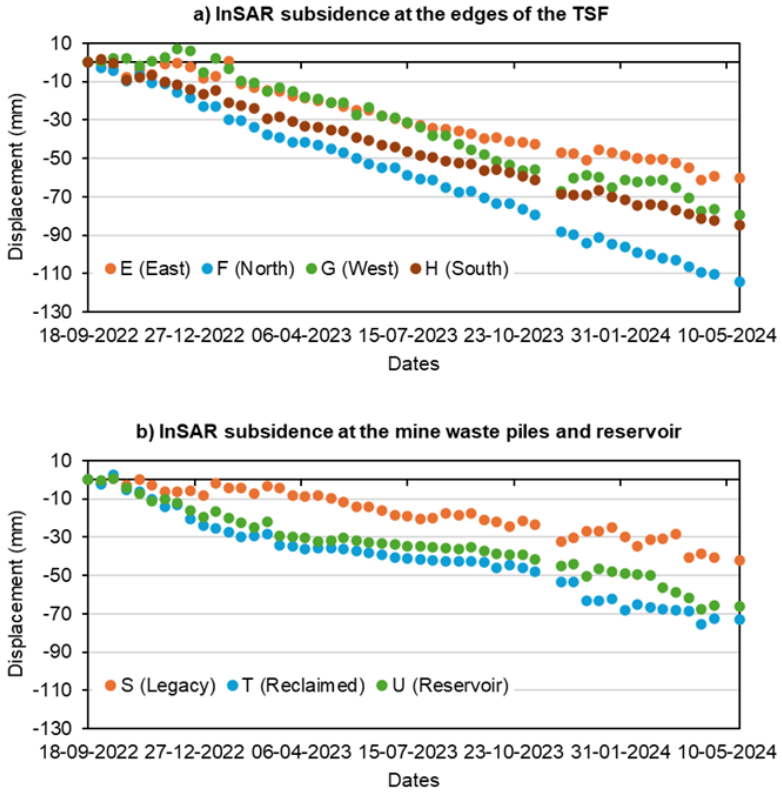

Figure 6: InSAR displacement time series after the collapse a) InSAR subsidence time series at the perimeters of the TSF (points E, F, G, H). b) InSAR subsidence time series at the mine waste stockpiles (points S, T) and adjacent to the water reservoir (point U).

Figure 6 illustrates the time series of displacement (subsidence and uplift) at several locations indicated in Figure 5. The northern point experienced the highest displacement, reaching -114 mm from September 2022 to May 2024. Likewise, the east, west, and south points exhibited maximum displacements of -61 mm, -80 mm, and -85 mm, respectively. The northern and southern edges, which collapsed during the event, show the most significant displacements.

Conclusion

The study underscores the efficacy of InSAR, particularly SBAS, in monitoring the Jagersfontein TSF both before and after its collapse in September 2022. Pre-collapse analyses revealed significant displacements along TSF boundaries and identified specific subsidence areas over legacy and reclaimed mine waste stockpiles. This highlights InSAR's capability in providing detailed insights for TSF monitoring and its

potential in early detection of instability indicators. Additionally, the pre-collapse analysis identified an uplift zone at one of the breach locations, potentially indicating horizontal movement of the south wall of the TSF. Future studies could employ amplitude tracking exercises to measure this horizontal movement accurately. Sudden accelerations observed in the displacement time series (in the pre-collapse period) can help identify potential time windows for failure. This data, in combination with deformation monitoring at specific locations and engineering experience, would provide indications as to how dam failure can be predicted as well as the necessary steps towards mitigating disaster risks and ensuring stability. Post-collapse observations further emphasized intensified displacements along TSF edges, indicative of ongoing instability. These findings underscore the critical need for continuous and effective monitoring of collapsed TSFs, which could serve as sources of future slope instability.

The Barriers to Widespread Adoption of Tailings Dewatering Technologies

Ljiljana Josic, AtkinsRéalis, Canada
Ashley Verge, AtkinsRéalis, Canada
Kasra Majdanishabestari, AtkinsRéalis, Canada

Abstract

Mining is an important contributor to the world economy, but tailings management is, and will continue to be in the coming decades, an increasingly difficult issue for governments, communities, regulators, and mining companies. It has been estimated that nickel, lithium, and cobalt production need to increase by 150% to supply the electric vehicle and clean energy sector in the coming years. This significant increase in metals production will result in a correspondingly significant increase in tailings production and a need for proper management. Currently, most tailings are managed conventionally. Conventionally deposited tailings contain a large amount of water, making tailings management facilities more complex and less stable. Recent catastrophic failures have resulted in enhanced oversight and calls for change. Identifying, developing, and adopting new technologies could help to eliminate the risks posed by the nature of conventional tailings facilities, which have been responsible for the failures that have occurred, and possibly remove them altogether. Dewatering of tailings is imperative for safer tailings management. By decreasing water content in the tailings, significant safety improvements can be achieved, and the risk of catastrophic dam failure and tailings runout could be eliminated.

This paper discusses tailings dewatering technologies currently available and in use. The adoption of different tailings dewatering techniques over time across the mining industry is analyzed, with particular attention to the proportion of mines using or planning to use dewatering techniques. The impact of industry-wide factors such as the catastrophic tailings dam failures that have occurred in the past decade, and the introduction of the Global Industry Standard on Tailings Management on the use of dewatering techniques, are examined. What are the key factors in making decisions on the deposition methodology selection, and what are the barriers to widespread adoption of dewatered tailings technologies? Comparison of tailings management technologies with respect to different aspects such as social, technical, environmental, and economics are presented in the paper.

Introduction

The consistency of tailings can be described on a continuum from conventional slurry (which is thickened only to the point that it can be pumped using centrifugal pumps) to a filtered tailings "dry cake," with increasing levels of dewatering. Storage of slurry tailings usually requires containment dams, with dam size typically decreasing with increasing dewatering of tailings. A major appeal of filtered tailings is the potential for stacking of the dewatered tailings without the need for any containment dams. Of particular concern are upstream dams, where portions of the dam are constructed on previously deposited tailings.

Tailings dam failures have led to catastrophic environmental and human tragedies. The Center for Science in Public Participation (CSP2, 2022) maintains a database of tailings storage facility failures worldwide that occurred between 1915 and 2022. The database documents 368 failures that resulted in 3,241 deaths and the release of over 250 million cubic meters of contaminated residues into the environment (CSP2, 2022). These failures almost exclusively occurred at conventional slurry tailings impoundments. If they reach a river, materials released from these failures can travel hundreds of kilometers. The threat of tailings dam failures can be expected to worsen in the coming years and decades due to the increasing severity and frequency of extreme weather events related to climate change. With a decrease in water content of the tailings via dewatering, the extent of runout from a failure and the resulting consequences are correspondingly minimized.

On August 4, 2014, a breach occurred in a section of the Perimeter Dam at the Mount Polley Mine Tailings Storage Facility in British Columbia, Canada. Although thankfully there was no loss of life, there were significant environmental impacts to the downstream area. The subsequent Report on Mount Polley Tailings Storage Facility Breach (Morgenstern et al., 2015) concluded that a move to application of best available technology (BAT) was required. Examples of BAT were given as filtered, unsaturated, compacted tailings, and reduction in the use of water covers commonly used to limit oxygen ingress to prevent acid mine drainage.

Two catastrophic failures in Brazil (the November 5, 2015, collapse of the Fundão Dam in Minas Gerais and the January 25, 2019, failure at the Córrego de Feijão Mine in Brumadinho), which together claimed the lives of approximately 289 people, prompted further actions by concerned parties. As part of the response, the International Council on Mining and Metals (ICMM), the United Nations Environment Programme (UNEP) and the Principles for Responsible Investment (PRI) co-convened a Global Tailings Review to establish an international standard for best practices on tailings storage facilities. The Global Industry Standard on Tailings Management (GISTM, GlobalTailingsReview.org, 2020) was launched in 2020, with ICMM member companies pledging to adopt the standard as a condition of membership. The GISTM requires the consideration of dewatering technologies for new facilities as well as expansions to existing facilities. At the same time, institutional investors are increasing their focus on environmental,

social, and governance (ESG) issues. Common ESG metrics used as investment criteria by some institutions, such as water use and total waste, can be directly improved by the adoption of dewatered tailings technologies (Karajeh, 2023).

Industry dewatering trends

Dewatering of tailings may be achieved using cyclones, centrifuges and various types of filters (vacuum filters including drum, disc, and belt types, or pressure filters including plate and frame and belt presses), or most simply, by spreading the tailings out and drying them in the sun. Farming of tailings using very low ground pressure equipment is used on red mud in Australia, and has been tested on other types of tailings including coal tailings, fly ash, and Canadian oil sands (Williams, 2021). Different methods of filtering tailings are summarized by Ulrich and Coffin (2013). Due to the removal of a significant amount (but not all) of the water in the tailings, filtered tailings are often referred to as "dry," with the disposal facilities often termed "dry stacks." Issues with this terminology have been discussed by others (e.g., Davies, 2011; Ulrich and Coffin, 2013). As such, the potentially misleading term "dry stack" will be avoided in this paper. Tailings may also be mixed with waste rock, which is referred to as co-disposal.

The use of cyclone separation can be considered the first stage in tailings dewatering, which was introduced in the 1960s to produce an economic coarse tailings product for embankment construction and increased water recovery. Thickened tailings were developed in the mid-1970s, filtered tailings in the mid-1980s, and paste operations around 1990 (Davies et al., 2011). As per Davies et al. (2011), while none of the dewatering methods besides cycloning had significant initial acceptance, all of these methods have been increasing in popularity since about 2000.

Vick (1990) reported on the contemporary state of practice that tailings collected from the thickener were "almost universally transported in slurry form to the tailings impoundment," which is described as a matter of convenience since the tailings are already mixed with water in the mill, with further dewatering to allow dry handling usually deemed economically prohibitive. Vick (1990) also reports "considerable controversy" regarding the economics, feasibility and advantages of belt filtration for tailings disposal, noting that the method is justified only when it is required for ore processing (e.g., in uranium milling that had been used extensively in France and South Africa by that time), rather than as a supplementary dewatering method.

As per Oxenford and Lord (2006), Canadian mines have been at the forefront of applications of paste and thickened tailings for surface disposal, beginning with the 1973 implementation of the first thickened tailings operation for surface disposal using the Robinsky method at Kidd Operations in Ontario. Filter stacking was also implemented in Canada at the Line Creek Coal Mine in British Columbia in 1981. Oxenford and Lord (2006) provide seven examples of mines in Canada that used paste, thickened or filtered

tailings technology as of 2006. While in each highlighted example there were various site-specific economic/engineering and environmental/social reasons to implement dewatering technologies, Oxenford and Lord (2006) also recognize the reduced risk of a tailings incident as a primary benefit of such technologies.

Ulrich (2008) reported on a poll of gold producers regarding their tailings dewatering practices in Nevada, which produces approximately 85% of the gold mined in the USA. This poll found that all responding facilities were operating conventional tailings facilities, with the region lagging behind the industry in dewatering techniques at that time. This was attributed to Nevada's regulatory framework, where the full basin area requires a liner system to achieve zero discharge. Ulrich (2008) suggested that a full lining system in addition to tailings dewatering was not economical.

Davies et al. (2011) summarized industry trends towards tailings dewatering, noting that the main objective for use of dewatering technologies was to reduce water consumption and water losses, rather than to reduce the risk of failure. The use of tailings filtration at a number of projects in Chile was noted, as were paste tailings – including Chile's first large-scale paste tailings project that was expected to soon be in operation. Davies et al. (2011) note that Chilean regulations encourage different types of tailings dewatering methods. Canada's use of tailings dewatering is noted as a slow but steady increasing trend, with greater adoption and greater success found in northern regions such as the Raglan Mine in northern Québec, and similarly at the Pogo Project in Alaska, both of which are filter stack facilities. While Australia was noted as the leader in thickened tailings application, it lagged behind other regions in the adoption of filtered tailings.

Research by dewatering equipment manufacturer Metso indicated that only 5% of the worldwide tailings produced in 2018 were dewatered to create thickened tailings or paste, and less than 1% were filtered for stacking. Metso is confident that this proportion will increase, estimating that, by 2025, 13% of all generated tailings will be subjected to some form of dewatering (Leonida, 2020).

Vargas and Campomanes (2022) discuss the current practice in Chile and Peru, where most tailings disposal is noted to be in conventional tailings impoundments; however, 11 filter stack facilities in Chile and six in Peru are profiled, demonstrating a significant contribution to the industry's experience in this technology. Copeland et al. (2023) present a summary of the South African adoption of dewatering technologies, stating that, although tailings filtration is commonly considered during trade-off studies, it is rarely implemented in South Africa, except in arid regions.

Very little information on China's tailings management practices was found in the publicly available literature. Wang et al. (2022) report that of China's 7,800 tailings storage facilities (the most of any country), 70% were built as conventional slurry impoundments. The remaining 30% of alternative tailings technologies represent the highest adoption rate of dewatering technologies found during the research for

this paper. The GRID-Arendal (2020) database contains data on only nine tailings storage facilities in China, eight of which use conventional tailings storage, with one example of in-pit disposal. Clearly, much of the true picture is missing from available public databases.

The Global Tailings Portal (GRID-Arendal, 2020) provides information disclosed by publicly listed companies. At the time of writing, a total of 2,056 facilities are listed. The database is noted to be incomplete due to the absence of information from non-publicly listed companies, including state-owned and privately owned companies, as well as many mid-size and junior companies. Tailings facilities in China and Chile are under-represented, with larger facilities being over-represented. Figure 1 presents the total number of tailings facilities constructed per year as well as the percentage of those that use filtered technology based on the GRID-Arendal (2020) dataset. Although the data is incomplete, it actually suggests a deceasing trend of filtered tailings facilities being constructed since the mid-2010s, with a peak in 2000 with 17% of constructed facilities using filtered tailings.

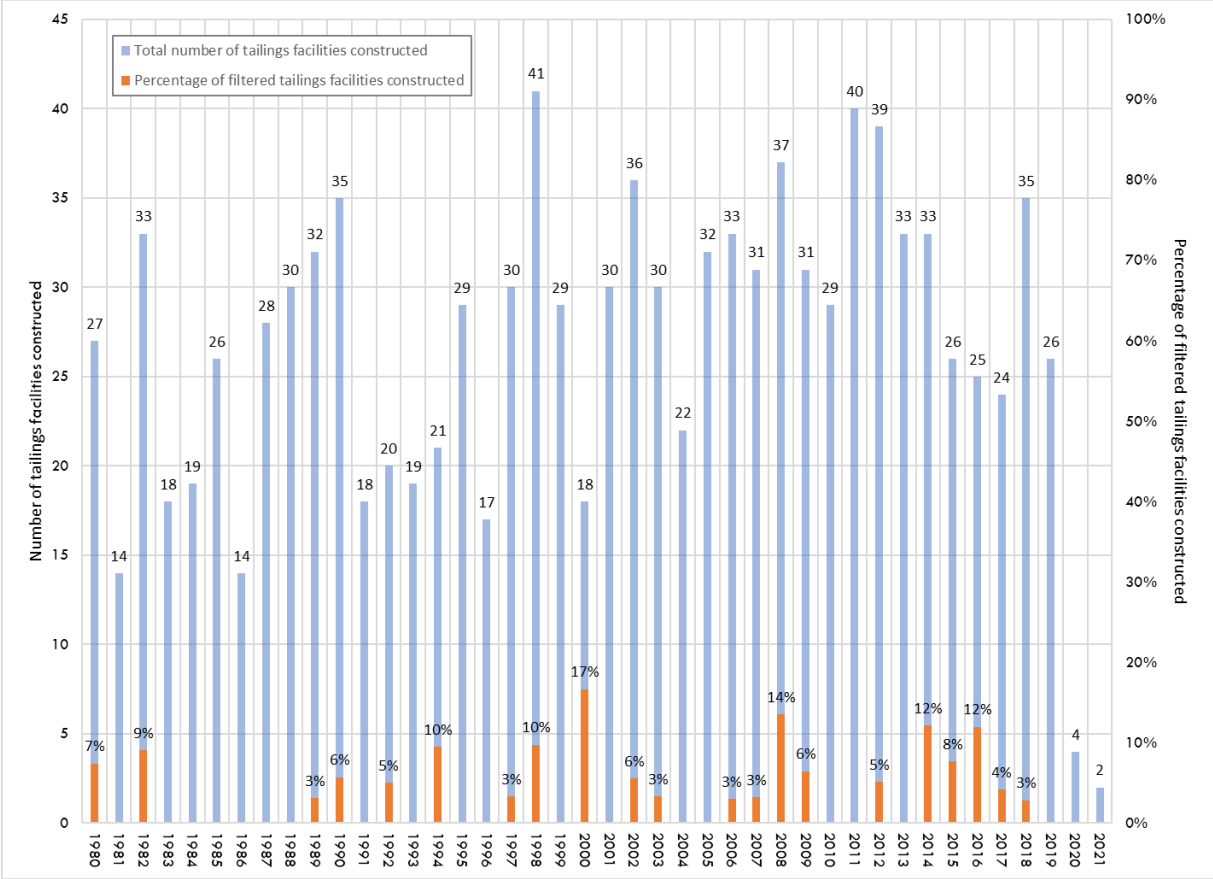

Figure 1: Total tailings facilities constructed and percentage of filtered tailings facilities (1980 to 2021)

Key decision criteria for tailings dewatering technologies

Trade-off studies are typically completed at the pre-feasibility stage of a project to determine optimal site selection, and increasingly, the selected tailings dewatering technology. GISTM Requirement 3.2 requires an analysis of alternatives for all new tailings facilities to rigorously consider all available options throughout the project life cycle, considering environmental, technical and socioeconomic aspects. Figure 2 illustrates schematically the authors' assessment of how some of the key decision criteria typically vary based on the chosen tailings dewatering technology (further comparisons provided by Boger and Hart, 2008; Carneiro and Fourie, 2019; Ulrich, 2019; Williams, 2021; Vargas and Campomanes, 2022). This is further compared in Table 1, providing the authors' more comparison of additional criteria such as footprint, potential environmental impact, and costs.

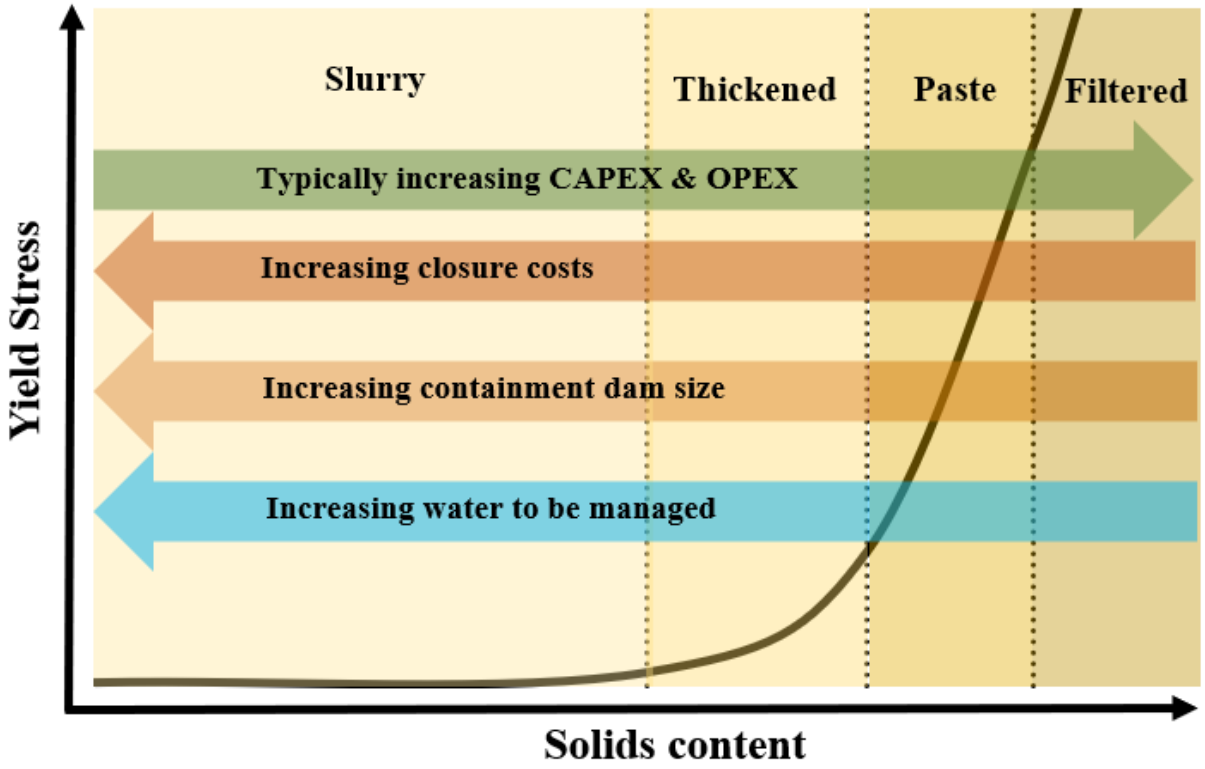

Figure 2: The tailings continuum (from slurry to filtered tailings) and key decision criteria

Table 1: Comparison of tailings disposal technologies

Criteria	Tailings disposal technology				
	Conventional slurry	Thickened	Filtered	Paste	Co-disposal
Storage technique	Surface, in-pit, offshore	Surface, in-pit	Surface, in-pit	Surface, underground backfill	Surface, in-pit
Water at disposal facility	More	Less	Less	Less	More
Footprint	Large	Smaller than conventional	Smaller and more flexible	Smaller	Reduced for tailings/waste rock combined
Risk of dam failure/environmental impact	High	Lower (small dams)	Low (no dam)	Less to none	High to moderate
CAPEX	Low	Moderate	High	High	Moderate
OPEX	Low	Moderate	High	High	Low
Sustaining capital	High	Low to moderate	Low	Low	Moderate to high
Closure cost	High	Moderate	Moderate but progressive	Low to none	High
Post-closure cost	High	Moderate	Low	Low to none	Moderate to high

Barriers to adoption of tailings dewatering technologies

While it is generally accepted that there is no one best method for tailings disposal that can be applied to any site, it seems apparent from the review of industry trends that tailings dewatering is not reaching its full potential. Typical arguments against the use of tailings dewatering technologies may be grouped into 3 categories: technical, cost and other.

Technical arguments

Historically, filtered tailings stacks were most often considered for sites located in arid regions (such as Chile and parts of Australia) or in cold regions (such as northern Canada and Alaska). In wetter climates, water management measures are essential, as described by Davies (2011). Trafficability during tailings placement can also be an issue in wetter climates. In regions with distinct rainy and dry seasons, filter stacks are often designed with an outer slope region that requires more stringent compaction criteria and need to be placed in favorable weather conditions. This outer slope region provides stability to the structure and allows for tailings placement in the interior portion of the stack during the rainy season at a lower compactive effort, which can greatly reduce trafficability concerns (Ulrich and Coffin, 2013). Torex Gold's El Limón Guajes Mine in Guerrero, Mexico is an example of a site with a filter stack designed for a climate

with a rainy season characterized by short-term, high-precipitation events (Torex Gold, 2020). Davies (2011) concludes that filter stacks can be effective in very wet climates with appropriate water management measures in place. With the relative dryness of the tailings in a filter stack, the generation of dust inevitably becomes more of an issue. Dust can be partially managed by progressive reclamation of the filter stack with placement of the closure cover to prevent erosion and usually to support vegetation growth (Davies, 2011). Binder material or chemical agglomeration can also be used to manage dust at filter stacks. Sites in windy areas could use tubular "pipe" conveyor belts to transport tailings to prevent dust generation prior to placement (Vargas and Campomanes, 2022).

Previously there were some concerns that fine tailings (particularly those with clay mineralogy) cannot be feasibly filtered; however, as reported by Ulrich and Coffin (2013), advances in filter technology are now allowing production of clayier filtered tailings. While the design and construction of filter stacks for finer tailings must adequately consider the behavior of these tailings, finer particle size does not necessarily preclude the use of a filter stack.

Acid mine drainage is caused when sulfide minerals that are often present in tailings oxidize in the presence of air and water. Traditionally, acid-generating tailings were kept saturated to prevent oxidation by subaqueous deposition in a conventional tailings impoundment with a water cover that must be maintained in perpetuity. The need to limit oxidation of acid-generating tailings may be seen as an argument to operate a conventional slurry tailings facility. As per Davies et al. (2011), attempts to prevent oxidation of acid-generating tailings using thickened and paste technology have been unsuccessful. The geochemical stability of acid-generating tailings in filter stacks depends on mineralogy, water content and mineral availability, and is the subject of ongoing research (e.g., Surrette et al., 2023). The construction of a filter stack for acid-generating tailings generally requires an encapsulation system consisting of a base liner under the stack and a cover that may be progressively placed. These additional costs may deter use of filtered tailings for acid-generating tailings, except in jurisdictions where a base liner is required for all tailings facilities, such as Québec and Nevada.

Production rates at thickened and paste facilities as of 2011 were mostly under 30,000 tonnes per day (tpd), with filtered facilities generally under 10,000 tpd. As per Ulrich (2019), filtered tailings technology has so far seen implementation at a limited number of relatively low-production tailings facilities, although higher production rate facilities are being tested. As noted by Crystal et al. (2018), further advancements in the industry can be expected, and the elimination of filter stacking as an option should not be solely based on high production rate. Vargas and Campomanes (2022) report on operating and planned filter stack facilities with maximum throughput of 50,000 tpd at Karara in Australia and Chingola in Zambia. Two significantly higher production facilities – Rosemont Copper in Arizona (75,000 tpd) and Metales in Mexico (120,000 tpd) – are noted to be in the regulatory approval or construction permitting process.

Many active conventional tailings impoundments have been in operation for decades. Due to increasing regulatory difficulty in opening new mines, the trend will likely be for fewer new facilities in favor of expanding existing facilities. If the existing facility is a conventional tailings impoundment (as most are), it is most likely that that process will be continued. Morgenstern et al. (2015) recommends against retrofitting existing conventional tailings impoundments with filtered tailings technology due to the continued risk of undrained shear failure or liquefaction of the underlying saturated tailings. On the other hand, GISTM Requirement 5.1 calls for investigation into the potential to refine the tailings technology for expansions to existing tailings facilities. Several examples of filtered tailings placement over existing conventional tailings were found in the literature. At the LaRonde Gold Mine in Québec, slurry tailings deposition was transitioned to filtered tailings placement in 2022 to reduce the risks related to slurry tailings management. In this case, a waste rock platform was constructed on the slurry tailings surface for trafficability to allow placement of the filtered tailings (Masengo et al., 2023). Examples like this can provide valuable insight for other conventional tailings facilities considering the implementation of dewatering technologies. Dewatering technologies could be used at existing mines where the conventional tailings impoundment is nearing capacity. Reducing the water content and thereby increasing the tailings density will result in a longer storage life for the tailings impoundment. However, as noted by Williams (2021), change will most easily be achieved for new mining projects, so the impact of these changes will necessarily be slow.

In summary, as stated by Morgenstern et al. (2015), “There are no overriding technical impediments to more widespread adoption of filtered tailings technology.”

Cost

Morgenstern et al. (2015) state that the primary reason for the limited industry adoption of filtered tailings to date is economic, noting that risk costs for the potential failure of conventional tailings dams are generally not considered in cost comparisons used for tailings methodology selection. The average losses resulting from a single large catastrophic tailings dam failure has been reported at $543 million based on seven dam failures that occurred between 1994 and 2008 (refer to Bowker and Chambers, 2015 for further details).

With the increasing adoption of tailings dewatering technologies, both capital and operating costs can be expected to improve due to economies of scale and advances in technology and design, as noted by Davies et al. (2011). Additionally, water use costs are increasing in many areas of the world, resulting in projects where tailings dewatering is the most economical choice.

Describing the South African state of practice, Copeland et al. (2023) report that costs remain a key factor in selecting a tailings management system, with the filter stacking option having higher capital and operating costs in most cases. However, an increasing number of projects are assessing risks and other

benefits in terms of reputation, sustainability and responsible mining, increasing the likelihood of adoption of dewatering technologies.

Carneiro and Fourie (2019) present a realistic hypothetical cost comparison for various tailings management solutions for a gold mine in Australia, using a total life cycle cost approach. They showed that using the commonly used net present value (NPV) approach, the slurry disposal method demonstrated lower costs compared to the filtered option, as may be expected. However, when compared using a total life cycle cost approach (considering potential increased rehabilitation costs as well as water costs, land use costs and carbon taxes), the filtered tailings option was found to be the most cost-effective option. Although these results may not hold true in cases with no or low water and land use costs, the filtered tailings option was also found to be the most resilient of the studied options, since there is less uncertainty regarding mine closure and future regulatory changes.

Williams (2021) suggests taking this a step further, and that a change in thinking is required in how the industry views the economics of tailings management – specifically, relying on a NPV approach with a high discount factor, rather than consideration of the full life-cycle costs. The NPV approach favors lower cost options in the short term and therefore tends to favor slurry deposition and the deferral of rehabilitation costs. As quoted by Boger and Hart (2008), this accounting approach reflects the attitude that the future matters less than the present. Espinoza and Castro (2022) describe a decoupled NPV method of financial analysis for a mining project, where risks (such as tailings dam failures) are evaluated as costs. This method allows for reductions in risk (for example, by adopting dewatering methods) to be translated to decreased cost to the project, compared to the traditional NPV approach where future rehabilitation or remediation costs are discounted and therefore additional upfront costs for dewatering technologies cannot be economically justified.

Cox et al. (2022) state that one of the current obstacles to greater adoption of tailings dewatering technologies is a poor understanding of the actual costs of conventional tailings storage. The study presents a unified costing metric to understand the actual cost of tailings facilities from the pre-feasibility stage to final closure. The study reported that data presented in the Canadian National Instrument 43-101 technical reporting standard typically underreports tailings facility costs due to data consolidation across varying cost categories and expense types. This is an issue that the authors have faced in the preparation of this paper as well as in trade-off studies for the selection of tailings disposal methods. The metric proposed by Cox et al. (2022) avoids the use of NPV and cost discounting for the reasons discussed earlier. It should be noted that the metric excludes risk costs of tailings dam failure due to the unavailability of a framework for establishing those costs; however, the metric could be expanded to include those risk costs. Although the proposed metric does not address filtered tailings storage, a clearer picture of the actual costs of conventional tailings disposal is likely to encourage greater adoption of tailings dewatering technologies.

Other factors

In their keynote address at Paste 2008, Boger and Hart (2008) explored the reasons why a larger proportion of the industry had not adopted more sustainable practices such as filtered tailings stacks. Their conclusion was that additional regulations mandating the use of a certain tailings disposal method was unlikely to be feasible. Following the two recent and significant failures of tailings facilities in Brazil, unprecedented changes were made to Brazilian regulations, including a total ban on upstream tailings dams. All existing upstream tailings dams in the country must also be decommissioned to remove the risk of failure. While not mandating the use of dewatering technologies, the regulations require consideration of alternative construction methods with the prioritization of safer methods.

On the conservative nature of the mining industry, Leonida (2020) invokes the old adage that miners prefer to be "first to be second" when it comes to adopting new technologies. It is understandable that mine owners wish to avoid the risk of technical issues related to being the early adopters of a given technology. One potential solution to this could be for more mines to implement partial dewatering of their tailings, allowing them to gain experience and confidence in the process while maintaining systems for managing conventional tailings. Leonida (2020) reports that the operational savings in terms of water and power savings could quickly offset the initial high capital cost of the filtration system, in addition to increasing the service life of existing tailings impoundments.

Additionally, in many regions of the world, there is no local experience with tailings dewatering technologies. In such an environment and in the absence of drivers such as regulations, the status quo may continue to prevail. As noted by Williams (2021), forms of tailings containment used in a given location appear to be primarily a result of past experience and established regional practices, which are noted to be difficult to change.

Conclusion

In 2011, Davies (2011) stated that "conventional tailings impoundments remain the best alternative for the majority of operating and proposed mines around the world." Notwithstanding the site-specific nature of dewatering technology selection, the authors question whether this statement stands in the post-GISTM landscape. Supporting this sentiment, Leonida (2020) noted near unanimous agreement among dewatering equipment suppliers, engineering firms, and mining companies that filter stacking is the most promising and broadly applicable method for tailings storage in the future.

A review of industry trends suggests that tailings dewatering technologies are not reaching their full potential. While there are technical arguments and other relevant factors such as resistance to change, the primary reason for this state of affairs, in the authors' view, comes down to cost. As stated by Morgenstern

et al. (2015) in the wake of the Mount Polley failure, "While economic factors cannot be neglected, neither can they continue to pre-empt best technology."

As per Williams (2021), "There is a commonly held perception that transporting tailings as a slurry is the most economical option." While this seems to be the prevailing belief in the industry, the authors question whether it reflects reality when the true costs of closure (sometimes requiring active management in perpetuity), risk of failure, and uncertainty are appropriately accounted for. The traditional NPV approach commonly used in selecting the tailings disposal option implicitly prioritizes minimizing up-front costs.

The following recommendations are suggested to support greater adoption of dewatering technologies:

- Research into technical aspects of tailings dewatering technologies should be continued to resolve remaining areas of uncertainty, such as consideration of tailings runout potential for dewatered tailings.
- Tailings management costs should be considered using a total life cycle cost approach, avoiding the use of NPV and cost discounting.
- Greater transparency in the costs of tailings management should be included in disclosures.
- The sharing of industry experience in conferences and the participation of practitioners worldwide is important in expanding the implementation of dewatering technologies in new regions.

Although it is too early to truly measure the impact of recent events such as the release of the GISTM on the adoption of tailings dewatering technologies, it does appear that there is growing knowledge of the benefits of dewatering in the industry and greater emphasis being placed on socioeconomic factors where filtered tailings demonstrate benefits over conventional tailings facilities. Transformative change is often triggered by catastrophic disasters, of which there have been many recent examples in the mining industry. It is our hope that the industry will continue to adopt dewatering methods at a greater rate for more sustainable and safer tailings management, without waiting for further loss of life.

Monitoring Tailings Saturation at a TSF Using Tensiometers and Laboratory SWCC

Mahmoud N. Hussien, WSP, Canada
Soumia El Mansouri, WSP, Canada
Vu Tran, Eldorado Gold, Canada
Eric Cloutier, Eldorado Gold, Canada

Abstract

This study investigates the significance of understanding and accounting for the unsaturated nature of tailings in the mining industry. It presents a case study of an upstream-raised dam in Quebec, Canada, covering the geotechnical campaign and material characterization carried out to determine the saturation condition of the tailings above phreatic surface. This article discusses the installation of tensiometer sensors to measure the matric suction and indirectly estimate the tailings' degree of saturation, as well as a brief overview of the calibration procedure used to improve the precision of water content measurements in these sensors. Data was collected using an automated system and the results, when combined with laboratory results in terms of soil water characteristic curves (SWCC) of tailings, show that the sensor properly represented the expected saturation profile, with saturations near 100% below the water table and progressively declining toward the tailings surface. The outcomes of this study stress the need for characterizing the unsaturated zone of tailings above the phreatic surface to gain a better understanding of the TSF's overall performance and to ensure robust design.

Introduction

Significant research has recently been undertaken on the degree of saturation in tailings above the water table (e.g., Rust and Rust, 2023; Souza et al., 2023). This type of assessment is critical when determining the extent of the liquefiable zone in a tailings profile, particularly when using the traditional subaerial deposition method with slurry tailings. The concept of full saturation below the phreatic surface and at the capillary fringe is well understood. Above this level, the profile usually comprises moist layers of finer (silty) and coarser (sandy) tailings, indicating desiccation, with pore water retained under suction (negative pressure). These strata have no hydraulic connection to the groundwater profile beneath them and will remain saturated until the suction surpasses the tailings' air entry value (AEV).

This study investigates the importance of recognizing and accounting for the unsaturated nature of tailings above the phreatic surface in the mining industry. It presents a case study of an upstream-raised dam in Quebec, Canada, including the geotechnical campaign and material characterization used to evaluate the saturation condition of tailings above the phreatic surface. This article discusses the installation of tensiometers sensors to measure the matric suction and indirectly estimate the tailings' degree of saturation, as well as a brief overview of the calibration procedure used to improve the precision of water content measurements in these sensors. The findings of this study highlight the importance of defining the unsaturated zone of tailings above the phreatic surface to get a better understanding of the TSF's overall performance and ensure robust design.

Case study: tailings storage facility

The tailings storage facility (TSF) is in Quebec, Canada, and tailings are deposited via traditional slurry deposition. The TSF was constructed utilizing the upstream method, in which each stage of the dyke was progressively raised on top of previously deposited tailings, causing the dyke's crest to shift inward (upstream) with each raise. Figure 1 shows one cross-section of the TSF's dykes, the geotechnical units that comprise the section, and the phreatic condition.

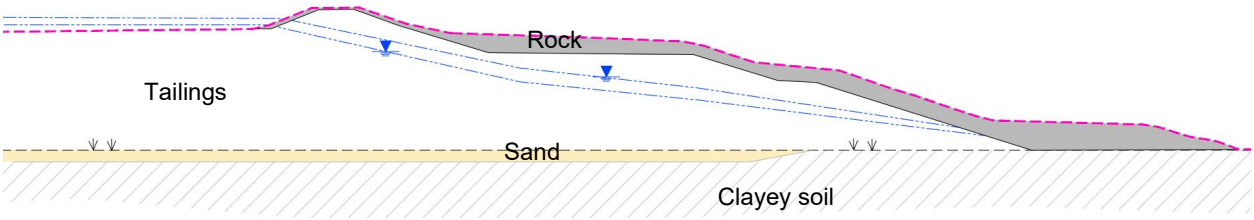

Figure 1: One cross-section of the TSF's dykes

Field investigation for tensiometers installation

As part of the continual improvement of the TSF operation, twenty tensiometers (TEROS-21, GEN 2 from Meter Group) were strategically installed at various depths in four geotechnical boreholes (5 tensiometers in each borehole) at three critical sections around the TSF to characterize the unsaturated areas of deposited tailings. The tensiometers were installed in the same locations as the existing piezometers to gain a complete understanding of both positive and negative water pressures at these sections. A geotechnical field investigation as well as laboratory tests were also completed, to measure the matric suction of deposited tailings and quantify their mechanical responses to feed the geotechnical model and to aid the detailed engineering design. The basic information regarding boreholes and tensiometers is summarized in Table 1.

The TEROS-21 system consists of a ceramic-tipped sensor, a datalogger, and a power supply. Figure 2 illustrates the components of a TEROS-21 sensor that can be used to measure the water potential and temperature of soil with porous ceramic discs. More specifically, the water potential is obtained from measuring the changes of moisture content of two engineered ceramic discs sandwiched between stainless steel screens and the circuit board.

Table 1: Basic information of tensiometers installed in each borehole

Borehole No.	No. of tensiometer	Elevation of the tensiometer (m)
TN-21-01	T-01	312.20
	T-02	313.20
	T-03	314.20
	T-04	315.20
	T-05	316.20
TN-21-02	T-06	313.00
	T-07	314.00
	T-08	315.00
	T-09	316.00
	T-10	317.00
TN-21-03	T-11	312.00
	T-12	313.00
	T-13	314.00
	T-14	315.00
	T-15	316.00
TN-21-04	T-16	313.00
	T-17	314.00
	T-18	316.00
	T-19	317.00
	T-20	319.00

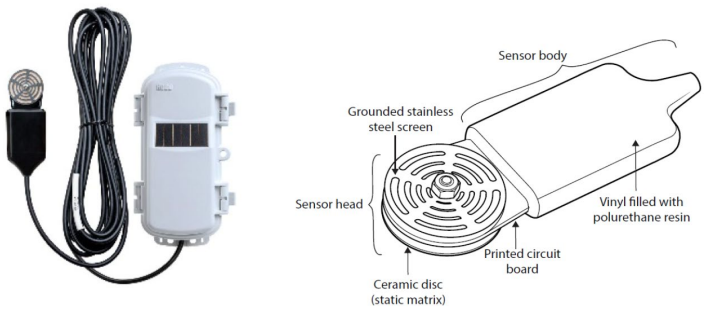

Figure 2: TEROS-21 sensor (source: TEROS-21 sensor manuals)

Five tensiometers were installed in each borehole (20 tensiometers were installed in total). The waste rock layer on top of the tailings layer was locally removed before starting the drilling. Figure 3 schematically illustrates the five tensiometers installed in a typical borehole.

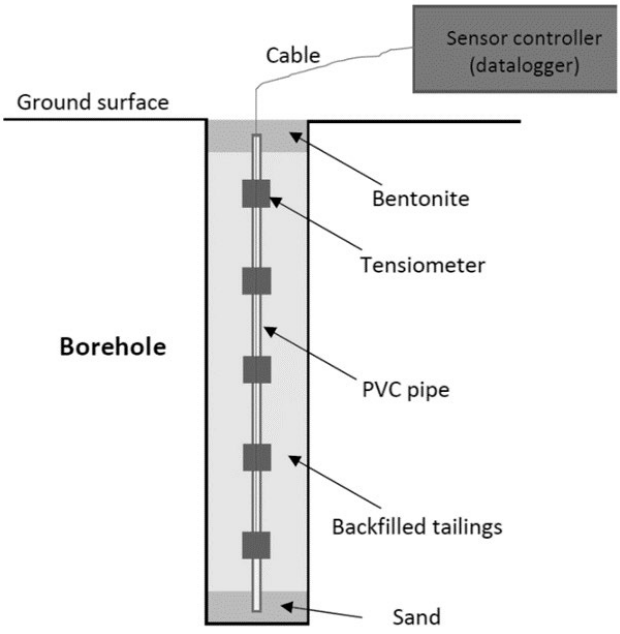

Figure 3: The schematical cross-section for tensiometers installed in a borehole

A split spoon was used to collect tailings samples from predefined elevations, and a tensiometer assembly (five tensiometers tied to a PVC pipe at a predetermined spacing) was carefully placed at each of the four drilled holes. As shown in Figure 3, a sand layer and backfilled tailings were placed on the borehole, whose top was sealed with Bentonite pellets. The datalogger (HOBO RX3000) is programmed and is being used for data collection.

Tensiometers calibration

TEROS-21 was designed to be a maintenance-free matric potential sensor designed for long-term, continuous field measurements. The TEROS-21 measures the dielectric permittivity of a solid matrix to determine the water content of the solid matrix. The relationship between water content and matric potential, known as the soil moisture characteristic curve, is used to calculate the soil matric potential. TEROS-21 is calibrated at a saturated state (0 kPa), at a dry state equivalent to −100,000 kPa, and at four calibration points between 0 and −100 kPa, resulting in accuracy of ± (10% of reading + 2 kPa) over the range of −9 to −100 kPa.

TEROS-21 calibration is not affected by soil type because the sensors only measure the water potential of the ceramic discs in equilibrium with the soil.

Laboratory tests

Basic laboratory tests (water content, specific gravity, and grain size analyses) on tailings samples extracted from tensiometers boreholes were completed in December 2022. The water content of the tailings was measured for 22 samples taken from the site. It varies between 9.40 % (TN-21-01) and 26.50 % (TN-21-04). For borehole TN-21-04, it is seen that the water content of tailings generally increases from the top to bottom, indicating an increased degree of saturation from surface to phreatic surface. This tendency is also observed for borehole TN-21-03.

Specific gravity of the tailings measured for 6 tailings samples vary between 2.751 (TN-21-03) and 2.856 (TN-21-04).

A total of four grain size analyses, by both sieve and hydrometer, were conducted on the tailings' samples at different depths. The results of sieve and sedimentation analyses for coarse and fine particles are illustrated in Figure 4.

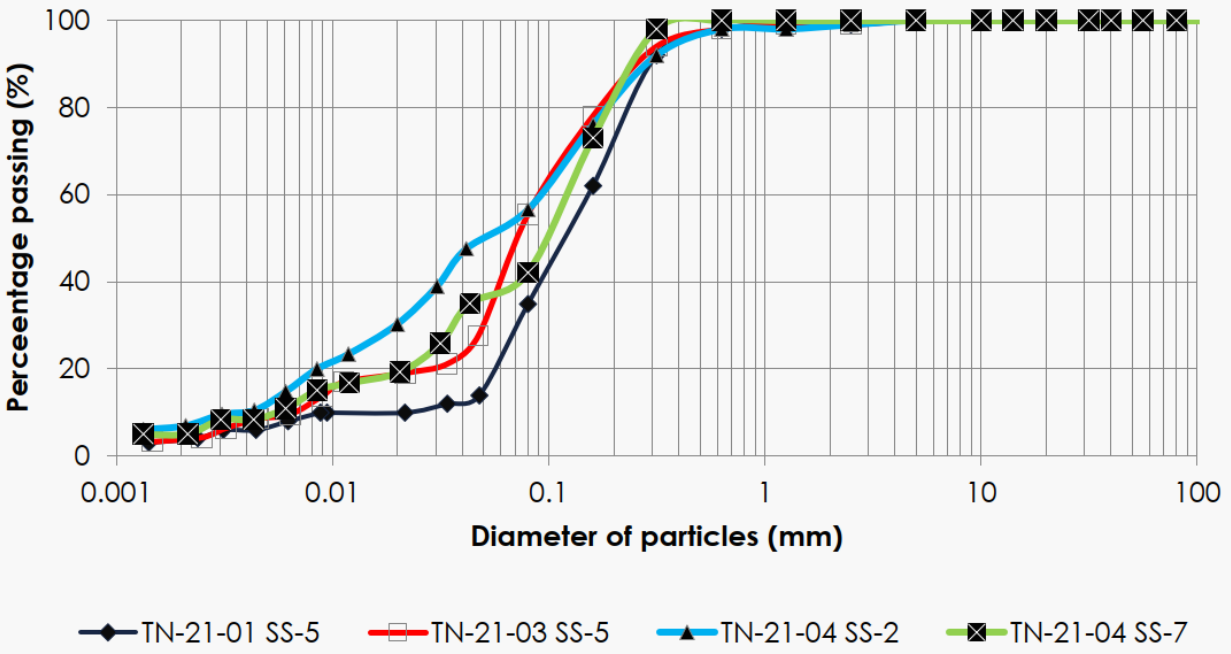

Figure 4: Particle size distribution of tailings samples

In December 2023, additional tailings samples were taken from the TSF from two additional boreholes drilled at 3 to 5 m away from the existing tensiometers boreholes (TN-21-01 and TN-21-04) to avoid disturbance. The driller went destructively to the target elevations and then the tailings were sampled using a split-spoon. These tailings samples were sent to a laboratory for Fredlund GCTS Soil Water Characteristic Curve (SWCC) testing to aid in the ongoing interpretation of the recorded tensiometer data. The SWCC defines the soil's ability to hold or release water. The curve depicts the mathematical relationship between

suction within a soil and water content or level of saturation. The curve generally exhibits two significant slope changes. The first change is the air entry value (AEV), which reflects the suction at which the soil transitions from saturated to partially saturated and is related with negative pore pressure. The second slope change indicates a state of equilibrium, which is known as residual moisture content. Figure 5 shows a typical SWCC.

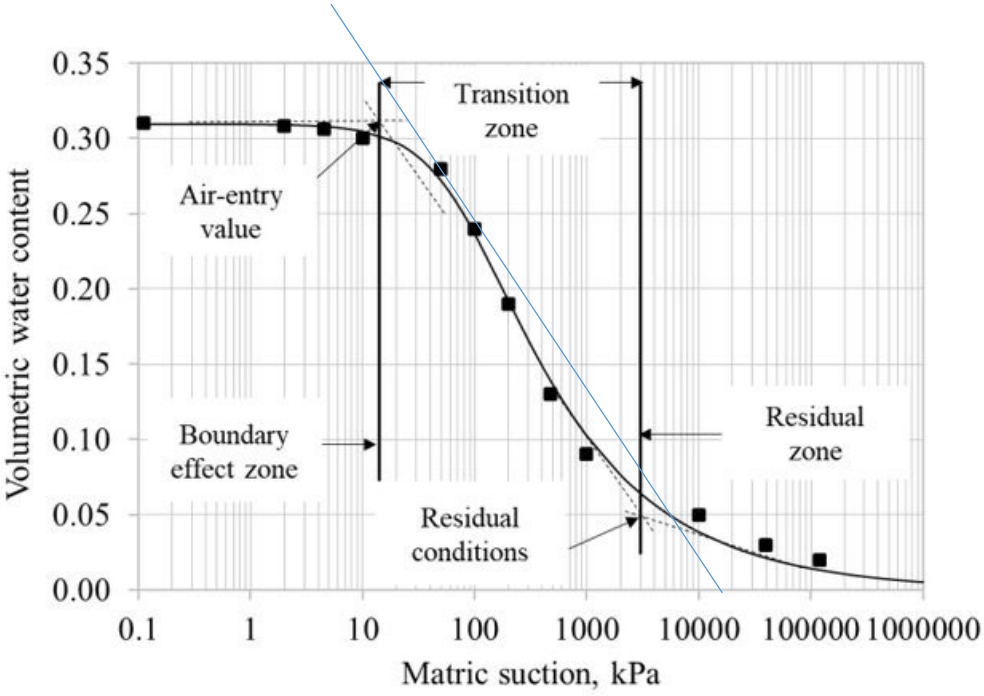

Figure 5: Typical soil water characteristic curve (SWCC)

One SWCC test was done, and the results are given in Figure 6. Figure 6 demonstrates that the AEV is 2 kPa, while the suction corresponds to %85 saturation of 17 kPa.

Tensiometers data interpretation

Figure 7 depicts a cross-section of the TSF dyke, along with the geotechnical units that make up the section and the phreatic condition. The tensiometer assembly TN-21-01 (T-01 to T-05) was installed in the same area as the piezometer (PW-21-30) to get a thorough understanding of both positive and negative water pressures in this section. Figure 8 shows the corresponding real-time data (piezometric data of PW-21-30 and suction of T-01). Suctions corresponding to the air entry value (AEV) and (%85 saturation) determined from a laboratory SWCC (Figure 6) are also shown in Figure 8 for comparison.

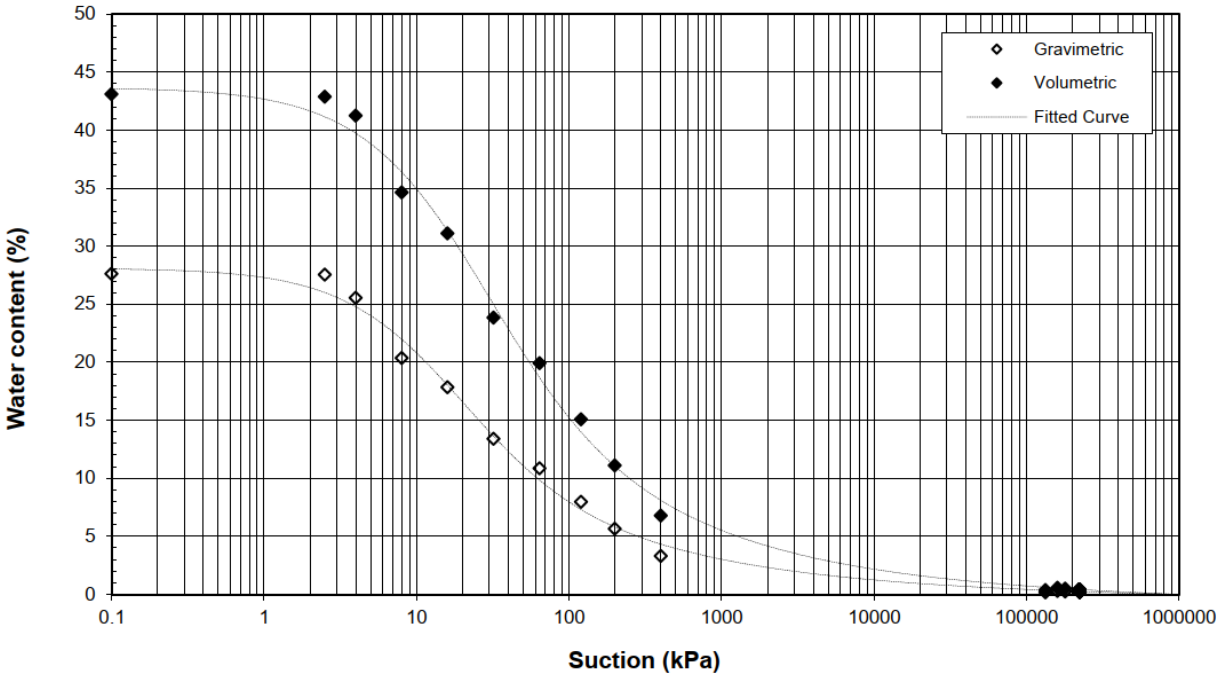

Figure 6: Laboratory soil water characteristic curve (SWCC) of tailings

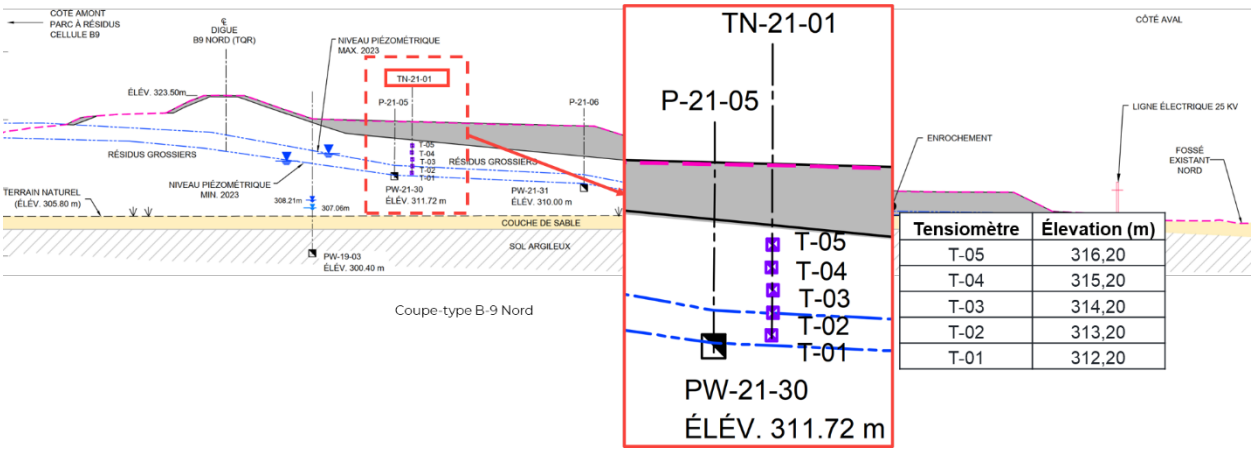

Figure 7: Tensiometers installed in the north dyke of B9 Cell

T-01 is the tensiometer that is closest to the phreatic surface. It was installed slightly above the phreatic surface and is subject to the fluctuation of water level. Figure 8 demonstrates that the tailings at the tensiometer T-01 have been typically saturated for the past year, with a trend toward unsaturation as suction gradually increases over winter (from March to May). However, the tailings at this level did not attain a true unsaturated condition since the suction value never exceeded the suction corresponding to %85 saturation (the dashed red line on the plot).

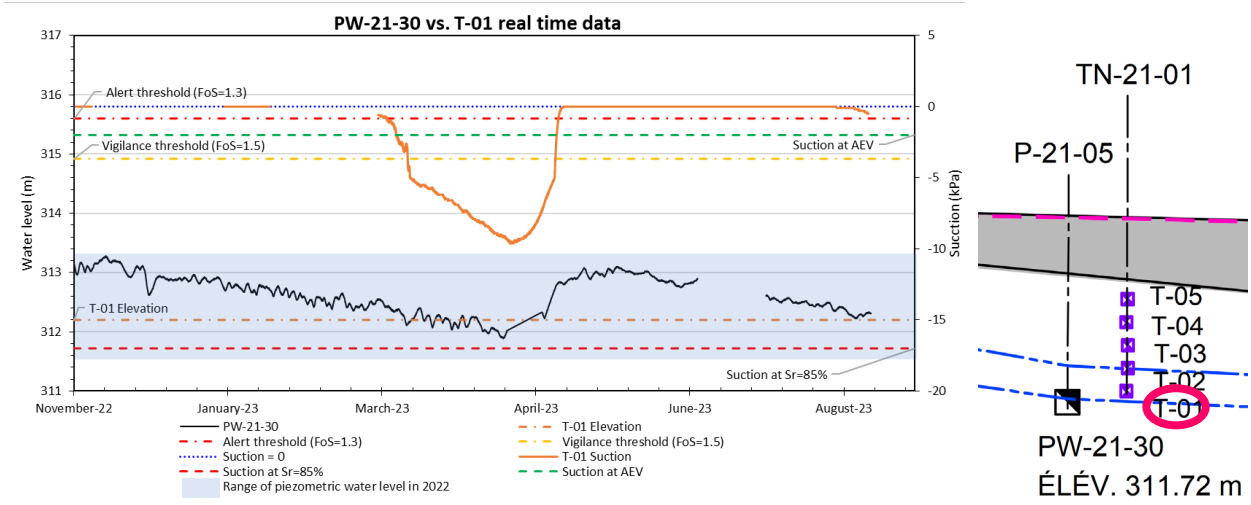

Figure 8: Real time data of piezometers (PW-21-30) and tensiometers (T-01)

Figure 9 shows the real-time data (piezometric data of PW-21-30 and suction of T-05). Suctions corresponding to AEV and (%85 saturation) are also shown on Figure 9 for comparison. T-05 is the tensiometer that is closest to the tailings surface. Figure 9 demonstrates that the tailings at the tensiometer T-05 have been typically unsaturated for the past year, and the recorded suctions exceeded the suction corresponding to %85 saturation at several occasions during the past year.

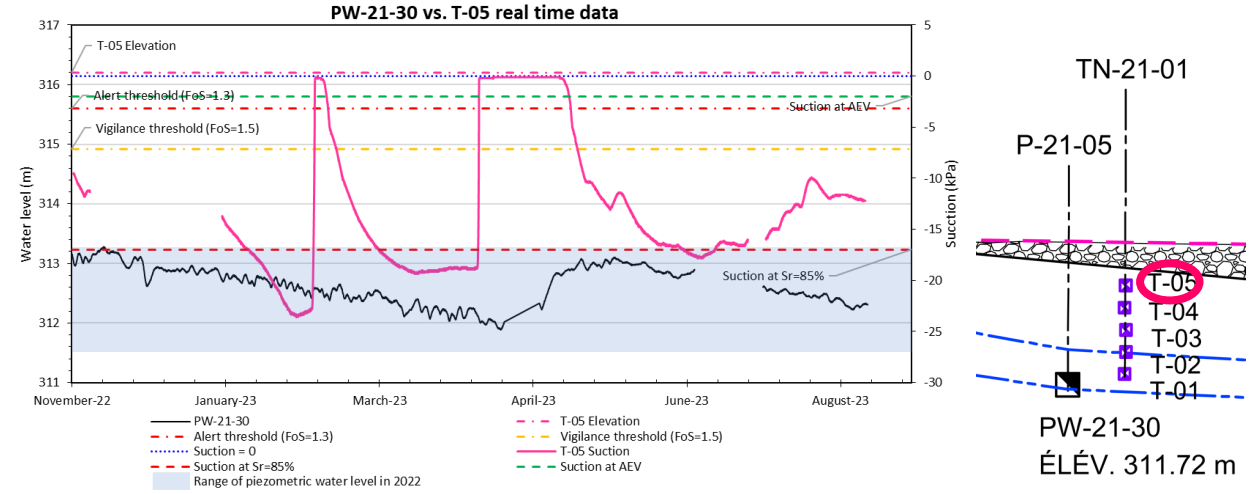

Figure 9: Real time data of piezometers (PW-21-30) and tensiometers (T-05)

Conclusion

This article discusses the installation of tensiometers sensors to measure the matric suction and indirectly estimate the tailings' degree of saturation. Data was collected using an automated system and the results, when combined with laboratory results in terms of soil water characteristic curves (SWCC) of tailings,

show that the sensor properly represented the expected saturation profile, with saturations near 100% below the water table and progressively declining toward the tailings surface. The outcomes of this study stress the need for characterizing the unsaturated zone of tailings above the phreatic surface to gain a better understanding of the TSF's overall performance and to ensure robust design.

A Framework to Determine Tailings Liquefaction – GISTM Conformance for the Holden Mine

Mohammad Rashidi, Stantec, USA
Phillip E. Crouse, Stantec, USA
Summer Y. Sun, Stantec, USA

Abstract

There are about 3,500 tailings dams worldwide storing billions of tons of mill and waste tailings from mineral processing activity at mine sites. Unlike traditional water storage dams, these structures possess distinct vulnerabilities due to factors such as multi-stage raising, utilization of mine waste materials in embankment construction, and regulatory deficiencies in certain regions. Alarmingly, over a third of these dams pose significant risks of catastrophic failure, endangering downstream communities, socio-economic activities, and ecological systems. One of the major risks associated with tailings dams is their potential vulnerability to liquefaction. This paper addresses this critical concern by presenting a practical, step-by-step liquefaction assessment process tailored for tailings dam engineers and practitioners.

The assessment methodology encompasses initial screening and straightforward liquefaction triggering analyses leveraging available field data, such as the cone penetration test (CPT) or the standard penetration test (SPT), followed by more in-depth numerical analyses. Furthermore, this study delineates the essential procedures for seismic deformation analyses of liquefiable tailings materials, encompassing aspects like constitutive model selection and calibration, site-specific modulus reduction and damping curve, and critical state line development.

Illustrating the application of this process, a case study of Holden mine (a legacy tailings storage facility) in the state of Washington is presented. The findings offer valuable insights into evaluating the liquefaction risk associated with tailings dams, serving as a preliminary guide for safer and more efficient tailings management practices and for achieving GISTM compliance.

Introduction

During the past decade, the mining industry has experienced a number of catastrophic tailings dam failures such as Mount Polley in the Cariboo region of central British Columbia in Canada (August 2014), and Samarco (November 2015), and Brumadinho (January 2019) in Brazil. Due to the severity of these major failures, the mining industry has significantly increased efforts to improve the design, construction,

operation, and management of TSFs. This increasing awareness has led to the development of the Global Industry Standard on Tailings Management (GISTM) (GTR, 2020). A fundamental part of these evolving guidelines is the emphasis on proper identification and evaluation of critical risks. For example, Principle 10 of the GISTM requires mine owners to establish and implement levels of review as part of a strong quality and risk management system for all phases of the tailings facility lifecycle, including closure.

Liquefaction has been one of the causes of the recent TSF failures. Therefore, a critical part of the risk assessment for any TSF is the liquefaction risk assessment. This assessment often involves two important parts: assessment of extent and location of where liquefaction is likely, and evaluation of the likely consequences of liquefaction.

Liquefaction occurs when saturated soil loses a substantial amount of its original shear strength due to pore pressure generation resulting from an earthquake. Static liquefaction is also possible due to redistribution of pore pressure. The pore pressure is generated during an earthquake because the soil particles tend to compact rather quickly without allowing for the generated excess pore pressures to dissipate. This increase in pore pressure, in turn, reduces the effective stress and shear strength. The risk of liquefaction is higher in contractive tailings materials, including relatively loose natural soils and poorly compacted or uncompacted fill materials.

Approach

A step-by-step approach to evaluate the liquefaction risk for Holden's tailings piles is illustrated in Figure 1 and discussed below. It should be noted that the approach proposed here is focused on the liquefaction of tailings material, with the assumption that the foundation materials are competent and non-liquefiable. However, the same approach may be applied to perform liquefaction assessment of the foundation or any other zone in a tailings dam.

Step 1: Seismic Hazard Assessment (SHA)

Deterministic seismic hazard analysis (DSHA) and probabilistic seismic hazard analysis (PSHA) are two distinct methods for assessing seismic hazards. DSHA involves selecting a specific earthquake scenario, typically the largest credible earthquake, to determine its effects on a site, providing a single estimate of ground motion parameters for this worst-case event. It is often used for critical active tailings storage facilities projects. In contrast, PSHA considers the probabilities of all potential earthquakes and their combined impact, producing probabilistic estimates of ground motion over time, typically presented as hazard curves and used in inactive tailings storage facilities and risk assessments. DSHA focuses on understanding the maximum potential impact from a single event, while PSHA provides a comprehensive view of seismic risk by integrating the likelihood of various earthquakes.

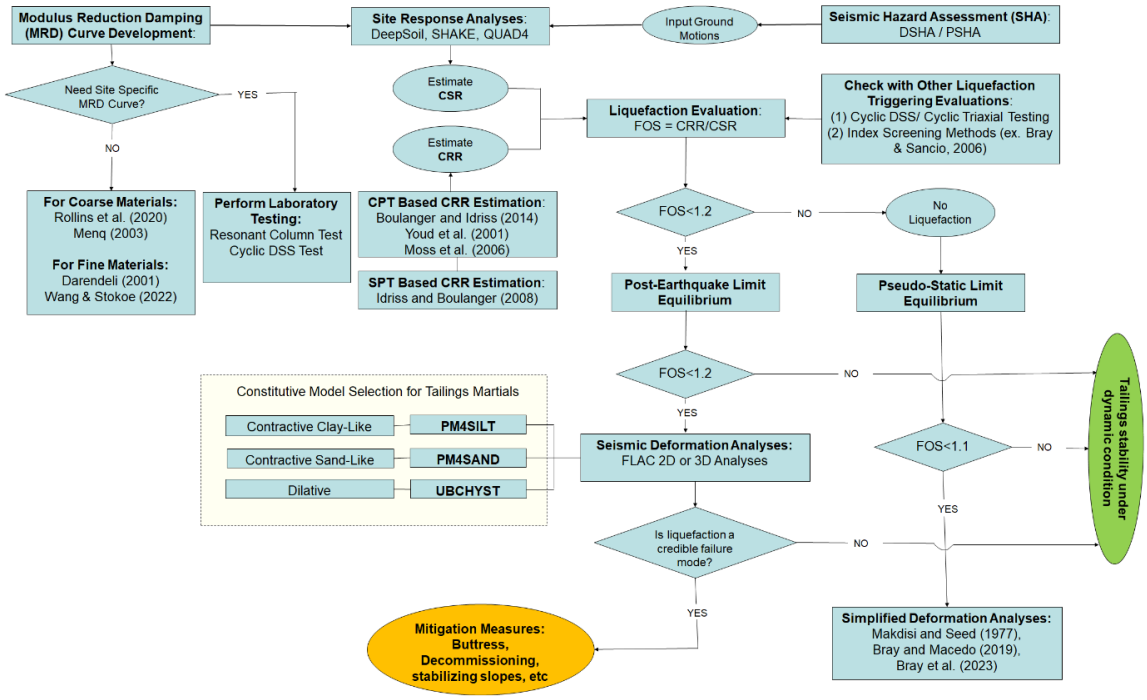

Figure 1: Assessment framework for tailings liquefaction in GISTM compliance

PSHA was used for seismic hazard assessment of Holden's tailings piles. An earthquake moment magnitude (Mw) of 6.3 and peak ground acceleration (PGA) of 0.33g for an earthquake, corresponding to an event with an annual exceedance probability of 1:10,000, was developed.

Seven time-histories corresponding to the three controlling earthquakes (including 1 Interface, 3 Intraslab, and 3 Crustal) were developed for seismic deformation analysis of Holden's mine tailings piles.

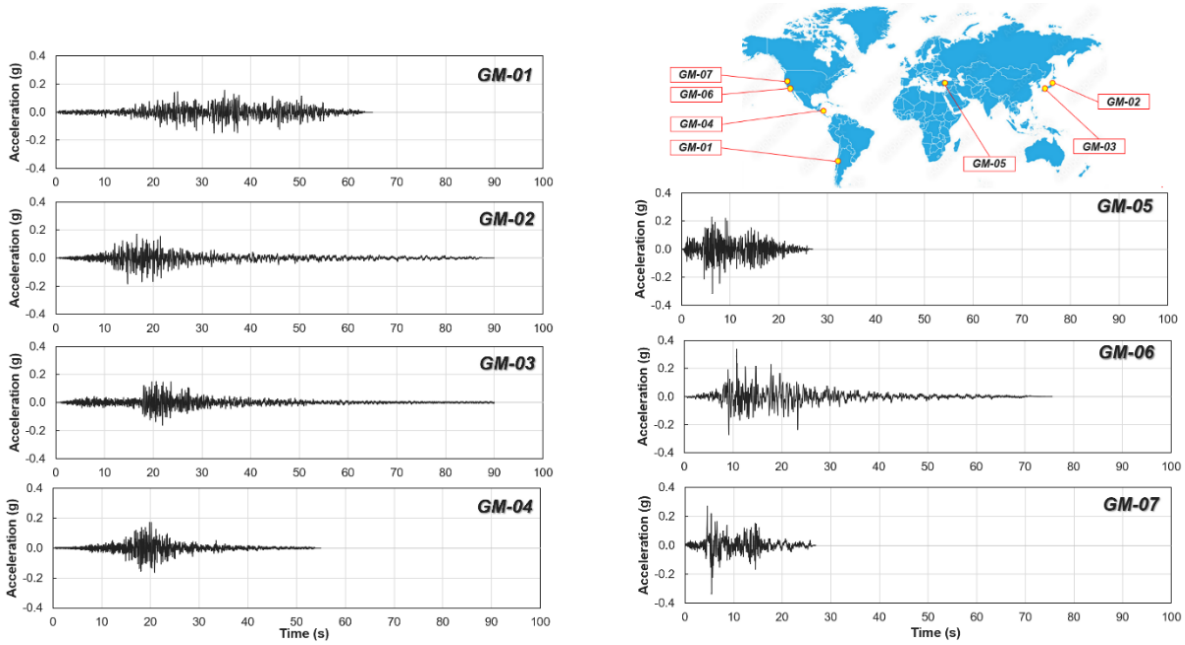

Figure 2: Developed time histories

Step 2: Shear modulus and damping curves

Shear modulus reduction and damping curves provide the change in stiffness and damping properties of tailings with increasing shear strain. These curves are non-linear and illustrate the behavior of tailings material during seismic events. They are used in the site response and dynamic deformation analyses.

The shear modulus reduction curve and equivalent damping ratio curve can be developed from laboratory test results, including resonant column tests for lower shear strains (<0.03%) and cyclic direct simple shear (DSS) tests for higher shear strains (>0.1%). Figure 3 illustrates the modulus reduction and damping curves developed for Holden's tailings materials from laboratory data obtained through cyclic DSS and resonant column tests.

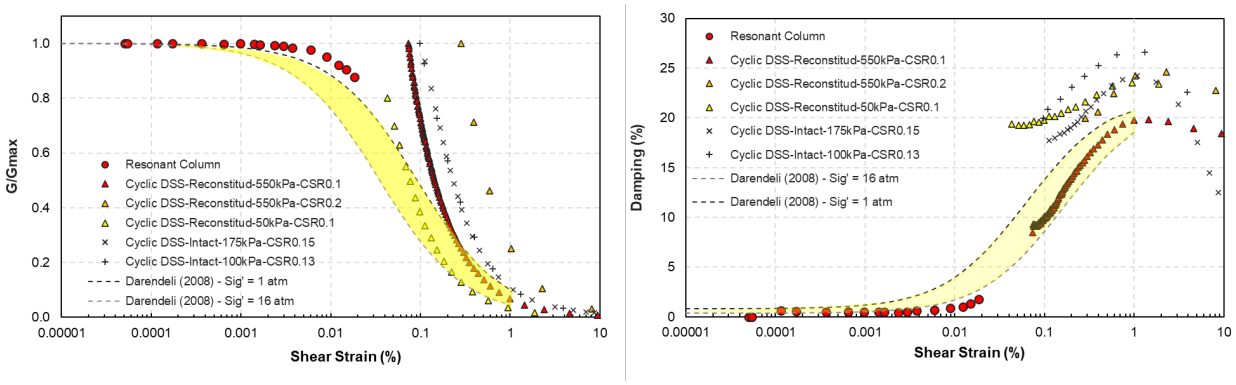

Figure 3: Shear modulus reduction and equivalent damping ratios (Holden Mine)

In the absence of laboratory data, empirical curves can be used to estimate the modulus reduction and damping curves. For coarse materials, references include Rollins et al. (1998) and Menq (2003), while for fine materials, references include Darendeli (2001) and Wang and Stokoe (2021). The developed curves for Holden tailings piles were compared with Darendeli (2001) for verification, as shown in Figure 3.

Step 3: Liquefaction triggering assessment

Liquefaction triggering analysis is used to assess the liquefaction potential of saturated tailings. In this project, a degree of saturation of over 80% was used as the basis for defining liquefaction in the tailings piles. However, this threshold may vary between 80% and 90% for other sites. The analysis consists of comparing calculated cyclic resistance ratio (CRR), as calculated from field exploration data, to the cyclic stress ratio (CSR) values calculated from the 2D site response analysis.

Cyclic stress ratio (CSR)

The site response analysis is to assess the ground motions and induced cyclic stress ratio (CSR) in response to the design earthquake event. The CSR can be developed using software such as QUAD4M, SHAKE, DEEPSOIL, QUAKE/W, FLAC, or PLAXIS. The results from the site response analysis are used to develop

a general understanding of the tailings impoundment seismic response, identify potentially liquefiable zones (e.g., using CPT- or SPT-based liquefaction triggering analysis) and subsequent consequences, and to assess the induced CSRs to guide the laboratory testing program (e.g., cyclic simple shear and cyclic triaxial tests).

Cyclic resistance ratio (CRR)

Both the cone penetration test (CPT) and the standard penetration test (SPT) can be used to estimate CRR. Multiple approaches are available to calculate CRR from CPT data by utilizing different empirical equations, including Boulanger and Idriss (2014), Youd and Idriss (2001), and Moss et al. (2006). The method developed by Idriss and Boulanger (2008) is used in industry for estimation of CRR from SPT data. The factor of safety (FoS) for liquefaction triggering analyses is estimated with the following equation:

$$FOS = \frac{CRR}{CSR}$$

A target FoS of 1.2, as recommended by Idriss and Boulanger (2008), was adopted to determine if seismic liquefaction would be triggered. Figure 4 presents the liquefaction triggering analyses for one of the TP-2 cross sections. As shown in the plot, liquefaction triggering analysis indicated that most of the saturated materials are prone to the liquefaction.

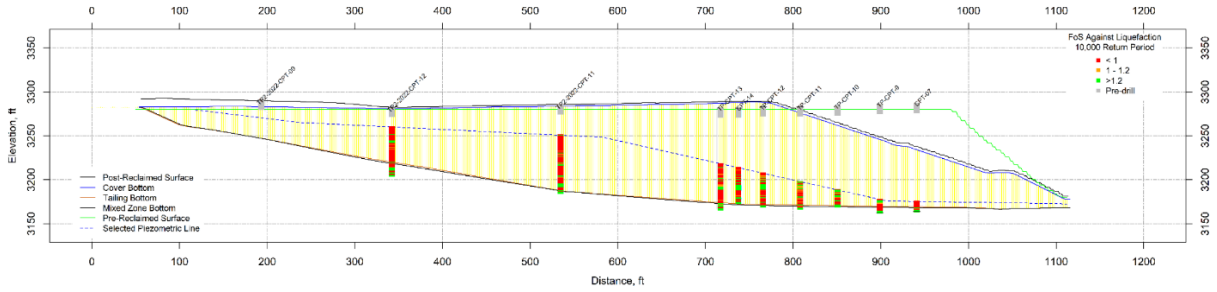

Figure 4: Liquefaction triggering analyses for TP-2

There are a few other checks for liquefaction triggering analyses of tailings materials that can be performed based on the available laboratory test results. These are:

1. cyclic testing methods (cyclic triaxial or DSS test), and
2. index screening methods.

The index screening method (Bray and Sancio, 2006) was performed for available samples. The results indicate that most of the samples fall in susceptible liquefaction zones, as shown in Figure 5, which was in line with performed liquefaction triggering analyses results.

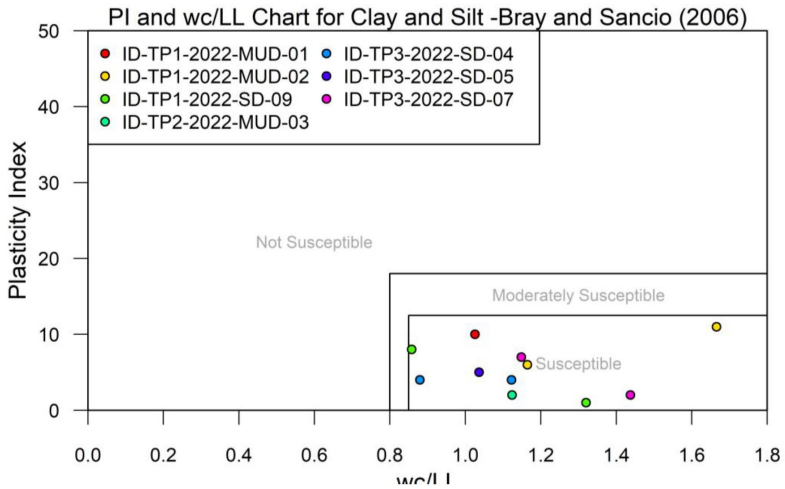

Figure 5: Index screening methods (Bray and Sancio, 2006)

Step 4: Post-earthquake limit equilibrium analyses

Upon completion of the previous step, the project team will have a good understanding of the potentially liquefiable zones within their TSF. If the analyses showed zones with a liquefaction FoS of less than 1.2, it indicates that these zones are potentially liquefiable. The next step would be to perform a post-earthquake stability analysis to evaluate the post-liquefaction stability of the tailings dam. This analysis can be done using a limit-equilibrium or other methods. In this analysis, the zones with a liquefaction FoS lower than 1.2 are assumed to liquefy, and therefore are given a post-liquefaction residual shear strength. Zones that are judged to be non-liquefiable but are not expected to be free draining (i.e., granular) will be modelled using a reduced strength to allow for potential strain softening during shaking.

Post-earthquake conditions reflect the state of the tailings immediately following the design earthquake. During such events, earthquakes can induce excess pore pressures in the saturated tailings materials. These increased pore pressures may result in liquefaction, cyclic mobility, or a reduction in strength, depending on whether the materials are in a contractive or dilatant state. The liquefied strength properties of the tailings materials were determined based on the results of liquefaction triggering analyses.

The calculated post-earthquake FoS can be used to evaluate the seismic stability of the tailings dam and judge whether large seismic displacements are expected. If the calculated FoS is larger than 1.2, it is typically indicative of the overall seismic stability with minimal anticipated seismic-induced deformations. If the FoS is between 1.0 and 1.2, performing a seismic deformation analysis may be warranted to estimate likely seismic deformations. A FoS of less than 1.0 is a likely indicator of large displacements, which also needs to be evaluated by performing a seismic deformation analysis.

Post-earthquake limit equilibrium analyses for the Holden tailings impoundment revealed that the FOS ranged from 0.9 to 1.6, with one of the eleven selected cross-sections falling below 1.0. Consequently,

we conducted seismic deformation analyses using FLAC (Fast Lagrangian Analysis of Continua). Detailed results of these analyses are presented in the next section.

Step 5: Seismic deformation analyses

Material properties for tailings materials

Tailings groups were assigned from group A through E based on the estimated fines content as demonstrated in Table 1. The material properties for each tailings materials group includes unit weight (γ), effective friction angle (ϕ'), peak and liquified undrained shear strength ratios, Poisson's ratio (v), and shear wave velocity (Vs).

Table 1: Tailings grouping criteria

Tailings group	Group A	Group B	Group C	Group D	Group E
Fines content limits	< 36%	> 36% and < 60%	> 60% and < 76%	> 76% and < 88%	> 88%

Selection of constitutive models and calibration process

This section provides the selection process for the constitutive models in each tailings gradation bandwidth group and calibration approach for the seismic deformation analyses. Constitutive models provide the numerical framework that relates increments of strain to increments of stress. The response of the constitutive model will determine the amount of plastic strain that occurs in the tailings material and therefore how much permanent deformation of the tailings pile is predicted. The response of the constitutive model depends on the initial conditions (i.e., state of stress from static initialization), the input parameters of the model, and the imposed loading. The behavior of nonlinear constitutive models may evolve during the analysis based on the loading and the response of the global analysis model.

The choice of constitutive models for advanced analysis should be based on how well each model represents the soil behavior that is considered important to the problem under consideration. Bedrock was assigned elastic behavior based on the consideration that these materials are not expected to experience significant nonlinearity. The Mohr-Coulomb constitutive model (linear elastic-plastic) was assigned to alluvium/glacial till, recompacted tailings, sludge filter, compacted waste rock, cover materials, and jet grout columns.

We tried to utilize more sophisticated constitutive models to simulate hardening/softening behavior and capture stiffness degradation and pore water pressure development for tailings materials. The constitutive models assigned to the tailings materials in the Holden mine project are shown in Figure 6.

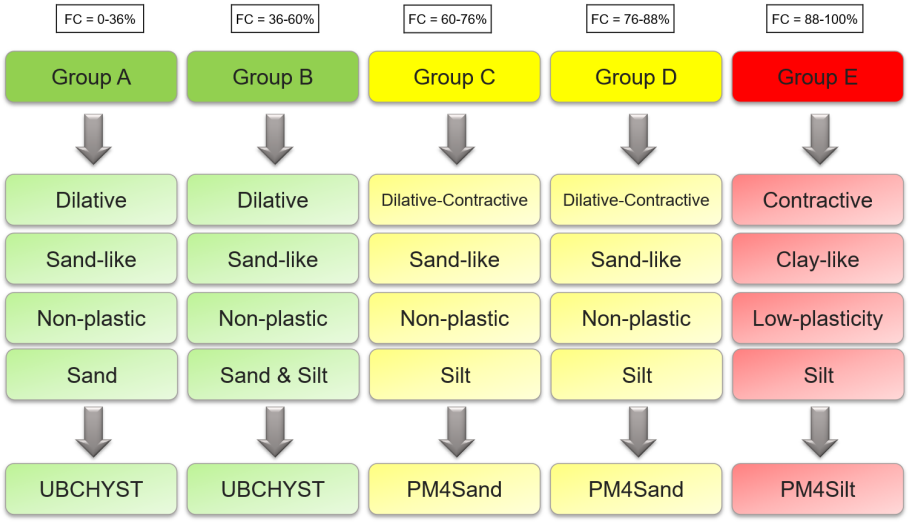

Figure 6: Selection of constitutive model for different tailings materials

As demonstrated in Figure 6, coarse tailings (groups A and B with fine content ranging from 0 to 60%) were assigned to the UBCHYST model (Naesgaard et al., 2011) as one of the robust constitutive models to simulate non-liquefiable soils subjected to earthquake loading. These layers are non-plastic dilative sand and silt, which are mainly located in the unsaturated tailings zones and are not susceptible to liquefaction.

Fine tailings materials (groups C, D, and E with fine content ranging from 60% to 100%) were assigned the PM4Silt and PM4Sand constitutive model to capture potential cyclic softening of the liquifiable tailings layers. PM4Sand and PM4Silt are nonlinear effective stress models that are coupled with pore water pressure response that can simulate flow liquefaction during a seismic event. As shown in Figure 6, PM4Sand was assigned to groups C and D since these tailings materials are sand-like non-plastic silt, while PM4Silt was assigned to the group E (finest group), which was categorized as a clay-like low-plasticity silt.

The PM4Silt (Boulanger and Ziotopoulou, 2018) model includes modifications, relative to PM4Sand (Boulanger and Ziotopoulou, 2015) that improve its ability to approximate the monotonic undrained strength, cyclic undrained strength, and secant shear modulus and equivalent damping ratio behaviors of low plasticity clays and silts, as opposed to those for purely non-plastic silts or sands. The calibration process for the UBCHYST, PM4Sand, and PM4Silt constitutive models were performed. The following section summarizes the calibration process for PM4Silt as an example.

PM4Silt calibration

The materials assigned the PM4Silt model were calibrated, using a single-element model to simulate monotonic direct simple shear (DSS) loading, cyclic DSS loading with uniform cyclic stress ratios, and

cyclic DSS loading at different cyclic strain amplitudes to obtain secant shear moduli and equivalent damping ratios. Figure 7 shows the calibration process for the PM4Silt constitutive model, which requires eight steps.

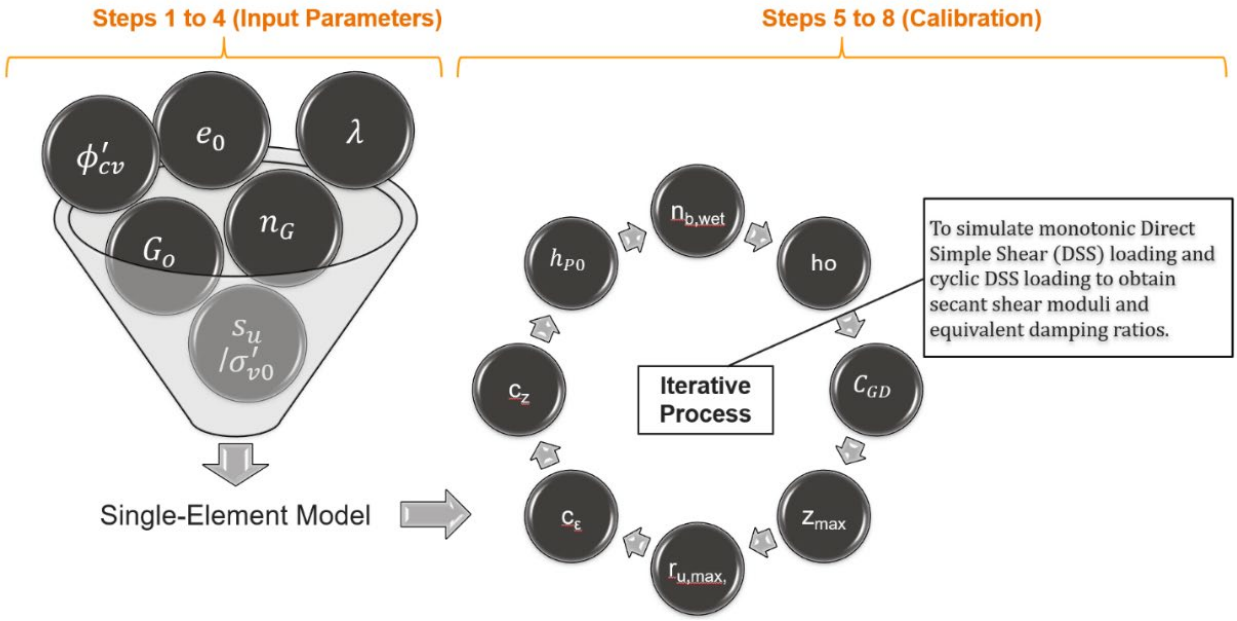

Figure 7: PM4Silt calibration process

Figure 8 demonstrates how the slope of slope of the critical state line (λ), shear modulus coefficients (G_o and n_G), monotonic loading asjuster ($n_{b,wet}$), and contraction rate parameter (h_0) were estimated or calibrated based on the available laboratory and field-testing results. Figure 9 shows that the fabric growth parameter (c_z), strain accumulation rate factor (c_ε), fabric term (Z_{max}), **and** modulus degradation factor (C_{GD}) have been calibrated to match stress path responses in undrained cyclic DSS loading.

Seismic deformation analysis results

The computer program FLAC was utilized to perform nonlinear seismic deformation analysis. The discretized analysis sections for TP-1 are shown in Figure 10. The seismic deformation analysis results indicated maximum horizontal deformations of 4, 6.5, and 5.5 for TP-1, TP-2, and TP-3, respectively. Figure 11 and Figure 12 present the total horizontal displacement and excess pore water pressure ratio for TP-1. As shown in the plot, there are limited zones where the pore water pressure ratios exceeded 0.85 (blue zones), indicating liquefaction. These deformations are considered acceptable since they occur near the upper section of the tailings piles and not at the toe.

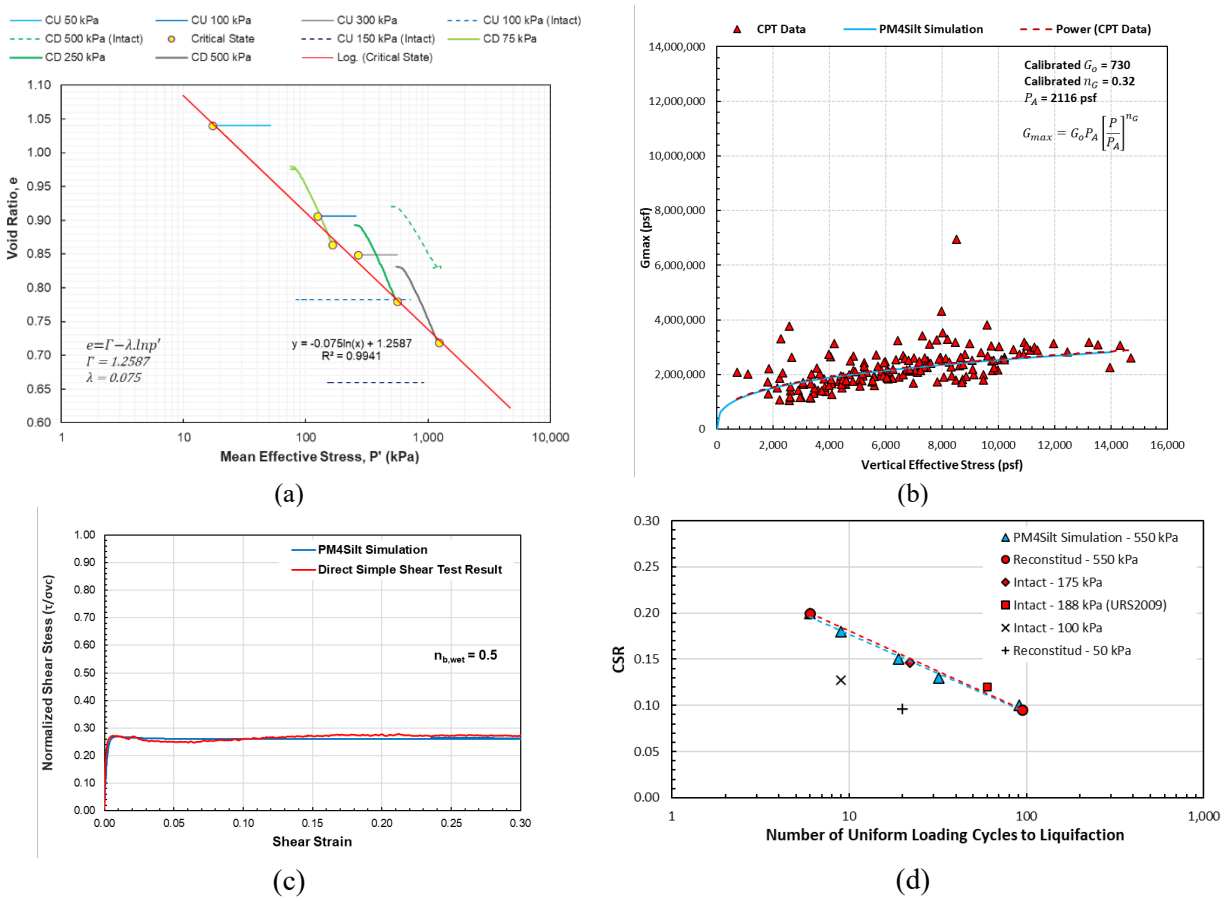

Figure 8: PM4Silt calibration: (a) slope of critical state line, (b) shear modulus coefficient, (c) monotonic loading asjuster ($n_{b,wet}$), and (d) contraction rate parameter

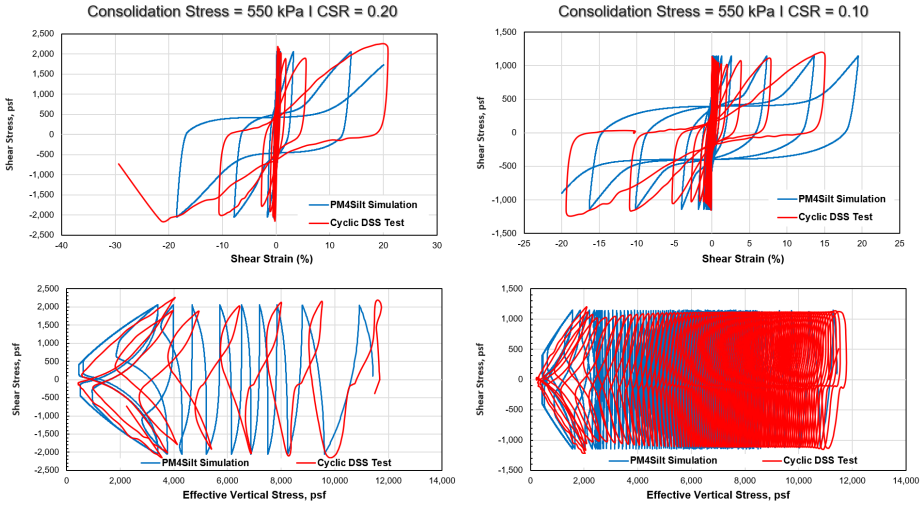

Figure 9: Stress path responses in undrained cyclic DSS loading

Three factors, including high confining pressure, high fine content, and a deeper groundwater table in Holden's tailings piles, inhibit the liquefaction process in the saturated slime layer. Observations from

various case histories reveal that the potential liquefaction zone typically spans from the ground surface down to a maximum depth of 30 feet (10 meters). It is noteworthy that deeper soil layers, influenced by augmented confining pressures, as indicated by Day (2010), tend not to undergo liquefaction due to these increased pressures. Examination of all tailings piles (TPs) shows that the layer prone to liquefaction resides at depths greater than 50 feet. This depth places these layers under excessive overburden pressure from the upper tailings materials.

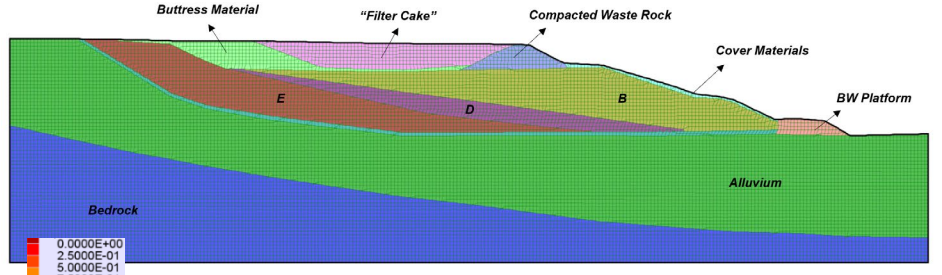

Figure 10: Discretized analysis section for TP-1

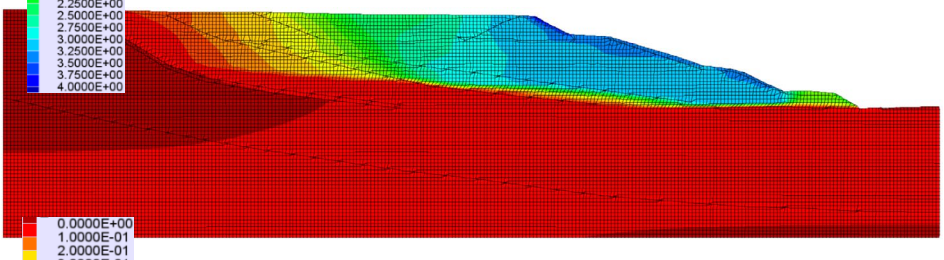

Figure 11: Horizontal displacement for TP-1

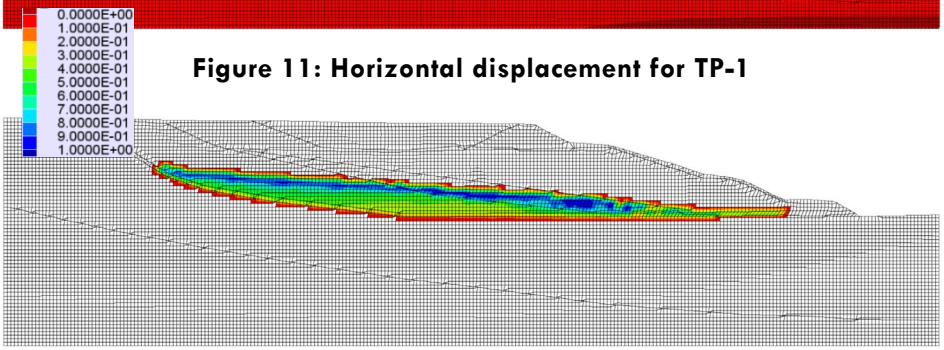

Figure 12: Excess pore water pressure ratio for TP-1

Conclusion

This paper outlined a methodology for assessing liquefaction risk in tailings dams, which possess unique vulnerabilities due to their construction methods and materials. The Holden mine case study applied the outlined assessment framework for tailings liquefaction in GISTM compliance. The study identified zones susceptible to liquefaction, conducted post-earthquake stability analyses, and used advanced numerical methods for seismic deformation analysis. These analyses indicated that while certain sections of the tailings piles were prone to liquefaction, the overall deformation levels were within acceptable limits. This comprehensive evaluation not only highlighted the specific risks associated with the Holden mine but also

validated the effectiveness of the proposed assessment process in real-world scenarios. By adopting this structured assessment process, engineers and practitioners can enhance the safety and efficiency of tailings management practices. The methodology aligns with the GISTM, providing a practical guide for compliance and risk mitigation. Ultimately, this approach helps to protect downstream communities, preserve ecological systems, and provide long-term sustainability of mining operations.

Challenges and Mitigations to Bring a Historical Tailings Facility into Compliance with Modern Standards

Anthony Zhang, Tetra Tech, Canada
Chris Johns, Tetra Tech, Canada

Abstract

This paper presents a summary of the work undertaken by Klondike Silver and Tetra Tech to assess and manage risk associated with tailings management facility (TMF) infrastructure at a lead-zinc mine in interior BC. The underground lead-zinc mine was developed in a historic mining district and the TMF was constructed in a steep-sided river valley in mountainous terrain. The TMF was originally constructed in the 1970s and built as three adjacent cells that were raised in stages using a variety of methods and materials. Klondike and Tetra Tech worked together towards compliance with modern standards for an inactive facility. Preliminary work included review of historic documentation and site visits to identify key hazards and develop plans to manage risk. Tetra Tech undertook consultations with the regulator and the owner, and undertook geohazard, hydrological, and geotechnical assessments to identify key risks and establish priority work. Design work progressed, and construction was initiated on erosion protection works to manage the primary risk, which was determined to be from perimeter erosion from potential debris floods and debris flows in adjacent creek channels. Geotechnical investigation, piezometer instrumentation, and stability assessment were undertaken to better understand and manage geotechnical risk. An instrumentation monitoring plan was developed and incorporated into the TMF Operation, Maintenance, and Surveillance Manual to support TMF risk management.

Introduction

Historical tailings facilities often grapple with a variety of common issues, primarily stemming from their outdated designs and inadequate documentation. Many of these facilities have limited design and construction records, or were constructed based on old codes that no longer meet current regulatory standards. This can present significant challenges, as these facilities must now comply with more stringent design and assessment criteria than those that were in place at the time of construction. The absence of detailed construction records and historical information further complicates the assessment of risk and compliance. Additionally, regulatory compliance requires these facilities to adhere to current standards,

which include comprehensive dam safety management systems, and include Operations, Maintenance, and Surveillance (OMS) manuals, Emergency Preparedness and Response Plans, risk registers, etc. Multiple ownership changes can exacerbate these problems, and lead to inconsistent monitoring and maintenance practices, and a lack of continuity in record-keeping. Moreover, financial constraints on junior mining companies, particularly in non-producing mines, add another layer of difficulty in ensuring the proper upkeep and compliance of historical tailings facilities.

Project background

The Silvana Mine is located near the town of Sandon, approximately 15 kilometers east of New Denver, BC, Canada. The lead-zinc and silver underground mine is located on a historical mining property with a mill and supporting infrastructure. The operation of the mine has been in care and maintenance with ongoing exploration activity since 2013.

The Silvana TMF comprises three adjacent tailing cells constructed in the Carpenter Creek Valley (Figure 1). The three cells, identified as Pond 1, Pond 2, and Pond 3, are side-hill impoundments. The TMF has been classified as "High Consequence" under the criteria of the Canadian Dam Association (CDA) guidelines (CDA, 2013). The combined capacity was estimated at 400,000 tonnes, with the facility covering approximately 6.4 ha. Ponds 1 and 2 are currently at their storage capacity, and Pond 3 is near its capacity.

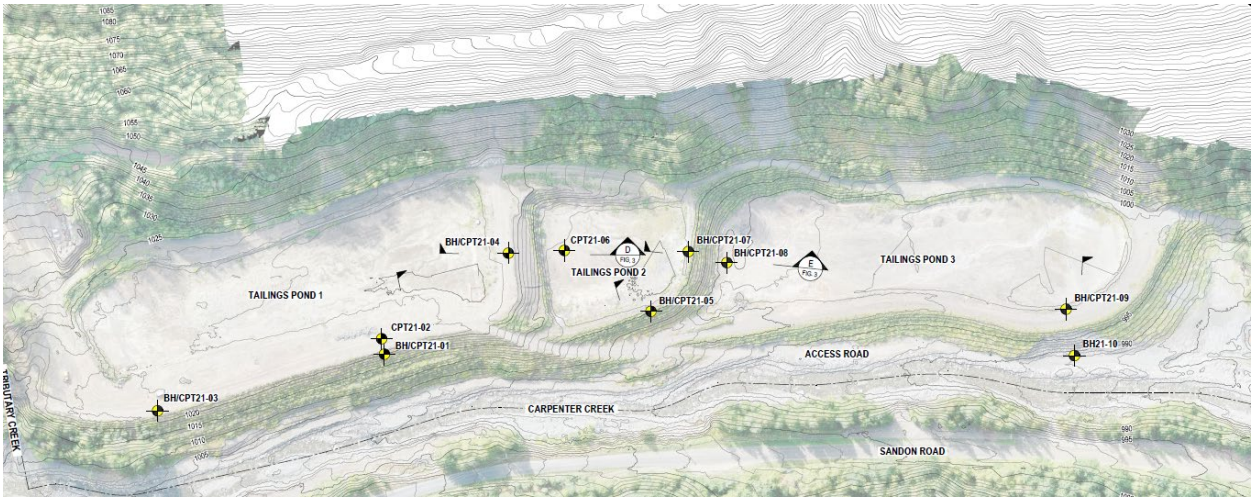

Figure 1: Layout of the Silvana TMF

The construction of the TMF commenced in 1970 with Pond 1 and 2 starter dams, and the ponds were both raised in stages between 1970 and 1980. Historical construction records indicate that Pond 1 was raised

by upstream methods and Pond 2 by centerline methods. Pond 1 was subsequently raised between 1982 and 1984 to its current configuration of approximately 22 m height and approximately 10 m crest width.

Construction of the pond starter dam was completed in 1988. A geotextile and sand filter zone on the upstream slope were part of the starter dyke. Pond 3 was raised by the downstream construction method in 1990 and 1992 to its current configuration.

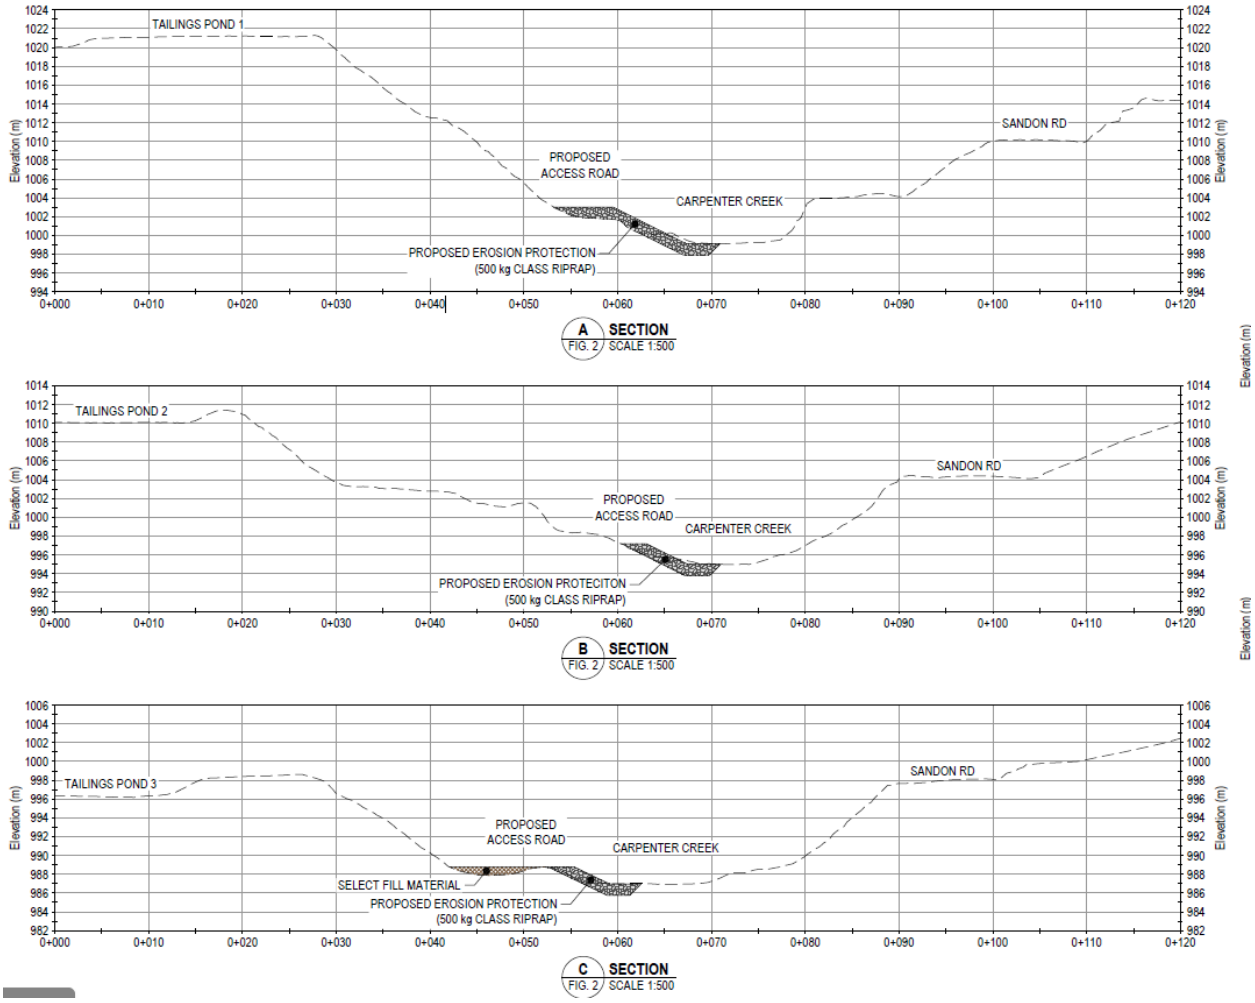

Figure 2: Selected cross-sections of Ponds 1, 2, and 3

No further raises of the TMF were reported after 1992. Construction activities reported other than regular maintenance include:

- In 2016, upgrades were completed to the TMF slopes to protect against a 1 in 200-year flow.
- In 2020, repair was completed along a washout area on the downstream slope of Pond 3.

The stratigraphy of the soils underlying the ponds consists of fluvial sands and gravels with historic tailings material. The perimeter embankments were generally constructed of granular fill excavated from

the adjoining hillside. Some Pond 1 and Pond 2 raises were constructed using coarse tailings sands with an external zone of native granular fill. The toe of the TMF embankments along Carpenter Creek were locally armored with rip-rap. The tailings material was considered non-acid generating.

Previous assessments by others had determined that Pond 1 did not meet minimum design requirements for stability and that TMF water management upgrades were required. In June 2020, regionally high spring runoff impacted the site and resulted in some erosion of the Pond 3 toe.

Photo 1: Wash-out event in June 2020

Geohazard assessment

Objective

A geohazard assessment of the Silvana TMF was undertaken to assess the facility's vulnerability to geohazard events. The assessment complemented a concurrent hydrotechnical evaluation to determine design flood events in the valley. The primary objectives of the geohazard assessment were to determine the likelihood of future geohazard processes impacting the TMF and to identify and recommend practical mitigation measures to protect the facility.

Approach

The assessment followed a systematic approach incorporating desktop reviews, historical air photograph interpretation, and field investigation. A comprehensive review of topographic mapping, bedrock geology, terrain stability, and other related technical reports was conducted. Historical air photographs and images from 1939 to 2018 were analyzed to identify previous slope and channel instabilities, documenting key geomorphological processes and historical landslide activities. The field investigation, conducted between September 28 and October 1, 2020, included traverses of Tributary Creek, Carpenter Creek, and the slopes above the TMF, noting subsurface soil conditions at road and creek exposures.

Findings

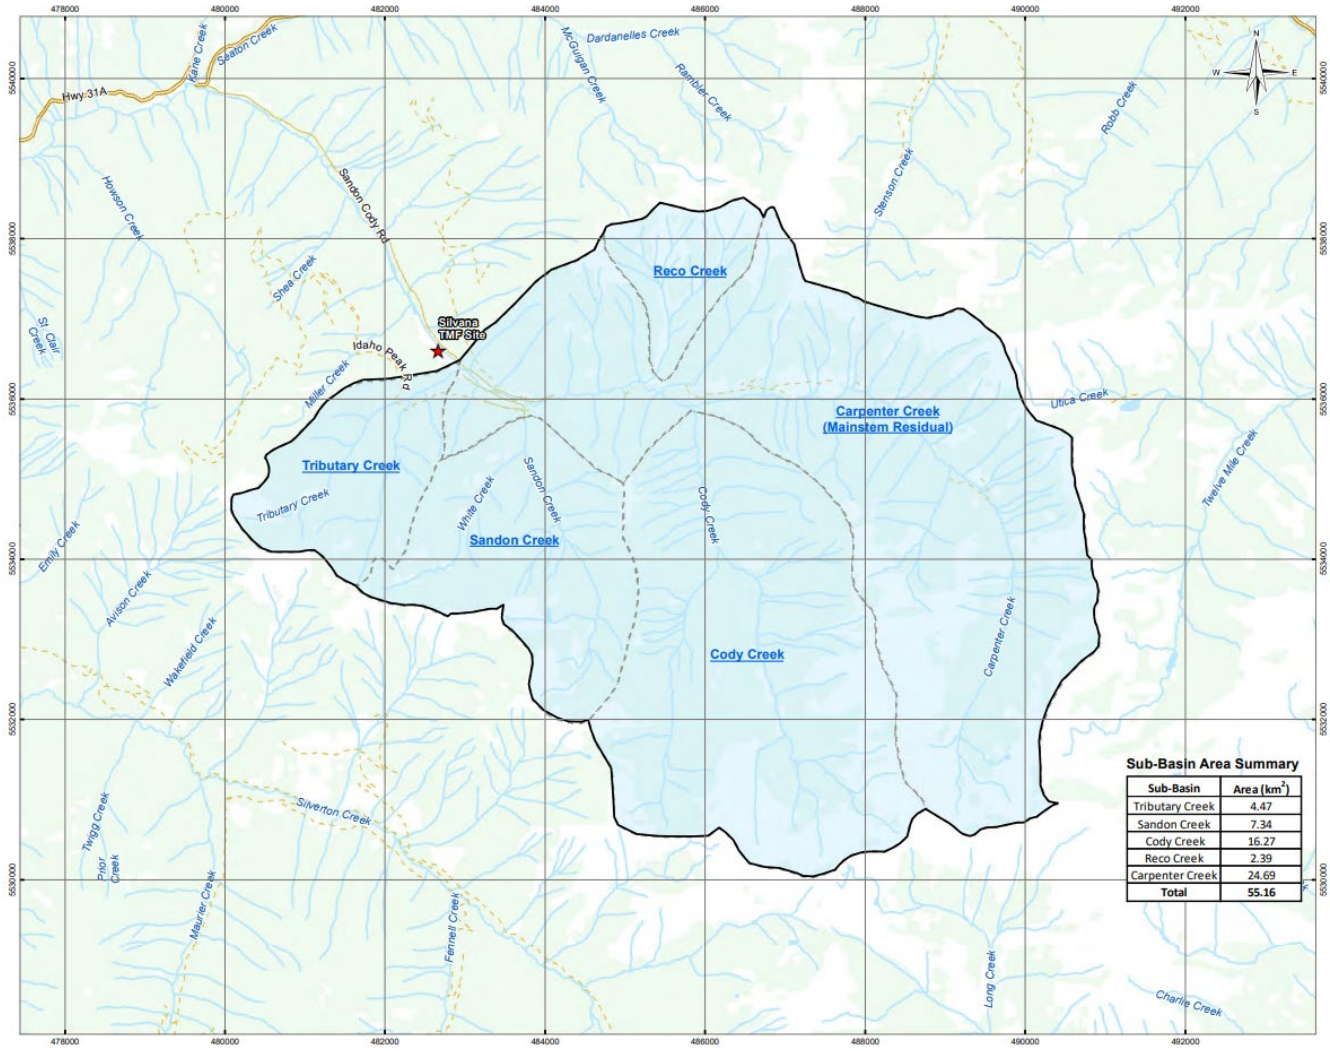

Figure 3: Terrain and Location of the TMF

The TMF site lies in a physiographic region where Carpenter Creek is a fourth-order stream with a watershed area of about 206 km². The creek flows 7.0 km from Mount Carlyle (el. 2,520 m) to Slocan Lake

(el. 820 m) at the community of New Denver, BC. The TMF is located upstream of Three Forks at ~1,000 m elevation, with a catchment area upstream of the TMF site being ~55 km². The bedrock geology consists of Triassic-aged sedimentary rocks, including argillite, slate, quartzite, limestone, and granitic dyke intrusions. Terrain stability mapping indicates that the area is generally stable. Historical flood and landslide events, such as those in 1894, 1933, 1934, 1955, 1999, and the significant event in May-June 2020, highlight the region's vulnerability to natural hazards.

Carpenter Creek, upstream of the TMF, is susceptible to debris floods, particularly downstream of Reco Creek, which is a significant sediment source. The stream channel gradient from the headwaters down to the TMF site shows that headwater reaches have steep channel gradients (25% to 45%) and are predominantly bedrock-controlled. Mid-watershed reaches extend from Cody Creek through the Sandon townsite to the TMF, with an average gradient of 5–10% and high connectivity to adjacent valley side slopes, making them significant sediment sources. The channel is incised within the banks near the TMF, with gradients becoming gentler (4–6%) but remaining highly confined.

Tributary Creek is capable of producing a full range of geomorphic events, from clear water floods to debris floods and debris flows. The middle reaches of Tributary Creek have numerous sediment sources, including large landslides observed during field investigations. The stream channel gradient in these reaches ranges from 18% to 30%, with the channel being tightly constrained by adjacent steep valley side slopes.

Mitigation recommendations

To enhance the resilience of the TMF against future geohazard events, several mitigation measures are recommended. Constructing a berm along the south boundary of Pond 1, increasing sediment storage capacity in the lower reach of Tributary Creek, and installing greater protection against slope material raveling are recommended. Continuous monitoring and maintenance of the lower reach of Tributary Creek are essential. Additionally, the geohazard assessment should be revisited after significant flood, debris flow, or slide events to document changes that may affect potential hazard and risk levels.

Conclusion

The geohazard assessment for the Silvana TMF provided a thorough evaluation of potential geohazard risks and offered practical mitigation measures to enhance the facility's resilience. This assessment underscored the importance of continuous monitoring and adaptive management to safeguard the TMF against future geohazard events.

Hydrotechnical assessment and erosion protection design

Objective

The primary objective of the hydrotechnical assessment was to propose a series of channel upgrades to protect the integrity of the Silvana TMF. The scope of work encompassed four main components: background review, hydrologic analysis, hydraulic analysis, and preliminary design. The background review included a site visit and review of historical data and contextual information. The hydrologic analysis assessed the intensity and frequency of recent freshet events and the design flows for Carpenter and Tributary Creek. The hydraulic analysis evaluated existing channel capacities and erosion mechanisms. The preliminary design work included erosion and geohazard protection measures.

Field investigation

The field investigation had several objectives:

- Inspection of Creeks: Inspect Carpenter Creek and Tributary Creek to identify signs of historical flood events, erosion, and debris flow. This inspection included visual assessments and photographic documentation of the creek banks, bed conditions, and any existing erosion protection measures.
- Assessment of 2020 Freshet Event: Evaluate the impact of the 2020 freshet event, which caused significant erosion and debris deposition. This assessment aimed to quantify the extent of the damage and identify areas most vulnerable to future events.
- Documentation of Emergency Measures: Document emergency erosion protection measures that were implemented in response to the 2020 freshet. These measures included temporary structures and modifications aimed at preventing further erosion and protecting critical infrastructure.
- Data Collection: Collect data using orthographic images and LiDAR surveys. This data was used for creating accurate hydraulic models and developing initial design plans for erosion and geohazard protection. Additionally, anecdotal historical flood information provided by the Klondike Silver was used to validate and supplement the field data.

Hydrologic and hydraulic analysis

The hydrologic and hydraulic analyses provided a detailed assessment of the water flow and erosion patterns affecting Carpenter Creek and Tributary Creek. Key components of these analyses included:

- Hydrologic Analysis: Estimating the intensity and frequency of freshet events. This analysis helped in understanding the severity and potential impact of extreme hydrological events on the mine site.

- Hydraulic Analysis: Assessing the current channel capacities of Carpenter Creek and Tributary Creek. This involved evaluating the validity of bulking factors and identifying erosion mechanisms. The hydraulic analysis aimed to determine the ability of the creek channels to convey floodwaters without causing significant erosion or damage to the embankments.
- Channel Erosion Mechanisms: Understanding the mechanisms driving channel erosion and identifying the areas most susceptible to erosion. This information was used for designing effective erosion protection measures for the long-term stability of the creek channels.

Design and recommendations

Based on the findings from the stability, hydrologic, and hydraulic analyses, preliminary designs were developed for erosion and geohazard protection measures. These designs included specific recommendations to enhance the structural integrity of the tailing pond embankments and protect against future hydrotechnical events.

Conclusion

The hydrotechnical study provided a comprehensive assessment of the hydrotechnical challenges faced at the Silvana TMF. The study findings highlighted the need for targeted erosion protection and stability enhancement measures to safeguard the tailing ponds and surrounding infrastructure. By addressing these challenges, the study aimed to support a safe and secure TMF and compliance with regulatory standards. The detailed recommendations and preliminary design plans provided a roadmap for implementing effective hydrotechnical management strategies and mitigating the impact of future hydrological events.

Geotechnical investigation, assessment, and conceptual design

Objective

The Silvana TMF geotechnical assessment evaluated the stability and compliance of the TMF structures with regulatory standards, including the Health, Safety, and Reclamation Code (HSRC) for Mines in British Columbia. The primary goal was to assess the stability of the TMF structures, identify potential risks, and recommend potential remedial actions to maintain safety and regulatory compliance.

Field investigation

A field investigation was conducted in April 2021 that included geotechnical drilling, vibrating wire piezometer (VWP) installation, Standard Penetration Tests (SPT), Cone Penetration Tests (CPT), and Seismic Cone Penetration Testing (SCPT). These activities aimed to gather comprehensive information on soil stratigraphy, strength parameters, and groundwater conditions to support stability analyses. VWPs were installed at six locations to facilitate groundwater level monitoring. The data collected from these

investigations was used to advance the understanding of the subsurface conditions and support stability assessment of the TMF structures.

Stability analyses

The stability analyses focused on assessing the stability of the tailing pond embankments under various conditions. Key components of the stability analyses included:

- TMF Stability Acceptance Criteria: Establishing criteria for acceptable stability levels based on regulatory guidelines and industry standards.
- Slope Stability Model Geometry: Defining the geometry of the slope stability models based on the physical characteristics of the embankments and surrounding terrain. Accurate modeling of the slope geometry supports reliable stability assessments.
- Material Properties: Analyzing the material properties of the embankment soils, including strength parameters such as cohesion and internal friction angle. These properties were determined from field and laboratory testing of samples collected during field investigations.
- Seismic Parameter Selection: Selecting appropriate seismic parameters for the stability analyses. This involved calculating a horizontal seismic coefficient (Kh) based on the site-specific Peak Ground Acceleration (PGA) value.
- Analyses Methodology: Implementing the generalized limit equilibrium method of Morgenstern-Price using Slope/W software (GeoStudio 2019). This method involved iterative calculations to identify potential slip surfaces and determine factors of safety (FoS) under both static and seismic conditions. The analyses also considered potential liquefaction of soil layers under seismic loading, which could impact the TMF stability. The liquefaction assessment involved evaluating the potential for cyclic loading during an earthquake to cause a loss of strength in the tailings and foundation materials.

Stability analyses summary

Summarizing the results of the stability analyses. The analyses indicated that most cross-sections of the tailing pond embankments met the target FoS, except for the static analysis of Section A-A' (Pond 1). It was determined that the liquefaction potential of the tailings and embankment foundation materials was low under design seismic events, but further work was needed to advance this assessment. Remedial design concepts were developed for sections requiring reinforcement to improve stability.

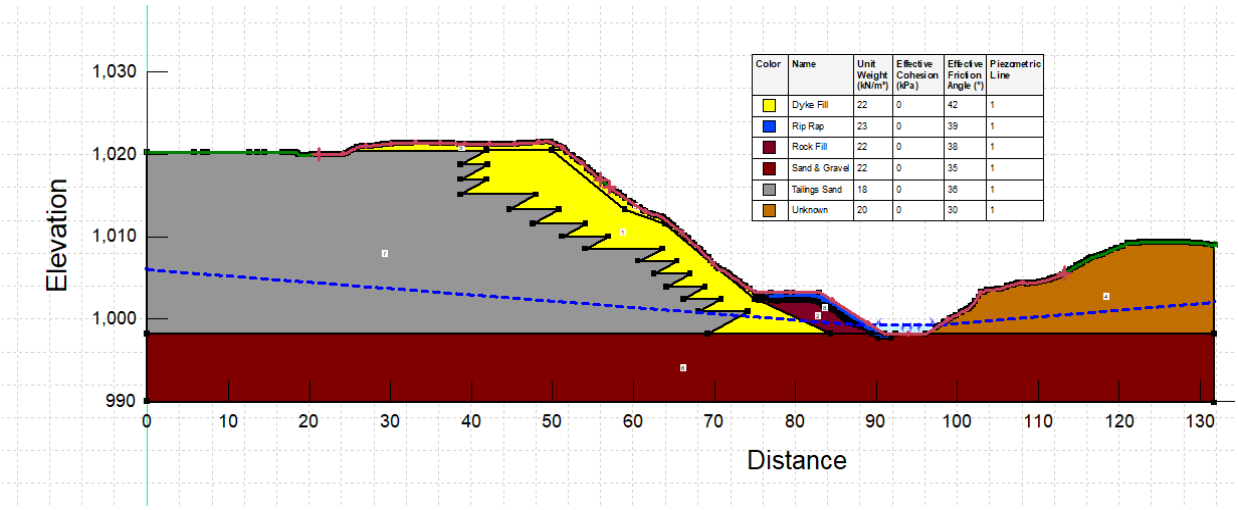

Figure 4: Existing condition of Pond 1

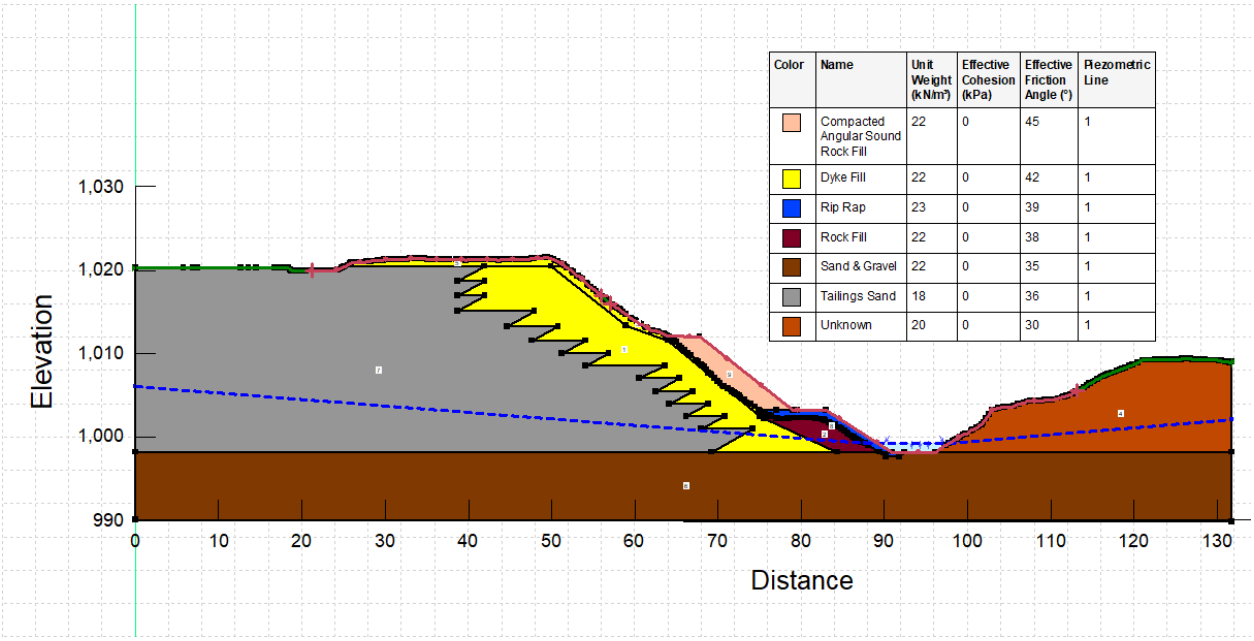

Figure 5: Conceptual remediation design

Conclusion

The stability results indicated that while most areas of the TMF met design criteria, a section of Pond 1 required remedial work to improve stability and comply with regulatory standards.

To enhance the stability of Pond 1, a conceptual remedial design involving a buttress has been proposed. The remedial measures include several recommendations for improving the slope stability of Pond 1 and mitigating potential geotechnical risks. A comprehensive program of visual inspection and instrumentation monitoring was recommended to develop further understanding of the TMF performance and to manage risk.

Regulatory and operation support

Addressing the complexities associated with historical tailings facilities necessitates a collaborative approach with owners, consultants, regulators, and stakeholders to establish a robust dam safety management system. The approach adopted at for the Silvana TMF included regular dam safety inspections, the development and implementation of an updated OMS manual, a TMF specific Emergency Preparedness and Response Plan, and the engagement of an Independent Tailings Review Board. The system includes continuous improvement protocols to incorporate new insights from ongoing evaluations and updating annually.

A collaborative approach was adopted to prioritize tasks and formulate a practical work plan that prioritized work on significant dam safety risks. The effort included regular liaison between consultants, owners and regulators. Support included periodic updates to a regulatory compliance tracking system.

Conclusion

Several challenges were encountered in identifying and addressing design and regulatory compliance issues at the Silvana TMF. Many of these issues are commonly encountered at other historical and inactive tailings storage facilities at properties where exploration and project development are the main focus. Recognizing these challenges, Tetra Tech employed a systematic approach to work closely with the owner and the regulator to develop a tailored plan that addressed the unique issues and circumstances of the TMF. This approach began with the compilation and review of historical information, providing a foundational understanding of the facility's past performance and existing conditions.

Effective communication with the client is an important component of the process to ensure that constraints, whether regulatory or financial, are fully understood and considered in the planning stages. This dialogue helps in aligning the project goals with the client's needs. A preliminary risk evaluation was carried out to identify potential issues and prioritize the tasks based on their risk and benefit. This risk-based prioritization lays the groundwork for a structured and phased approach to the plan.

The execution of the plan at Silvana TMF was carried out in distinct phases, and significant work has been completed to date. Initially, a geohazard assessment and a hydrotechnical assessment were conducted to identify and propose potential mitigation options for risks associated with natural hazards and surface water management. Preliminary design work of erosion protection and flood mitigation measures was then undertaken to address priority risks. A comprehensive geotechnical investigation and assessment was performed that provided advanced insight into the subsurface conditions and supported the design of remedial measures.

An important component of the plan was the development and implementation of a Dam Safety Management System. This system provided a structured framework for the ongoing monitoring and maintenance of the dam. The consultative and phased risk-based approach was focused on effective identification and management of dam safety risk.

Abstract

Mine waste rock is often produced in large volumes during mining, particularly when ore is extracted from an open pit. When exposed to atmospheric conditions, waste rock can react and generate contaminated mine drainage, characterized by concentrations in various metals and metalloids that exceed regulatory limits. The reactivity of waste rock is a function of different parameters such as grain size distribution, mineral type and content, water content, and temperature. In the context of mine reclamation in Arctic environments, it is often proposed to favor the aggradation of permafrost within potentially problematic waste rock storage facilities to reduce chemical reactivity and to control contaminant transport by freezing the pore water. Previous studies have demonstrated the impact of temperature on the oxidation rate of sulfide minerals.

However, much less is known about the influence of temperature on the reactivity of arsenic-bearing minerals. In waste rock, these minerals are frequently found in the form of sulfides or sulfosalts such as gersdorffite (NiAsS), and it is often assumed that the latter will react in the same way as sulfides when the temperature is lowered. To gain a better understanding of the influence of temperature on As-generating waste rock, three column tests were set up using materials from an active mine located in the Canadian low Arctic. Arsenic in the tested waste rock was mainly contained in gersdorffite. Column tests were performed at temperatures of 21, 5, and –2°C to assess the effects of temperature on arsenic leaching. Columns were submitted to twenty wetting and drying cycles. Volumetric water contents and temperatures were monitored throughout the tests and water quality was analyzed at each flush. The results showed that arsenic release decreased with temperature, from 15 mg/L at 21°C to 7 mg/L at –2°C, indicating that none of the tested temperatures completely prevented arsenic leaching.

Introduction

The mining industry has a significant positive impact on the Canadian economy, but is also known to generate significant volumes of solid and liquid waste during operations. Of these, waste rock is one of the most important, quantitatively speaking. Waste rock is a non-economic material that needs to be excavated to reach ore-bearing rock. It is usually stored in piles at the surface, where it is exposed to atmospheric conditions. As a result, many waste rock facilities end up generating acid mine drainage (AMD) due to the oxidation of the sulfide minerals. Contaminated neutral drainage (CND) is another type of mine drainage that is also a source of concern. In CND, the pH remains neutral but concentrations of various problematic elements such as arsenic, copper, nickel, lead, and zinc can exceed legislative limits. The focus of this article is on arsenic-contaminated neutral drainage (As-CND), through the study of an arsenic-generating waste rock from a mine located in Arctic conditions.

The studied waste rock material came from a mine in a subarctic environment. The actual mine closure plan consists of reducing the reactivity of the material and, consequently, the As generation, by using an insulation cover. To ensure that the remediation system will work properly, it is important to assess the relationship between temperature and arsenic generation.

In this study, the effect of temperature on arsenic generation was characterized by monitoring leaching columns at different temperatures (21°C, 5°C, and –2°C). These columns were run for 40 weeks. Results were then used to assess the arsenic generation reaction rate as a function of temperature for the tested material using the Arrhenius equation.

Materials and methods

Material selection and properties

The material selected to test the effect of temperature on arsenic leaching (identified hereinafter as NK) was chosen because, according to previous preliminary studies, it was the most at risk to generate arsenic. The material was collected onsite directly after blasting in order to obtain fresh, non-weathered samples. The sample was sieved onsite to produce five different particle sizes: 50–15 mm, 15–5 mm, 5–2.4 mm, 2.4–0.85 mm, and <0.85 mm (Figure 1). The different NK materials were then sent to the *Unité de recherche et de Service en Technologie Minérale – Université du Québec en Abitibi-Témiscamingue (URSTM-UQAT)* laboratory where they were homogenized and characterized.

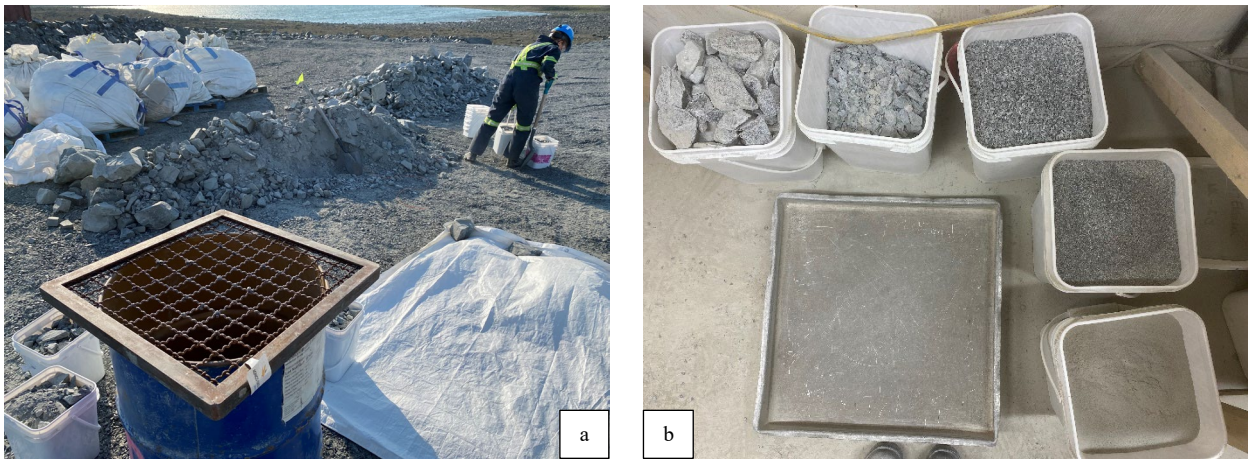

Figure 1: 50 mm hand sieving using a grid placed on a barrel (a) and the result of finer sieving using a mechanical sieve shaker, from left to right: 50–15 mm, 15–5 mm, 5–2.4 mm, 2.4–0.85 mm, and <0.85 mm (b)

The particle size chosen to assess the influence of temperature on arsenic generation was the second finest, between 2.4 and 0.85 mm. This particle size fraction was chosen after several flushes of leaching tests on all the size fractions at laboratory temperature. This choice was made because it offered the best compromise between arsenic leaching and ease of flushing (a pump had to be installed on one of the columns, complicating the collection of leachates).

The relative density and particle size distribution were assessed at the URSTM laboratory. The particle size distribution was obtained by dry mechanical sieving (ASTM D422-63, 2007e2) and laser analysis (Merkus, 2009) with an accuracy better than 1% on particle size estimation, depending on the sample and its preparation (Malvern Instruments Limited, MRK 1954-01-FR-01). Specific gravity (Gs) was measured using a helium pycnometer (ASTM D5550-14, 2014) with an accuracy of 0.003%.

The sulfur and carbon contents, major and trace element contents, acid-generating potential, and sulfur speciation were assessed to characterize the environmental properties of the material. The sulfur and carbon contents were measured using an induction furnace ELTRA CS-2000 Carbon/sulfur determinator (ELTRA GmbH Germany, 2005). Trace and major element contents were measured using inductively coupled plasma atomic emission spectroscopy and mass spectrometry (ICP-AES and ICP-MS) solid analyses and whole rock analyses. Acid generation potential was assessed using the modified Sobek test procedure (Lawrence and Wang, 1997). The sulfate sulfur was determined with a 40% HCl extraction based on Sobek et al. (1978). All chemical analyses were carried out with a relative error of approximately 5%.

The quantitative and semi-quantitative mineralogical analyses consisted of X-ray diffraction (XRD) analyses with the Diffrac.EVA v5.2.03 and Rietveld-TOPAS v4.2 software. The quantification method and automated mineralogy were conducted with a detection limit of 0.5 to 2%, which strongly depended on the crystallinity of the mineral.

The particle size distribution of the material showed a grain diameter at 50% (D_{50}, 50% of the particles have a diameter smaller than this value) of 1.45 mm, a coefficient of uniformity ($C_U = D_{60}/D_{10}$) of 1.67, a coefficient of curvature ($Cc = (D_{30}^2)/(D_{10}/D_{60})$) of 0.97, and a specific gravity (G_S) of 2.86. The material was classified by the USCS classification system as a well graded sand (SW; McCarthy, 2007; ASTM 2021). The hydrogeological characterization showed a saturated hydraulic conductivity of 2.5×10^{-5}m.s^{-1}, an air entry value (AEV is the suction at which the air starts to enter in the saturated material) of 1kPa, and van Genuchten parameters α_{vG} (cm^{-1}), m_{vG}, and n_{vG} of 0.076, 0.866, and 7.478, respectively (van Genuchten, 1980).

The porosity was calculated based on mass-volume relationships at 0.49. The mineralogical composition showed a majority of silicates (56%) with anthophyllite as the main silicate (22%) followed by carbonates (43%) with a group of carbonates undifferentiated by the analytical laboratory as "mixed carbonate" followed by dolomite (5%) and a gersdorffite content of 0.09%.

Other sulfides such as pyrrhotite (0.15%) or pyrite (0.02%) were found in such low concentrations that we considered them negligible for this study. The material showed a Net Neutralization Potential (NNP) greater than +20 kg$CaCO_3$/t, which categorized it as non-acid generating (MEND, 2009); this was validated by a low sulfur concentration (0.1%) and a higher carbon concentration (1.82%). Table 1 summarizes the results of these characterizations.

Table 1: Physical, hydrogeological, chemical, and mineralogical parameters of the material

Parameters	NK 2.4–0.85	Parameters	NK 2.4–0.85
D_{10} (mm)	0.97	S_{tot} (%)	0.10
D_{30} (mm)	1.23	C_{tot} (%)	1.82
D_{50} (mm)	1.45	AP (kg $CaCO_3$/t)	3.1
Cu	1.67	NP (kg $CaCO_3$/t)	151
Cc	0.97	NNP	148
Gs	2.89	NP/AP	49
k_{sat} (m.s^{-1})	2.5x10^{-5}	Gersdorffite (wt%)	0.09
AEV (kPa)	1	Other minerals in order of importance: dolomite, calcite, antophyllite, chlinochlore, biotite, quartz (wt%)	95.9
n	0.49		
α_{vG} (cm^{-1})	0.076		
m_{vG}	0.866		
n_{vG}	7.478		

Water quality measurements from the column tests included pH, oxidation reduction potential (ORP), electrical conductivity, acidity, alkalinity, and elemental concentrations. The pH measurement was performed with a SympHony B30PCI with an accuracy of 0.002 pH units. The same device was used to measure the ORP with a relative precision of 0.2 mV. The electrical conductivity was measured with a VWR Traceable expand range conductivity meter with an accuracy of ±1%. The acidity and alkalinity of each solution were measured with a Metrohm 848 Titrino plus automatic titrator with a relative error of 5%. Inductively coupled plasma optical emission spectroscopy (ICP-OES) analyses were then performed with the Agilent ICP-OES 5800.

Arsenic speciation was defined using the following method. First, the SAX (strong anions) and SCX (strong cations) cartridges were preconditioned with deionized water, methanol, and phosphoric acid; then, 30mL of water sample was passed through the cartridges. Positively charged organic arsenic (V) was retained on the SCX cartridge, while negatively charged inorganic arsenic (V) was retained on the SAX cartridge. Uncharged arsenic (III) was not retained and ended up in the residual water. The various cartridges were then rinsed with acetic and nitric acid to recover the different species (Watts et al., 2010; Bondu et al., 2017; Rakotonimaro et al., 2019). Each sample was then analyzed by ICP-AES to quantify the different arsenic species present in solution.

Column configuration and instrumentation

The columns used for the tests were made of transparent acrylic and were 14 cm wide and 100 cm long. A geotextile was placed at the base of each column to avoid loss of fine particles in the leachates. The columns were filled in 15 to 20 cm lifts. The lifts were put in place by pouring 5 kg of materials and compacting with the energy required to reach the targeted height. The final height of the columns was 90 cm (approximately 20 kg of dry NK materials), yielding a porosity of 0.49. The volumetric water content and temperature were monitored continuously by METER Group Teros 11 (T11) probes with an accuracy of $0.03 m^3/m^3$ and 0.5°C.

A calibration curve was developed to obtain more precise volumetric water content measurements (Cobos and Chambers, HOBO Data Loggers). Temperature was also monitored by a nickel temperature sensor (RT1 sensor from METER Group) with an accuracy better than 1°C. Those sensors were located in the middle of each column, at 45 cm below the surface (Figure 2). The frequency of measurement depended on the stage of the rinse cycle: measurements were taken every 5 minutes during the wetting stage, every hour during the draining stage, and every 4 hours during the drying stage.

Each column was then stored in its environment: the column at 21°C (C4) was stored directly in the laboratory and subjected to the laboratory's ambient temperature; the column at 5°C (C4') was stored in a refrigerator normally used to store liquid samples, where the temperature was maintained at 5°C at all times;

and the column at –2°C (C4") was stored in a large cold room with other columns and other tests in progress, where the temperature was maintained at –2°C.

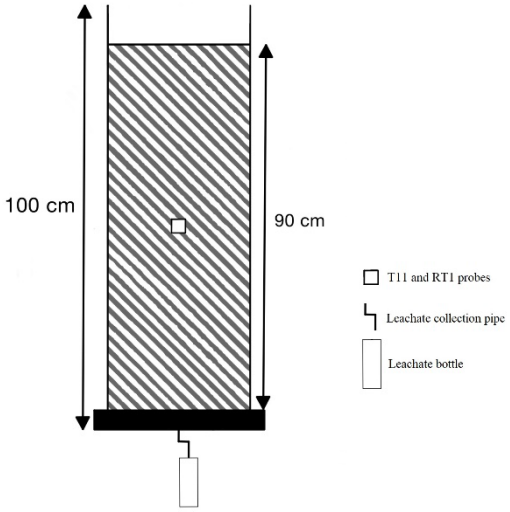

Figure 2: Schematic diagram of a mounted and instrumented column

Flushes were carried out once every fortnight using 1.54L of water; every column underwent 20 rinses. The quantity of water used was selected based on previous studies (e.g., Kandji et al., 2017; Roy et al., 2020, 2023; Poaty et al., 2021) that showed a good correlation between real and laboratory water quality at this flushing volume. Additionally, the selection was based on typical monthly rainfall for rainy months in humid climate conditions (i.e., approximately 100 mm). This wetting period was followed by a drainage period of 24 hours and a drying period of 13 days before the beginning of the next cycle. The column stored at –2°C was thawed for 3 days prior to each rinse and then reinstalled in the cold room for its drying period (Figure 3).

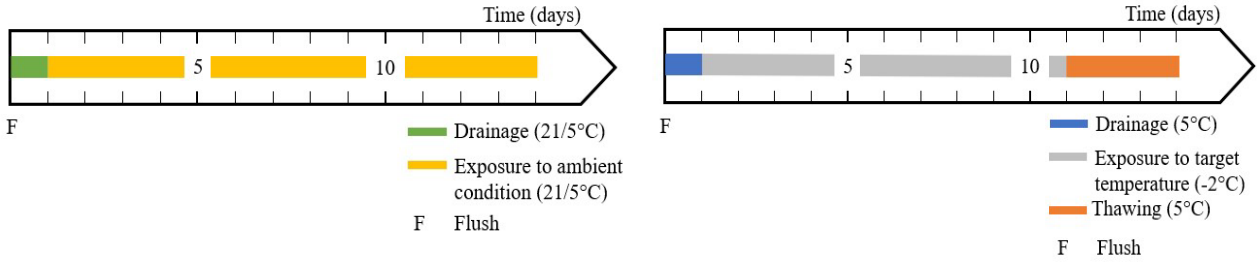

Figure 3: Typical testing cycles at ambient (21 and 5°C) on the left and target temperature (–2°C) on the right

The leachate was collected at the end of the drainage period and analyzed for geochemical parameters including pH, ORP, electrical conductivity, acidity, alkalinity, and dissolved species.

Results

Evolution of temperature

The temperatures monitored throughout the leaching tests are provided in Figure 4. Relatively stable temperatures were observed for the columns stored at 21 and 5°C. Some minor anomalies were observed due to a refrigerator breakdown (i.e., day 42) and power outages for the column at 5°C. For the column stored at 21°C, we observed a maximum of 23.5°C, a minimum of 18.2°C, and an average of 20.6°C. For the column stored at 5°C we observed a maximum of 8.0°C, a minimum of 2.9°C, and an average of 4.4°C.

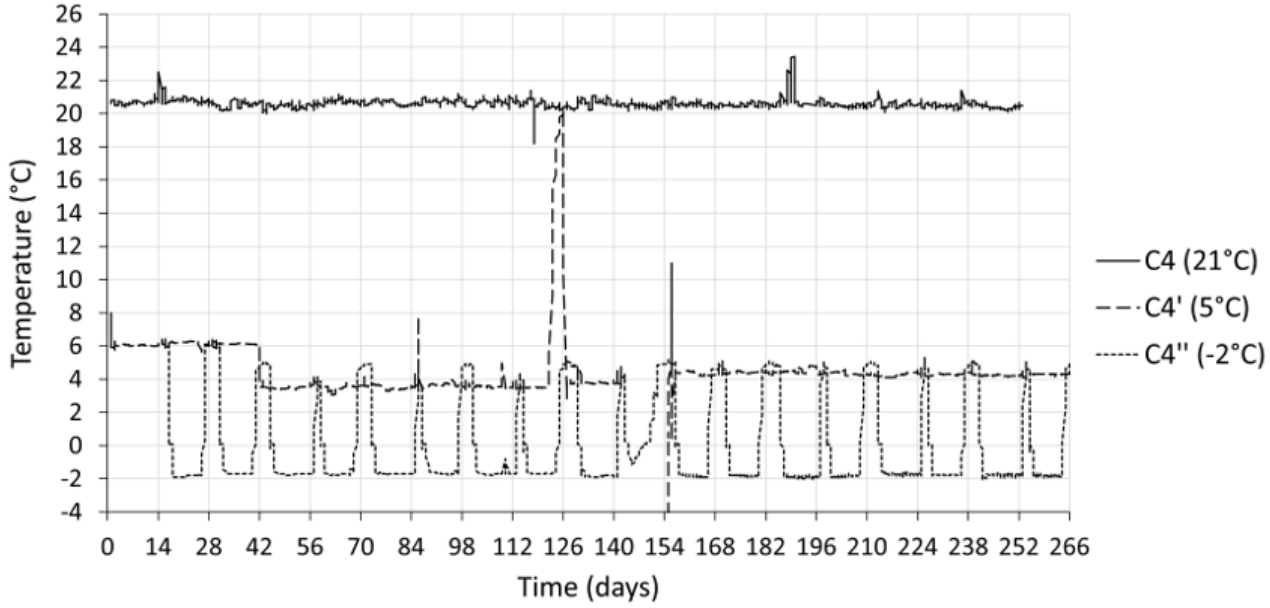

Figure 4: Evolution of the temperature during the experimentation

Figure 4 also shows the freeze-thaw cycles that were applied to the column at –2°C. Thawing events were performed at a temperature of 5°C for 3 days before the column was returned to the cold room at –2°C after the drainage phase. For this column, we observed a maximum of 6.1°C, a minimum of –2.0°C, and an average of –1.7°C when stored in the cold room and 4.8°C when stored in the 5°C environment.

Evolution of water quality

Changes in physicochemical parameters and water quality over the course of twenty rinses (266 days) are presented in Figure 5.

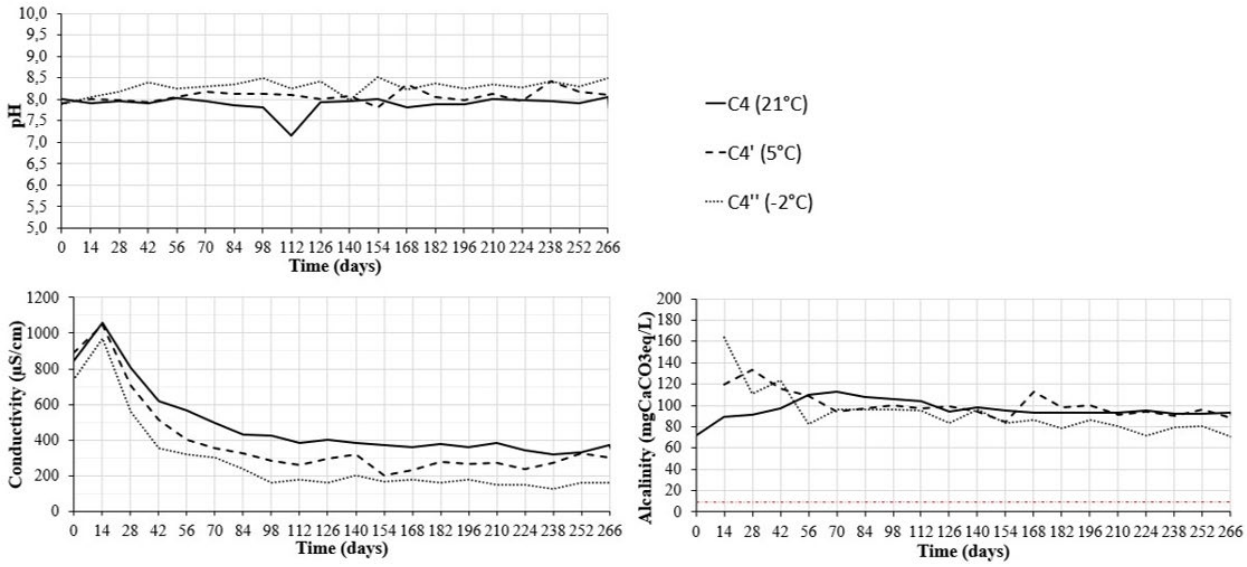

Figure 5: Evolution of pH, electrical conductivity, and alkalinity during the column tests

The pH showed a stable and similar trend for all three temperatures: it ranged from 7.2 to 8.5, with an average of 7.9, 8.1, and 8.3, respectively, for 21, 5, and –2°C. The redox potential (not shown here) showed no particular trend and ranged from 731 to 396 mV, with an average of 619, 570, and 564 mV, respectively, for 21, 5, and –2°C. The electrical conductivity of the three columns followed a similar pattern, starting at relatively high values of approximately 1,000 µS/cm before stabilizing around 400, 300, and 200 µS/cm for temperatures of 21, 5, and –2°C, respectively.

Acidity (not shown here) was systematically measured at less than 10 $mgCaCO_{3eq}/L$ for the three temperatures. Alkalinity showed a relatively stable trend at around 100 $mgCaCO3_{eq}/L$ for the three temperatures (96 for 21 and 5°C, and 84 for –2°C; see Figure 5).

Evolution of arsenic quantities and arsenic speciation

Arsenic was the main element of concern in this study. The quantity of arsenic in the leachates was monitored every fortnight until stabilization and then every month thereafter. The results shown in Figure 6 exhibit similar trends for columns C4 and C4', where a rapid increase in arsenic concentration during the first rinses was observed, followed by a stabilization. Column C4'' had a different behavior, with a progressive increase in arsenic concentrations followed by a stabilization. Stabilized arsenic concentrations were 16, 14, and 7 mg/L for the columns at temperatures of 21, 5, and –2°C, respectively. Based on the observed results over the entire test period, the arsenic generation rate was 32, 25, and 24 mg/kg/week for the 21, 5, and –2°C columns, respectively.

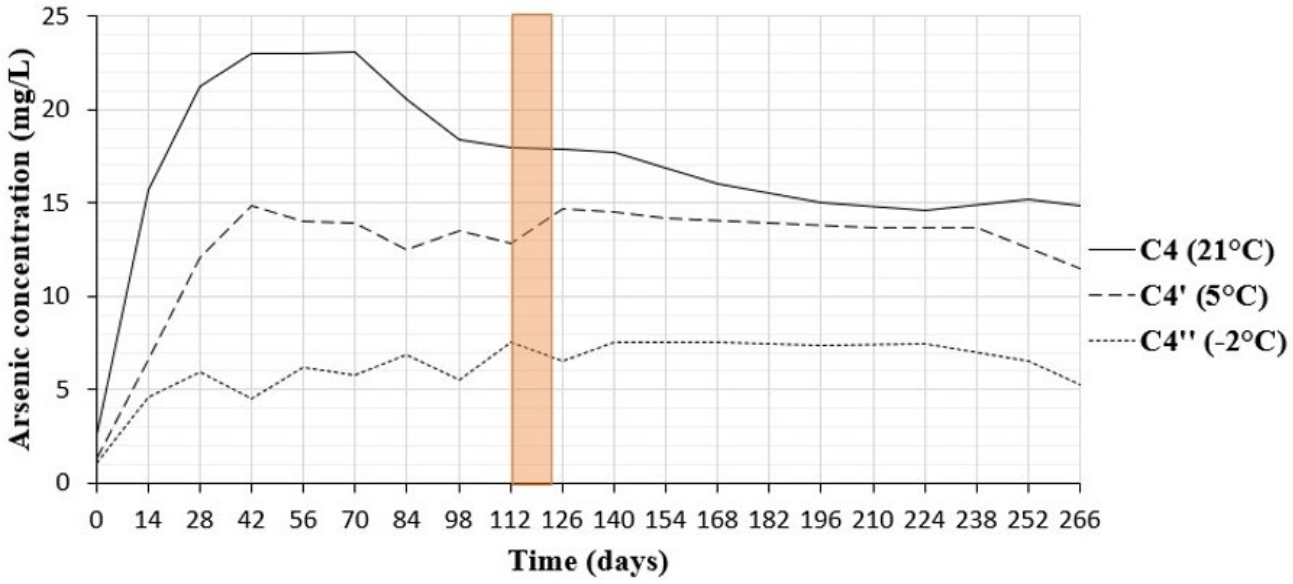

Figure 6: Arsenic concentrations during the experiment. The colored band shows when the arsenic speciation analyses were carried out

Using Eh and pH data and Pourbaix diagrams (Figure 7a), it was hypothesized that arsenic was found mainly in the form of $HAsO_4^{2-}$ or in the form of As(V) arsenates. Water concentrations of other metals were also measured, but showed low values, as for iron, where the concentration varied between 0 and 0.015 mg/L for the three columns. Although concentrations are low, we are in the hematite precipitation range (Figure7b), which could affect not only the amount of iron present in the water, but also the amount of arsenic, as iron oxyhydroxides can sorb and/or coprecipitate arsenic.

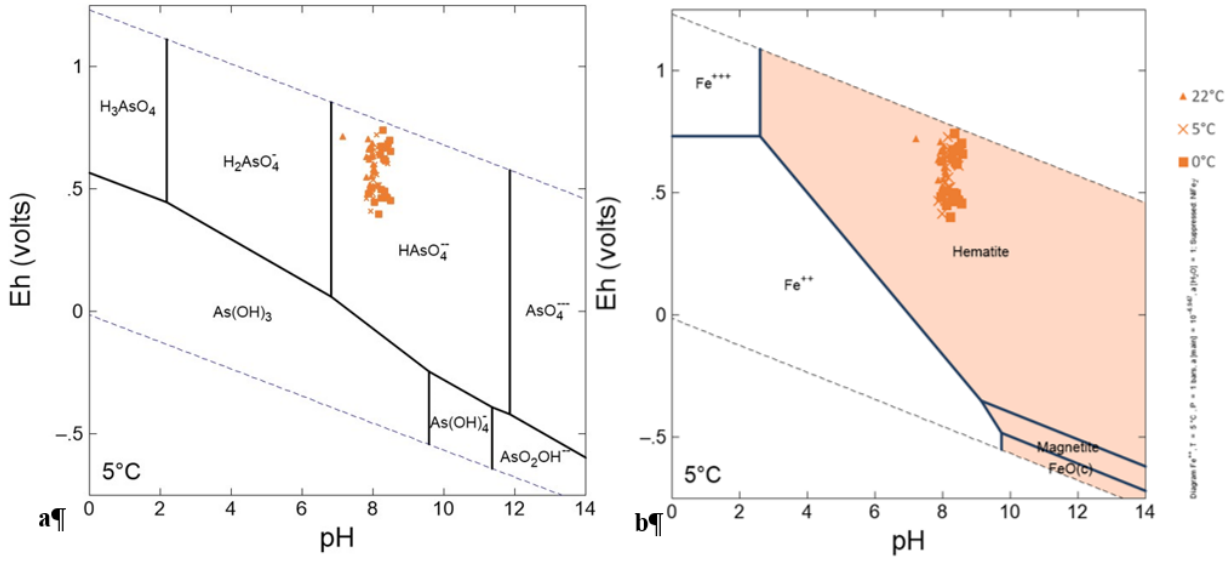

Figure 7: Plotting of Eh and pH values measured during the tests in a Pourbaix diagram for an average arsenic concentration (a) of 8.51x10^{-5}mol/L and iron concentration (b) of 1.13x10^{-7}mol/L at 5°C and 1 bar

The Pourbaix diagram presented in Figure 7 was constructed using the Geochemist's Workbench software for typical arsenic concentrations (8.51×10^{-5}mol/L) and iron concentrations (1.13×10^{-7}mol/L) found in the samples at 5°C and 1 bar.

These data for arsenic speciation were obtained by using Bond Elut SAX and SCX ion exchange cartridges to separate As(III) and As(V) in the leachates. ICP-OES analyses showed less than 0.15% of the total As was in the As(III) form, confirming the results predicted with the Pourbaix diagrams.

Conclusion

The three column tests showed that the pH remained stable during the testing period at values close to 8, regardless of temperature. These results were expected considering the low acid generating potential of the NK material. Water quality measurements also showed that Eh, acidity, and alkalinity were not significantly affected by temperature. However, electrical conductivity tended to fall as temperature decreased. The total mass of As decreased with decreasing temperature. The stabilized concentrations were similar (≈15 mg/L) at 21 and 5°C, and lower (≈6 mg/L) at –2°C.

Reducing the storage temperature of As-CND-generating waste rock that contains gersdorffite from a mine located in a cold region does not appear to be sufficient to totally prevent arsenic production in leachates when water percolates through the waste rock, unfrozen for a short period of time. This implies that to eliminate the risk of arsenic generation, the pore water within the waste rock facilities would have to stay continuously frozen. This requires that an insulation cover placed on top of this waste rock unit must have a configuration and thickness that is optimized to contain the active layer within the cover materials. This condition should be met for the actual climate context, but also for future climatic conditions that will be affected by climate change.

Results presented in this article are integrated into a larger study on the As leaching potential of waste rock located in cold climatic conditions. Presently, other column tests are being analyzed to assess the influence of grain size distribution. The column test results will also be used to calibrate a reactive transport model with the MIN3P software (Mayer et al., 2018). The calibrated model will then be used to make long-term projections for more realistic geometries and climate conditions.

Abstract

Designing an efficient soil cover system for a tailings storage facility (TSF) is crucial for long-term reclamation. The efficiency of a soil cover system depends on factors like the nature of the mine waste, local climate, and regulatory objectives. Modern design relies on numerical modeling using 1D, 2D, or 3D domains, as well as incorporating climate conditions as flux boundary conditions. Sensitivity analyses help us to understand the dynamics of cover system elements by altering soil water retention and hydraulic conductivity curves, layer thicknesses, and geometrical arrangements. These simulations are challenging due to extended run-times, complex results, and large data volumes.

The authors recently conducted a conceptual study for the design of a soil cover system for a TSF in an arid climate to reduce tailings infiltration and manage surface runoff. Two distinct cover systems were proposed and applied at strategic locations on the TSF: a store-and-release (SR) concept, and a flow control layer (FCL) with drainage ditches. Groundwater flow simulations were conducted using GeoStudio's SEEP/W module. The arid climate's sudden precipitation patterns required careful consideration of time step size, convergence criteria, and geometry adjustments. Boundary condition setups were trialed to reflect the effect of the drainage ditches accurately. The hydrogeotechnical properties' uncertainty was addressed through sensitivity analyses. This paper reviews the challenges faced while performing the numerical modeling required for the conceptual study and provides recommendations for similar analyses.

Introduction

Description of the mine site

This study is conducted for designing a soil cover system for a tailings storage facility (TSF) located in a region subjected to an arid climate. The TSF has a rectangular shape with peripheral dikes and an area of

around 400 ha. Over the years, several dams were built to manage the tailings deposition. The tailings and process water are deposited on alternating sides of the TSF using the central deposition method. The tailings have little to no potential for acid mine drainage (AMD) generation and show arsenic leaching potential. Cyanide contamination could occur in the short to medium term and it is carefully monitored for.

Climate conditions

The TSF is exposed to a semi-arid climate characterized by an intense rainy season, where high rainfall events are measured over short periods of time. The potential evaporation greatly exceeds rainfall on a yearly basis. The average annual rainfall and evaporation at the site are approximately 430 mm and 3,000 mm, respectively. Strong seasonality is observed; most of the annual rainfall occurs from June to September, during the summer months. However, the potential evaporation being substantially higher than rainfall results in an overall negative water balance for the entire year. Figure 1 shows typical daily temperature, rainfall, humidity, and wind speed readings recorded at the mine site over a typical year.

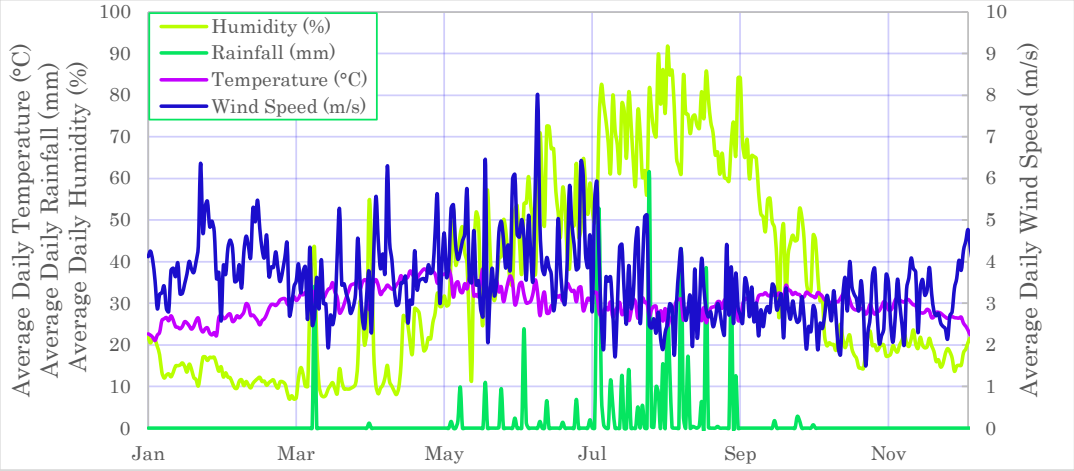

Figure 1: Typical climatic conditions recorded at the mine site

Soil cover systems

The main design objectives of soil cover systems are to limit water percolation into the tailings, ensure efficient surface water drainage, limit wind erosion, promote beneficial land use for local communities, and ensure long-term stability and sustainability with minimal maintenance requirements, all while being adapted to the specific environmental conditions of the site. In arid or semi-arid climates, cover systems experience extended dry periods, which significantly impacts evapotranspiration. However, subjecting the cover system to evaporative demands can be beneficial in such climates, leading to reduced infiltration into the underlying waste material (Bussière and Guittonny, 2021). The store-and-release (SR) cover system relies on the cover material's ability to retain sufficient moisture. Water infiltrating the cover system is "stored" within the cover material during wet periods and subsequently "released" into the atmosphere

through evapotranspiration during dry periods. As a result, net percolation into the underlying waste is minimized, making the SR cover system an appropriate option for arid climates. A typical SR cover consists of a SR layer (usually a fine-grained soil) placed over a capillary break (CB) layer (usually a coarse-grained material). The CB is created by the difference in hydraulic properties between the layers, particularly the pore size, which disrupts capillary action and effectively limits water infiltration. The flow control layer (FCL) with CB is another suitable cover system for a mine site subjected to an arid climate. The principle of the FCL relies on the capillary break effect to ensure a lateral deviation of rainfall water toward drainage ditches and prevent deep water percolation into the underlying waste material, as well as minimize soil erosion. This cover system is generally composed of a coarse-grained material (lower layer) to allow a rapid lateral transport of the water and a fine-grained material (upper layer) to create the CB and limit water infiltration. These two soil cover systems were studied for the TSF discussed in this paper.

Numerical model setup

Distinct numerical models were set up to evaluate the performance of the two soil cover systems designed for the site. While the materials used for both models were identical, the geometry definition and the boundary conditions used differed. The following sections detail the methodology followed for the study.

Methodology

The numerical simulations of water flow through the soil cover and the tailings are carried out using the SEEP/W module from GeoStudio (Seequent. 2024). The transient water flow dynamics in unsaturated soils was analyzed through finite element calculations, over a simulated period of 7 years to consider a wide range of possible climatic conditions. The steps carried out for these analyses are as follows: geometry and mesh definition; boundary and initial conditions definition; materials definition; time step adjustment; model convergence check; water percolation calculation.

Geometry definition

Geometry simplification is essential in numerical analysis, especially in preliminary engineering phases where laboratory data for hydrogeotechnical properties are not yet available, such as is the case for this project. Using a detailed 3D model for a complex mine site can sometimes create more problems than it solves. Simplifying the site into 2D or even 1D domains is often essential. While oversimplification is a risk, a 1D analysis can be useful for infiltration-percolation studies, helping identify potential convergence issues with complex boundary conditions. This study uses a 1D domain of the proposed SR cover system (Figure 2), consisting of 0.7 m of sand and 0.3 m of gravel. The lower portion of the domain consists of 9 m of tailings representing the mine waste deposit to be covered.

Vertical percolation is assumed to be the dominant seepage mechanism for the portions of the TSF where the SR cover system is used. The lateral slope in these areas is negligeable compared to the site extent. Since lateral flow should be minimal, the 1D idealization is deemed acceptable.

The second geometry defined for this study is a 2D representation of the proposed FCL cover system, consisting of the same material layers configuration used for the SR cover. The combination of an inclined surface and an effective capillary barrier promotes lateral flow through the upper sand layer toward a drainage ditch. These drainage ditches are to be located at regular intervals throughout the proposed FCL cover. Hence, only a cross section of the TSF is modeled, as shown in Figure 3.

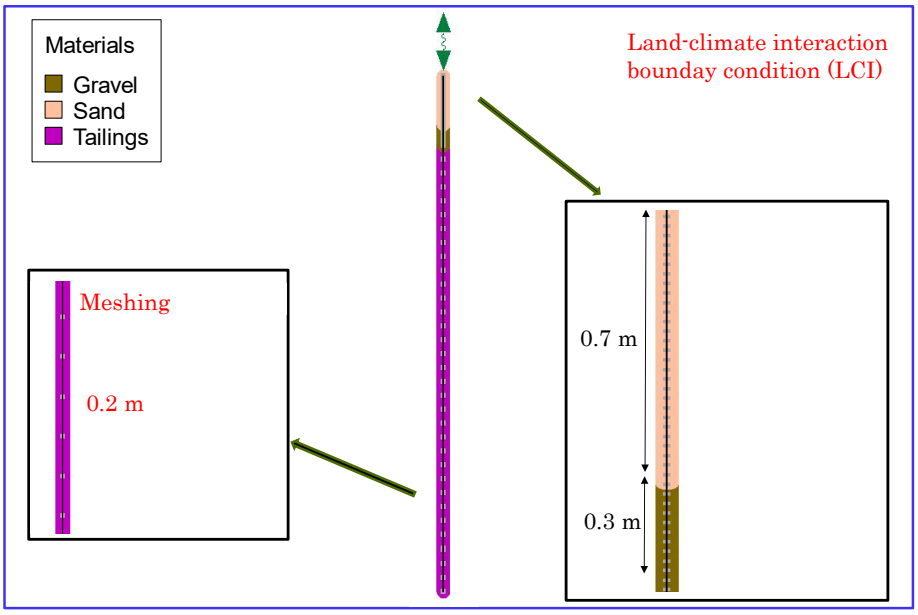

Figure 2: 1D geometry of the store and release cover system, meshing and boundary conditions

Finite elements mesh and time steps

Defining a high-quality mesh and associated time step size is paramount for the performance of any finite element analysis, whether in terms of solution accuracy or run-time. Mesh refinement is especially important at the top of domains where transient boundary conditions are applied, as is the case for this study. Where water transfers are not as important, a coarser mesh should be defined to promote faster solving. Time step size should be defined proportionally to the mesh density. Finer meshes will require smaller time steps, and conversely, so that convergence issues are avoided.

Meshing for both geometries defined for this study is shown in Figures 2 and 3. For the 1D geometry (Figure 2), the mesh size is set at 0.006 m for the sand and gravel layers. While a 0.01 m mesh size is generally a good starting point when land-climate interaction boundary conditions are used, it was decided to use a finer mesh to solve convergence issues (discussed further down). The mesh size is set at 0.2 m for the tailings layer, where water transfers are less important than in the upper layers.

For the 2D geometry (Figure 3), the mesh size is set at 0.1 m by 1 m. This mesh is considered relatively coarse, especially when compared to the 1D geometry. Since water flow can occur both vertically and laterally in 2D, convergence is not a concern as it can become in 1D. The coarser mesh size defined in 2D also promotes faster run-time, which can become substantial for such large domains.

Finally, time steps are set at 1 h for both geometries. Calculation results, however, are only saved every 24 steps, which amounts to a single save point per day. Given that the simulations cover a 7-year period, saving results every time step would result in over 60,000 save points, at every node in the domain. Saving every 24 steps reduces the number of saved points to around 2,500, which is more manageable. Note that the climate data used to define the land-climate interaction boundary condition varies daily.

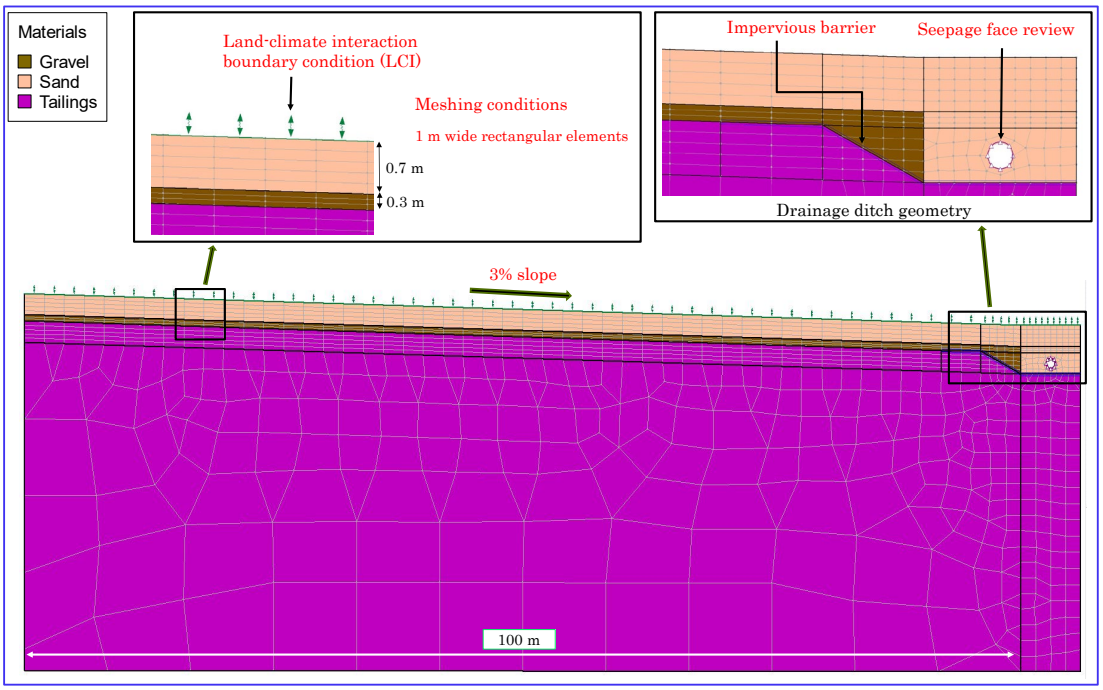

Figure 3: 2D geometry of the flow control layer cover system, meshing and boundary conditions

Boundary conditions

Similarly to defining meshing conditions, accurately defining boundary conditions is an essential step in any numerical model. Poorly defined boundary conditions significantly impact the simulation results and lead to misinterpretation of the physical situation that is modeled. These input parameters must be carefully thought through to simulate realistic study conditions.

For the two soil cover system designs, a land-climate interaction (LCI) boundary condition was applied to the very top of the domain. This boundary condition simulates actual climatic conditions measured at the site over a 7-year period, requiring the compilation of temperature, humidity, rainfall, solar

radiation and wind speed data for the period considered. Transpiration through root uptake was neglected at this stage of the engineering design process.

For both geometries, the bottom of the domain is considered impervious to represent the presence of a geomembrane installed at the bottom of the TSF on top of the natural foundation. Although it is expected that some water flow will occur through the geomembrane, it is numerically convenient to assume it to be completely impervious at this stage of the engineering design process.

Finally, the 2D model for the FCL cover system includes a drainage ditch to be lined locally with a geomembrane which will be installed on top of the tailings deposit. A drainage boundary condition is applied to the drain itself, which allows water flow when the pore water pressure at the interface reaches 0 kPa.

Initial conditions

Transient analyses require initial conditions. These generally come from a parent steady state analysis, or another transient analysis. For this study, transient "spin-up" analyses were set up for both geometries used. These analyses include the LCI boundary condition to be used for the 7-year analyses, but only applied for a limited 1-year period. The spin-up analyses are initiated using a parent steady state analysis where a 1 m total head boundary condition is applied at the bottom of the domain. The goal of the spin up analyses is to mitigate the impact of the steady state initial conditions used by letting the porewater pressure and water content within the domain respond to a full year of climate data. The results of the spin-up analyses are passed down to the child 7-year transient analyses and serve as initial conditions. Whenever LCI boundary conditions are used, spin-up analyses should be used, unless the initial conditions can be properly defined otherwise. This type of analysis is also very common for numerical simulations of thermal flow problems.

The version of GeoStudio used (2024.1) does not support spin-up analyses natively. If a parent spin-up analysis feeds its results to a child transient analysis, this analysis' start time will obligatorily be tied to the spin-up analysis. So, a 1-year spin-up analysis will force the subsequent 7-year analysis to start at the 1-year mark. Fortunately, a workaround is possible: if the spin-up analysis lives in another file, then GeoStudio allows for the transient analysis' start time to be reset to whatever value is desired by the user.

Materials definition

One of the major challenges in this study arises from the limited hydrogeotechnical data available for on-site materials. To generate the water retention curves and hydraulic conductivity functions for the simulated materials, estimation tools available in SEEP/W were used at this preliminary engineering stage. Grain-size distributions available for on-site materials were used to define the soil water retention curves and hydraulic conductivity functions shown in Figure 4 via SEEP/W's estimation functions. As shown in Figure 4, a sand material is defined, and two gravels are considered.

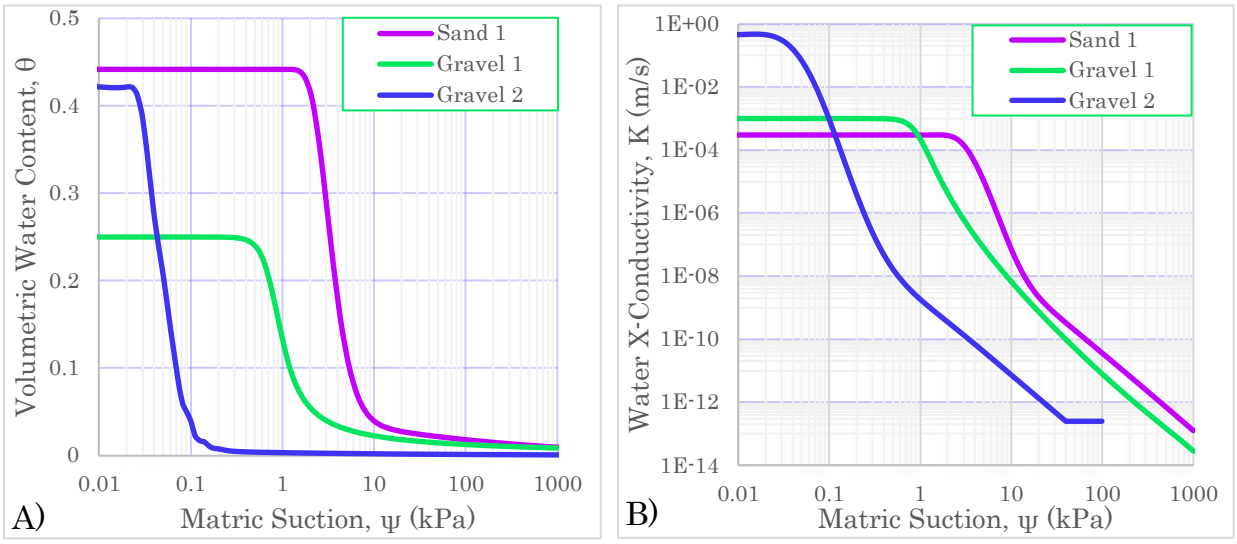

Figure 4: Soil water retention curves (A) and hydraulic conductivity functions (B)

Challenging numerical results in 1D

Extensive numerical simulations using the simpler 1D geometry ensured a proper understanding of the flow dynamics affecting the cover system before transitioning to the more challenging 2D geometry. Initiating modeling with a 1D domain facilitates detection of numerical challenges arising from complex boundary conditions. For infiltration-percolation analyses, applying the land-climate interaction (LCI) boundary conditions is crucial to simulate realistic study scenarios. However, such conditions can bring significant numerical issues due to the intrinsic temporal fluctuations of the climate data.

While 1D modeling significantly simplifies the numerical exercise, it does not prevent convergence issues. Monitoring convergence is essential to achieve accurate results. The use of LCI boundary conditions renders convergence monitoring even more resource intensive than for other types of analyses: unconverged pressure head nodes must be monitored, together with water balance checks.

Water balance interpretation

To assess the performance of the studied soil cover system, water percolation was calculated based on the water balance results obtained from the numerical model. In Figure 5, results for cumulative rainfall, runoff, infiltration, evaporation and percolation are shown for a full year. Infiltration refers to any water entering the domain via the soil-climate interaction boundary condition. Whenever the top node of the domain is unsaturated, infiltration is possible if rainfall occurs. If the top node is saturated, runoff occurs. Percolation represents water that infiltrates through the sand and gravel cover layers and penetrates the underlying tailings. A performant design minimizes percolation. Percolation being a subset of infiltration, it is always less than or equal to infiltration, and does not contribute to the overall water balance.

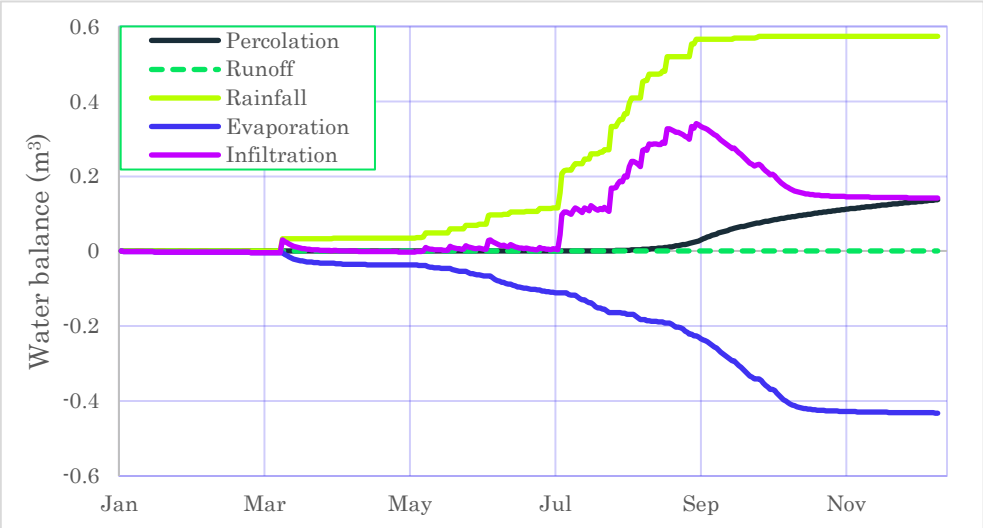

Figure 5: Water balance at the tope node of the 1D domain

As part of the convergence check requirements, the sum of infiltration, evaporation and runoff must be equal to rainfall. Water change in the domain via the boundary conditions must also be checked: the cumulative water mass transiting through boundary conditions (the LCI boundary condition in this case) must be equal to the cumulative change in water mass inside the domain. The error between these two measures must be minimized by appropriately adjusting the time steps, mesh size and convergence criteria.

Challenging convergence

Together with water balance convergence, pressure head convergence must also be monitored to ensure accurate results. By plotting the number of unconverged pressure head nodes for each solve step, remediation actions can be taken if non convergence is observed. As described by Castonguay (2023), unsaturated flow calculations are inherently prone to convergence issues because of the iterating procedure required to solve the finite element equations when nonlinear hydraulic conductivity functions are used.

To remediate pressure head convergence issues, the under-relaxation criteria used in SEEP/W can be altered. By setting the initial rate and minimum rate of under-relaxation to 0.65 and 0.01, respectively, the solver will inject a larger proportion of the previous calculated results into the current results to cautiously proceed toward the appropriate solution. This adjustment should be made to the solver's parameters whenever repeated substitution is observed when inspecting the unconverged pressure head plot.

Very low unsaturated hydraulic conductivity values should also be removed from the materials' definition if they cause convergence issue. This can be readily viewed when inspecting the hydraulic conductivity plot displaying the target functions versus the used functions. As a rule of thumb, hydraulic conductivities lower than $1x10^{-13}$ m/s can generally be removed without much effect on the general results.

Even when no pressure head convergence issues are apparent, water balance error can still occur. Rounding errors resulting from the application of the convergence criteria used in SEEP/W can sometimes cause these errors. From one iteration to the next, pressure head values at a given node will be deemed "converged" if equal once rounded down to two significant digits (default value). For most larger-scale flow problems, this is acceptable. However, it might be quite different for smaller-scale flow problems, such as those where LCI boundary conditions are applied to regions meshed at 0.01 m (or lower) intervals. Significant rounding errors can arise when accumulated over the numerous time steps used for LCI-type simulations. Increasing the convergence criterion relating to significant digits to a larger value is a way to minimize these possible rounding errors, which become apparent when monitoring the water balance.

Failure to meet the objectives of the soil cover system

The water balance results (Figure 5) showed percolation rates into the tailings reaching above 20 % of the total rainfall, irrespective of the available gravel material options used. Using the sand and gravel materials readily available at the mine site without any modification to their original grain size, although practical and economical, does not lead to adequate performances for the cover system. In this context, synthetic hydrogeotechnical properties for the granular materials were devised to perform sensitivity analyses and identify material combinations that would lead to adequate performance in terms of percolation through the tailings. Two new water retention curves and hydraulic conductivity functions were generated for both the Sand 1 and the Gravel 1 materials. The original curves were translated horizontally by 40% and 250%, as shown in Figure 6.

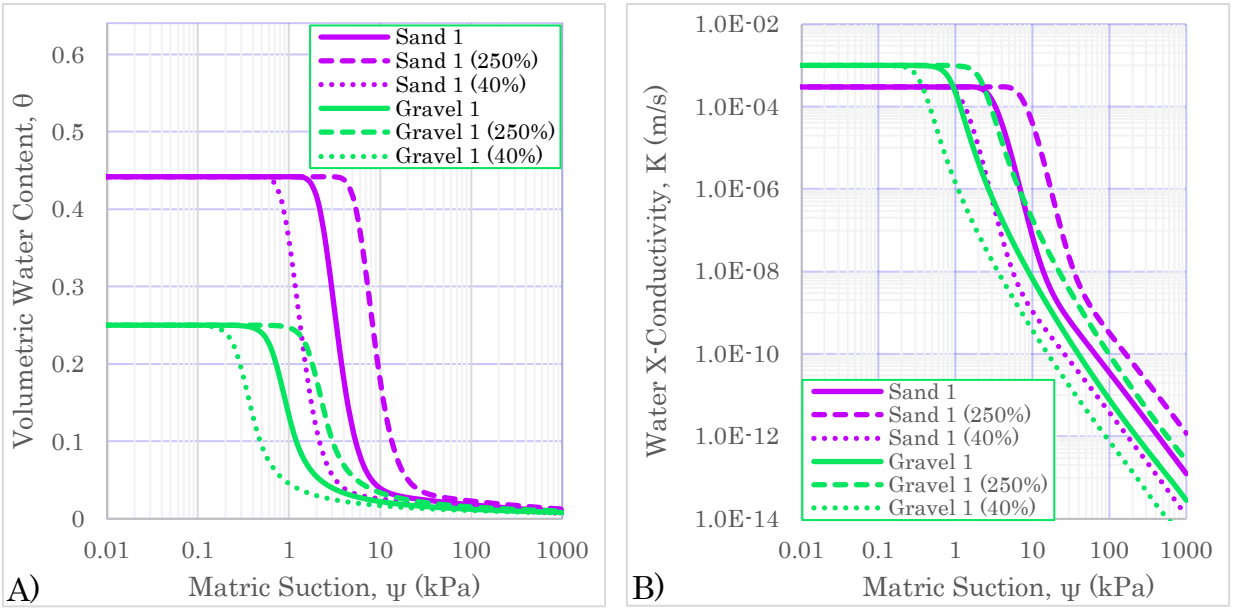

Figure 6: Soil water retention curves and hydraulic conductivity functions for site/existing and synthetic materials

The proposed water retention curves and hydraulic conductivity functions were intentionally designed to create and control the relative size of the capillary break zone between the two cover materials. Capillary break occurs when an underlying material becomes less permeable than its overlying counterpart as matric suction increases. For example, the capillary break zone that exists between the original Sand 1 and Gravel 1 materials extends from matric suction values of 1 kPa and larger. The thickness of this capillary break zone is however quite modest, which results in very comparable hydraulic conductivities, even when the capillary break exists.

On the other hand, the capillary break zone for Sand 1 (250%) and Gravel 1 (40%) extends from matric suction values of 0.4 kPa and larger, and is of very large size, creating a significant hydraulic conductivity contrast between the two materials at any given matric suction larger than 0.4 kPa. The new water balance results obtained from these sensitivity analyses yield significant improvements in the cover system performance. Very low percolation rates were observed, particularly for material pairs which showed larger capillary break zones.

Challenging numerical results in 2D

The experience gained through the 1D numerical analyses was used to tackle the increased complexity of the flow control layer cover system's 2D geometry. Irrespective of convergence issues that still might arise both in 1D and in 2D geometries, the latter brings additional challenges in terms of managing extended run-time and file size. A full 7-year numerical simulation would now extend beyond a 24-hour run time and create file size reaching over 10 GB. While extended run times can be managed through careful planning, heavy file sizes can pose significant performance issues when viewing and plotting simulation results.

Convergence issues remain one of the main challenges for 2D geometries. Close examination of the results often reveals that non-convergence arises on days where rainfall becomes suddenly intense. The sudden and stark changes in rainfall quantities inherent to the site's climatic conditions heavily contribute to numerical instability. To tackle these convergence issues, time step sizes were reduced for periods where intense rainfall occurs, which further exacerbates the already extensive run times.

An additional challenge for 2D simulations relates to meshing conditions. While generating good quality meshes is straightforward for simple geometries, integrating complex geometry features like a drainage ditch makes meshing intricate and requires careful consideration. Rectangular finite elements generated by SEEP/W's "surface layers" tool are generally easier to work with for LCI type problems, as they allow for easy mesh discretization in the vertical direction and larger dimensions in the horizontal direction. This will however only work well if the 2D geometry does not include more complex geometry features. In such cases, clever meshing strategies must be devised to obtain an efficient mesh, such as specifying the number of divisions on lateral sides of regions and forcing the use of rectangular elements.

Requirement for a drainage ditch

To simplify 2D domains, the model geometry is defined as a slice of the real field geometry. But where should the geometry extend to? A reflex might be to model a section where no feature intersects the geometry, making it representative of field conditions between distinct structures (like dykes or drainage ditches). This would be ideal if there was a way to allow lateral water flow in and out of the sides of the 2D geometry to represent an infinite domain. However, no such boundary conditions exist. The "drainage" boundary condition, which allows water to flow out of the domain, is not suitable as it only permits water to exit if the pore-water pressure reaches 0. Figure 7 shows the right-side edge of the 2D geometry where a drainage boundary condition is applied to the lateral edge of the sand and gravel layers. During a high rainfall event around the 195-day mark, saturation increases in front of the drainage boundary condition, but since complete saturation is never reached, the drainage boundary condition does not allow water to seep out. Instead, water travels downward and backward, breaching the capillary break and promoting percolation toward the tailings, as shown in Figure 8A.

For this project, the only efficient way to account for lateral flow at the edge of the 2D domain was to properly model a drainage ditch, as shown in Figure 3. Lateral water flow exits the domain via the drainage boundary condition inside the ditch. The impervious bottom (geomembrane) of the ditch allows water to accumulate and eventually exit the domain via the drainage boundary condition. Figure 8B shows how water flows to the drain instead of through the tailings once the drainage ditch is modeled.

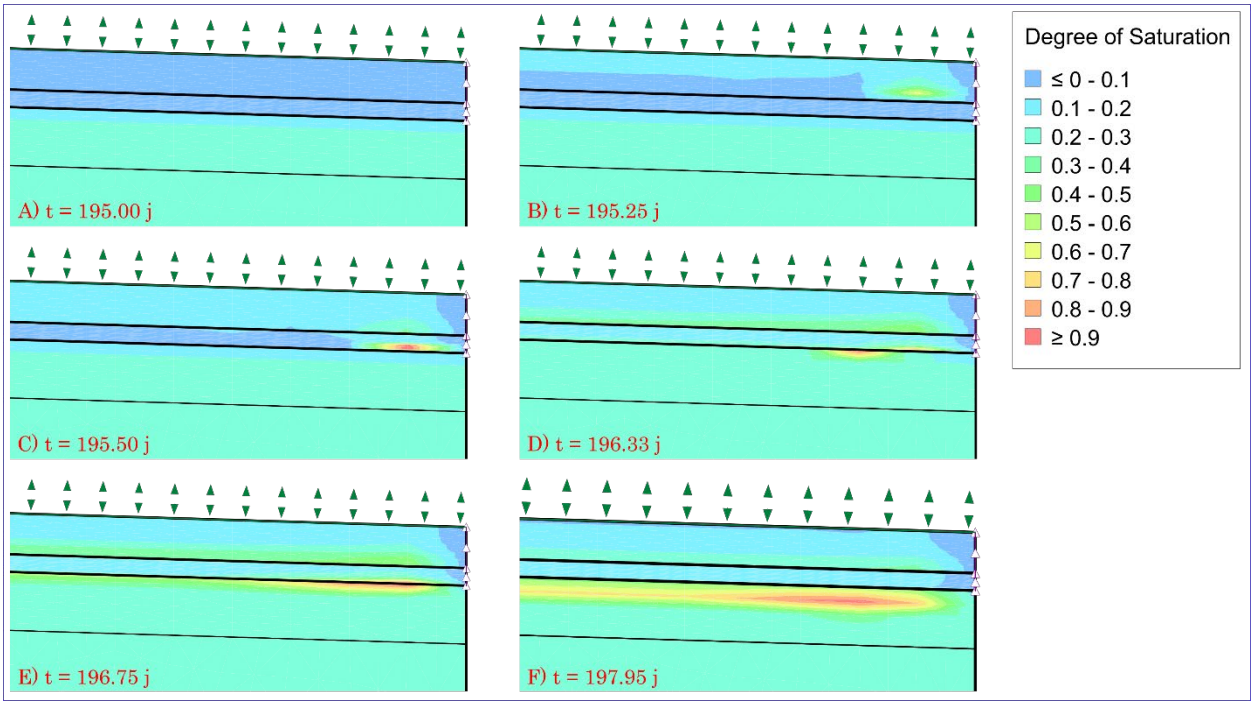

Figure 7: Retro-saturation of the flow control layer caused by the drainage boundary condition

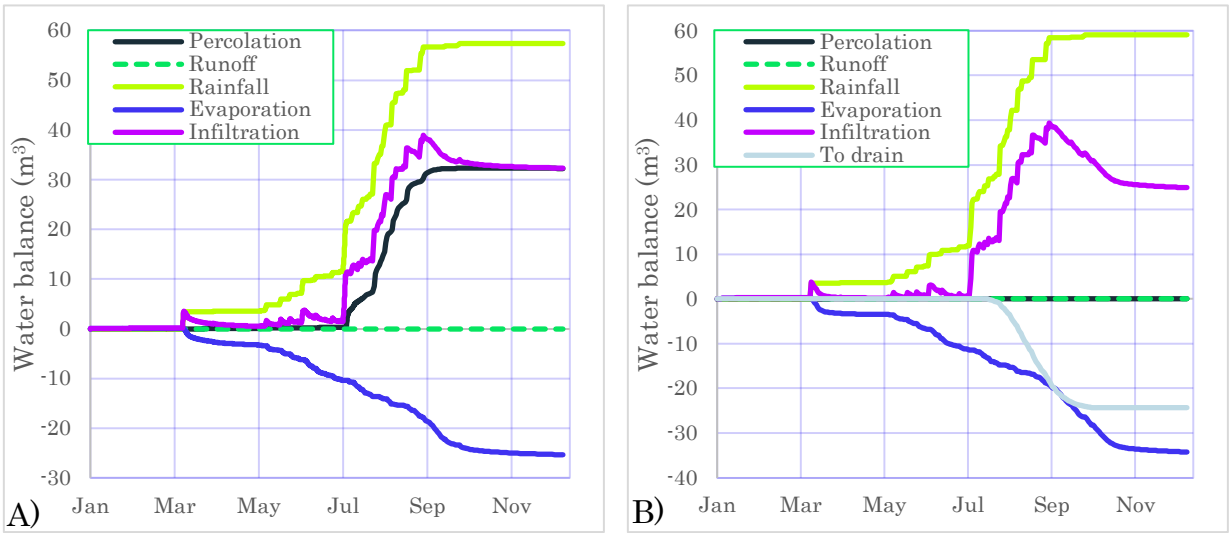

Figure 8: Water balance without (A) and with (B) the drainage ditch

Conclusion and recommendations

Modern soil cover system design for tailings storage facility relies on challenging numerical modeling, especially in arid climates with sudden and intense precipitation patterns. This study elaborates several practical steps that can be followed to simplify these simulations and ensure reliable solutions. Starting the exercise with a simple 1D geometry is a critical step to identify the numerical challenges before tackling more complex 2D geometries. Finer meshes with smaller time steps are required for domains subjected to transient boundary conditions. Coarser meshes can generally be used in 2D analyses because of the possibility of lateral flow. To tackle convergences issues in a structured manner, various elements must be checked including the porewater pressure convergence, water balance components, and consistent water changes in the domain. Finally, 2D geometries require careful consideration to elaborate consistent boundary conditions at the lateral edges of the domain to properly allow or restrict water flow, as required. The next step for the project discussed herein is to measure hydrogeotechnical properties of the soils used for the various soil covers design, account for the presence of vegetation, and refine the overall designs.

Abstract

Effective management of tailings storage facilities (TSFs) is a critical aspect of sustainable mining operations, particularly post-closure. Cover systems are key elements for sustainability to help maintain the long-term stability of the TSF, particularly when designed to reduce infiltration and oxygen ingress so as to limit the rates of sulfide oxidation, thereby reducing the potential for acid rock drainage (ARD) and metal leaching (ML). We propose a novel modeling process applied to cover systems that harnesses the analytical strengths of Hydrus-1D coupled with the versatility of Python scripting and the data management and analysis capabilities of Power BI. Our methodology provides an understanding of the cover's infiltration and degree of saturation, which is crucial for determining the efficacy of cover systems and their enhanced variants with additional low hydraulic conductivity layers. Our research is expected to contribute to the body of knowledge in TSF management and closure and to provide a foundation for future innovations in cover system design.

The practical application of our modeling approach is demonstrated through a theoretical example where the automated modeling approach is used to examine key variables of the cover system performance over a wide range of input values. These variables include hydraulic conductivity, soil water characteristic curves, cover thickness, and the influence of climatic conditions as boundary constraints. The analysis results provide an understanding of the cover's degree of saturation, which is crucial for determining the efficacy of limiting oxygen transport as well as relative rates of infiltration, which in turn is crucial for predicting the performance of systems designed to reduce the potentially impacted seepage (ARD/ML) downstream of the TSF. The simulation outputs are graphically depicted using a 2D color gradient plot that dynamically represents the fluctuation of saturation levels across different temporal and spatial dimensions.

Introduction

This paper presents the integrated use of Hydrus-1D, Python, and Power BI as tools for cover design and evaluation. Hydrus-1D is an industry-standard one-dimensional time-dependent code that simulates water and solute transport in variably saturated porous media. Python is employed to automate the input process, communicating with Hydrus-1D to run the models and retrieve the outputs (Noël et al., 2023). Power BI is used to perform post-processing of the outputs and aid the engineer to interpret and easily compare the results of multiple models. This integration significantly enhances the efficiency and value of the modeling process for the engineering design.

The proposed tool is aligned with existing cover design studies in the literature, as outlined by the Mine Environment Neutral Drainage program (MEND, 2004) and the International Network for Acid Prevention (INAP, 2017).

To demonstrate the application of this integrated process, a cover example was conducted to assess the expected performance of a tailings storage facility (TSF) cover system as part of a mine project. The TSF contains potentially acid-generating (PAG) and metal leaching (ML) mine waste that could affect the water quality of the seepage leaving the TSF. The cover system function is to limit water infiltration and oxygen ingress. If the cover remains at a high degree of saturation, it will limit oxygen ingress, and the impact of the PAG/ML mine waste into the TSF seepage.

The primary focus of the modeling exercise is to determine the degree of saturation of the cover material after the TSF has drained drown, as the degree of saturation is one of the controlling variables on rates of oxygen ingress through the cover. A threshold of a minimum 0.8 degrees of saturation was established for the cover to perform effectively as an oxygen barrier.

Four types of cover configurations were evaluated. Additionally, a range of saturated hydraulic conductivity values for one of the configurations was analyzed. Average climate conditions (precipitation and evapotranspiration) were also studied in detail for both cold humid and cold arid zones, as the exercise can be repeated regardless of the TSF location. The key objective is to ensure that the cover is effective under quasi-steady state conditions for a range of climatic and material property scenarios.

Cover system

The primary functions of the cover system considered in this paper are: 1) to function as an oxygen ingress barrier for the underlying waste material by maintaining a high degree of saturation within a layer of the cover system, thereby minimizing the effective oxygen diffusion coefficient and increasing the loss of oxygen concentration; and 2) to function as a barrier to reduce water infiltration to the underlying waste material, thereby reducing the quantity of poor water quality seepage leaving the TSF.

The appropriate type of cover system primarily depends on the climate, which is defined by factors such as annual precipitation, potential evapotranspiration, and temperature. Figure 1 illustrates the optimal cover system options based on these variables (GARD Guide, 2011).

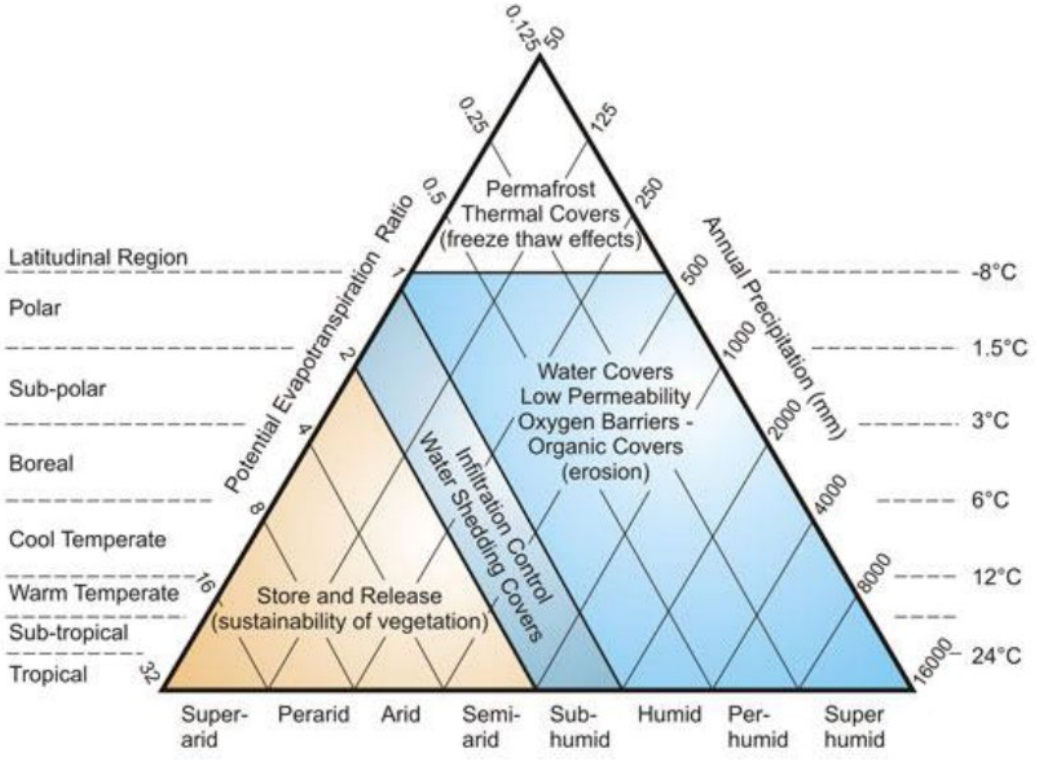

Figure 1: Cover systems and climate types (GARD Guide, 2011)

The design of a cover system for mine closure must balance cost-effectiveness with achieving an acceptable level of risk. The design should minimize additional rework and have minimal sustaining capital expenditure associated with ongoing monitoring and maintenance after closure.

Effect on degree of saturation

The degree of saturation in fine-grained materials has a strong impact on the oxygen diffusion coefficient. Figure 2 illustrates an example of the change in the diffusion coefficient of oxygen, decreasing rapidly as the degree of saturation increases. This occurs because higher saturation limits the movement of oxygen due to its lower solubility in water.

During slurry tailings deposition, the degree of saturation is high. However, after tailings deposition ceases, drain down occurs, and the phreatic surface lowers, allowing greater penetration of oxygen. As the tailings drain, the degree of saturation decreases. Oxygen diffusion is expected to be the dominant oxygen transport mechanism in tailings, whereas oxygen transport via advection and convection are also expected to be significant transport mechanisms in the waste rock environment.

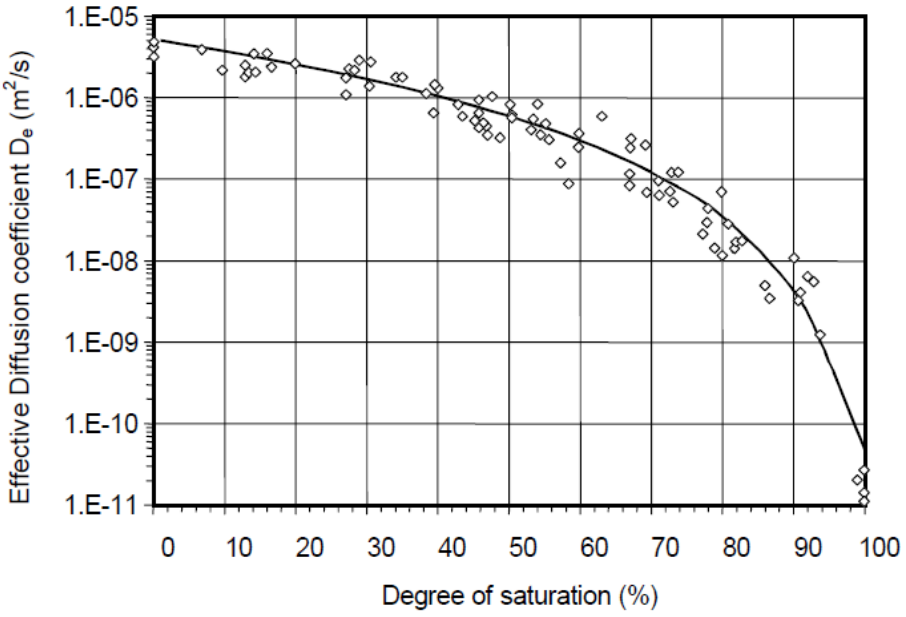

Figure 2: Effect of the degree of saturation on the oxygen diffusion coefficient (Mbonimpa et al., 2003)

Methodology

Description of Hydrus-1D and its capabilities

Unsaturated flow modeling is performed using Hydrus-1D software. The water transport is based on Richards' equation for the saturated/unsaturated water flow with various types of boundary conditions, and material properties such as the soil water characteristic curves (SWCC) and hydraulic conductivity functions are represented by theoretical models like van Genuchten (1980).

Boundary and initial conditions are crucial in simulations as they significantly influence the accuracy and reliability of the results. Hydrus-1D can accommodate detailed boundary conditions, which are also available in the modeling tool presented here. The initial conditions are set by specifying the water content or pressure head along the model's profile.

Integration with Python and Power BI for automation

The integration of Python and Power BI with Hydrus-1D represents a significant advancement in automating the flow models. A Python script was developed to streamline the modeling process. The script reads the input data (e.g., cover properties, boundary conditions, initial conditions) provided via text or spreadsheet files by the user, prepares the Hydrus-1D input files, runs the simulations, and processes the outputs. This automation has the benefit of significantly reducing the user time to conduct sensitivity analyses, which include variations of one or multiple parameters at a time such as hydraulic conductivity, cover thicknesses, saturation levels, and climatic conditions.

The Power BI is primarily used to visualize and compare the pre-processing variables and post-processing results outside the Graphic User Interface (GUI) of Hydrus-1D, enabling the creation of user-defined plots, and comparing the results of multiple models on the same plot.

Cover example

Geometry

The base case modeled geometry consists of a 6-meter cover material placed atop 10 meters of tailings, as illustrated in Figure 3. This exercise uses a cover composed of non-acid generating tailings, built during deposition above the PAG tailings. This can be a cost-effective solution, and provides the designer with flexibility to modify the cover thickness, thanks to the availability of the material. The water table (WT) was assumed to be below the model domain, and the top boundary was defined by climatic conditions. Three cover configurations include a single 6-meter cover layer, and one of the configurations involved placing a thin layer of the best-performing cover material on top of another cover material.

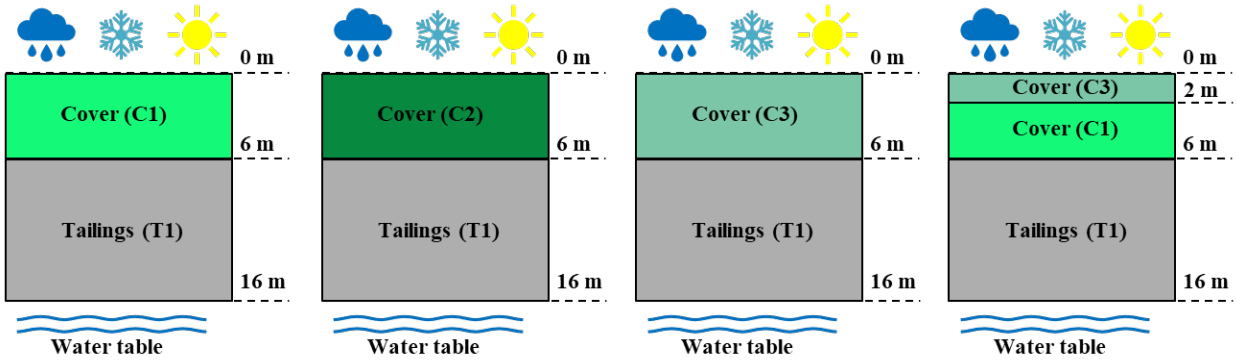

Figure 3: Cover profiles

Material properties

Four material types were used as inputs for the seepage modeling: cover (C1, C2, C3) above the tailings (T1). The properties for these materials are usually derived from geotechnical laboratory testing. As part of a testing program, a series of SWCC, saturated hydraulic conductivity, and particle size distribution (PSD) tests are conducted to characterize the hydraulic properties of the cover. It is essential that the tested samples represent densities expected in situ to ensure accurate results. If information on the PSD is available but SWCC data is lacking, the Rosetta Lite v1.1 tool (Schaap et al., 2001) inside Hydrus-1D can be employed to obtain the necessary van Genuchten parameters.

The selected hydraulic properties are fitted using the van Genuchten model (van Genuchten, 1980). The selected soil water characteristic curves for the cover and tailings are illustrated in Figure 4. The

corresponding parameters are listed in Table 1. Hydraulic properties employed in this exercise were made up by increasing the porosity and Air Entry Value (AEV).

When examining the van Genuchten parameters, it should be noted that the α parameter is inversely proportional to AEV, while the n parameter is directly related to the steepness of the SWCC slope. The AEV represents the suction state at which air begins to enter and desaturate the soil.

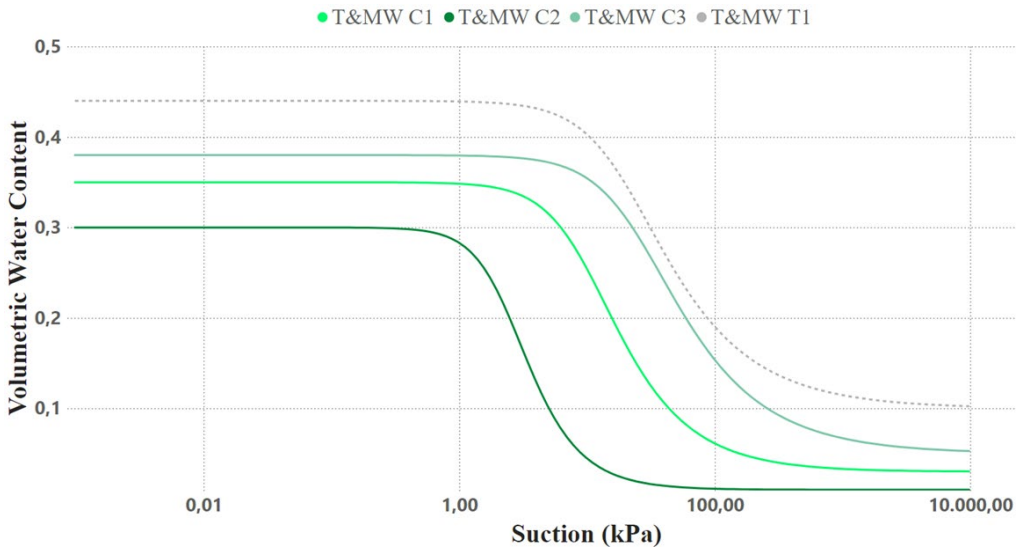

Figure 4: SWCC covers and tailings

Table 1: Hydraulic properties of the cover and tailings

Parameter	C1	C2	C3	T1
θ_r [m^3/m^3]	0.03	0.01	0.05	0.10
θ_s [m^3/m^3]	0.35	0.30	0.38	0.44
α [1/m]	1	4	0.4	0.5
n [-]	2.0	2.5	1.8	1.8
l [-]	0.5	0.5	0.5	0.5
K_s [m/sec]	1.00e-8	1.00e-8	1.00e-8	1.00e-7

Initial conditions and model time

The initial conditions were set by specifying a water content at or near saturation for both the cover and tailings, reflecting the state of the slurry tailings at the end of deposition in the TSF. These near-saturation conditions were chosen to facilitate the numerical convergence of the model.

All simulations were conducted over a five-year period to minimize the influence of the initial conditions and ensure quasi-steady state conditions (e.g., degree of saturation and infiltration) along the model's profile. The results were interpreted based on output print times at monthly intervals throughout the duration of the simulation.

Top boundary conditions

The top boundary was assigned as atmospheric, incorporating climatic data. The climate inputs for both the cold humid and cold arid scenarios were derived from Daymet, which provides long-term, continuous, gridded estimates of daily weather and climatology variables. The mean annual precipitation (MAP) from 1979 to 2019 is 252 mm for the arid scenario, while it is 360 mm for the humid scenario, representing a 40% increase. The difference in mean annual evapotranspiration is even more pronounced, with the arid scenario at 1,246 mm and the humid scenario at 247 mm, indicating that the arid scenario experiences approximately five times higher evapotranspiration.

Figure 5 shows the variation of the ambient air temperature presented as the daily average over the 40-year dataset. The daily average variation of the potential evapotranspiration is also shown in Figure 5, along with the daily average ambient air temperature, illustrating the dependency of potential evapotranspiration on ambient air temperature.

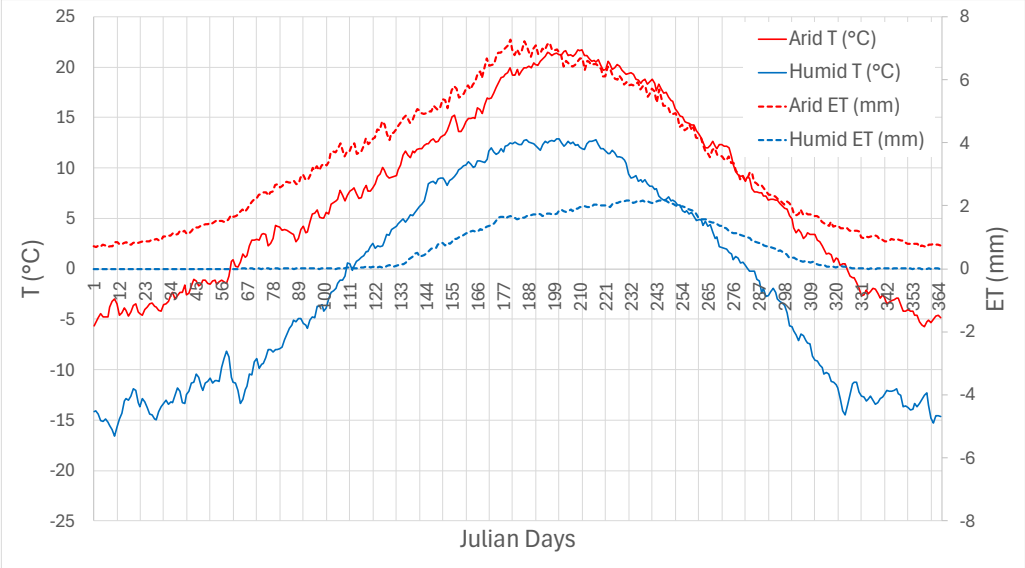

Figure 5: Average of daily ambient air temperature and evapotranspiration

An average year of precipitation and evapotranspiration from the 40-year dataset was selected for the humid climate and for the arid climate.

Daily precipitation and evapotranspiration values of each average year were specified as the top boundary conditions. The values of the average year were cycled over the entire five-year simulation period.

Bottom boundary conditions

The cover models assume that the WT position is within or near the bottom of the TSF, which is situated beneath the model domain. The bottom boundary was then assigned a free-draining condition, assuming that the base of the profile will be drained with no water uptake and that water will flow due to gravity.

Results

The main output presented in this section, as previously described, is the effective degree of saturation in the cover. Profiles are shown as lines at specific time intervals, with a color gradient (light to bold color) indicating the advance of time.

An improvement for interpretation over the line plots is the use of saturation profile plots that combine in a single figure the changes in the degree of saturation over time and depth (e.g., Figure 8). The x-axis represents time, while the y-axis represents depth. Regions with saturation levels exceeding 0.8 are denoted by dotted hatching, indicating high saturation levels. Areas with saturation levels ranging between 0.6 and 0.8 are represented by slanted hatching, distinguishing them from other regions. This comprehensive presentation of results allows for a visual understanding of how saturation levels evolve over time and depth, alongside the influence of precipitation and evapotranspiration dynamics. By using the Power BI tool to incorporate simulation results, the volume of water in the system is plotted over time.

A set of 33 simulations was run, and only the most relevant ones are shown in this paper. The title above the plot indicates the simulation number (n), cover material (C), tailings material (T), climate used as the top boundary condition (H or A), and the number of years considered in the simulation (yrs). The title may include additional parameters corresponding to further variations.

Base case

For the base case scenarios, cover material C1 was evaluated under both humid and arid climate conditions. The results are shown in Figures 6 to 9. Figure 6 illustrates the drain down. It can be observed that within the first two years the evolution from saturation to a quasi-steady state is achieved for the humid climate, but not for the arid climate. Figure 7 shows the final two years of the simulation, highlighting the upper portion of the cover as the “active zone” affected by the boundary conditions in the humid scenario. In the arid scenario, the saturation of the cover profiles continues to decrease over time, achieving the quasi-steady state by the end of the fifth year. These two figures show the limitation of the modeler to have both the detailed transition (e.g., 3 months or less) and long-term data (e.g. 5 years or more), requiring creating multiple figures and separate evaluations.

Figure 8 presents an improved view of the line profiles, as described in the results introduction, consolidating all results into a single figure, which allows depicting a fine resolution (as low as desired, in this case one month was selected), for any time period, along the entire vertical profile. While steady state can be defined in terms of the degree of saturation, when no change (or repeated variation) is reached, Figure 9 aids in interpreting the profile results, showing the moisture storage in the entire profile, and steady state is achieved when no change (or repeated variation) of the moisture storage volume is achieved.

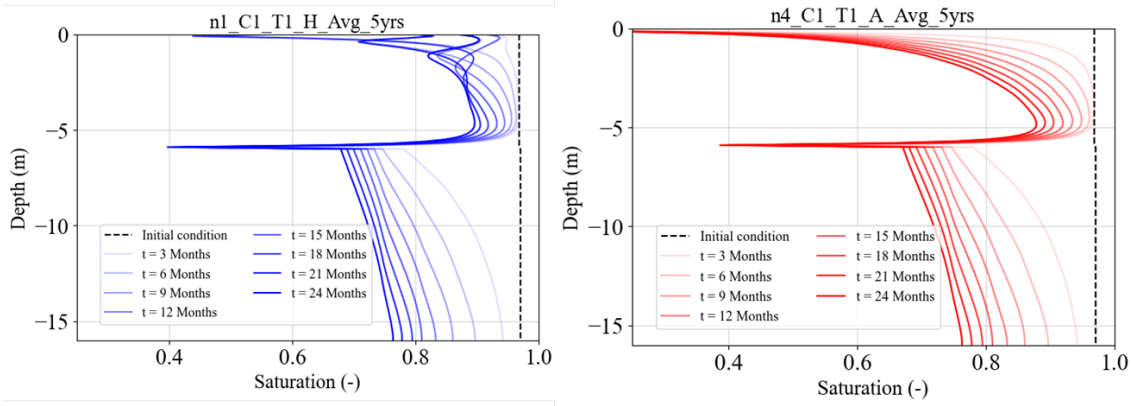

Figure 6: Saturation profile in the first two years (humid left, arid right)

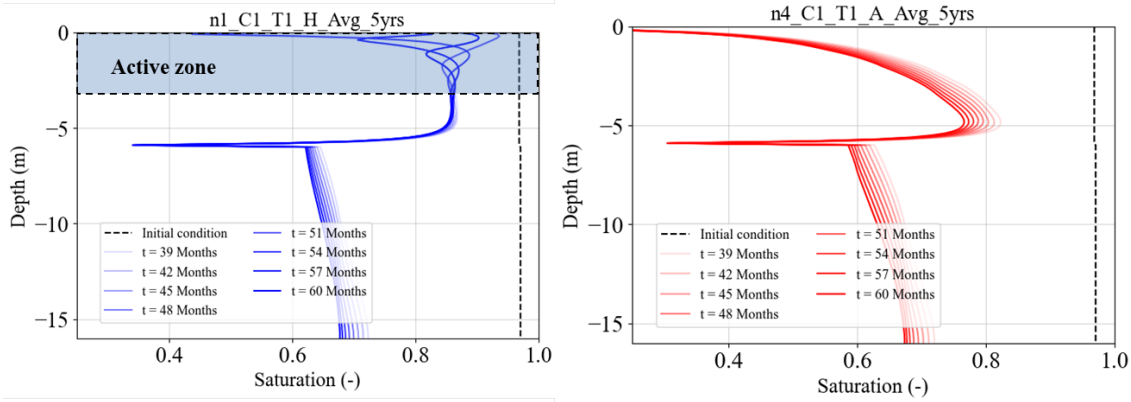

Figure 7: Saturation profile in the final two years (humid left, arid right)

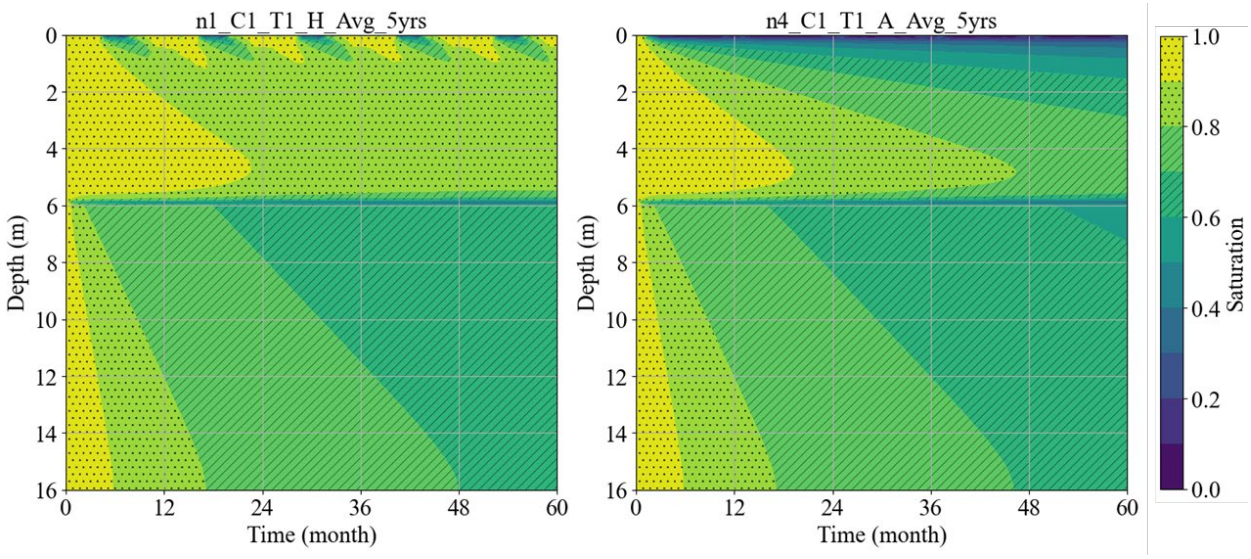

Figure 8: Base case saturation profile (humid left, arid right)

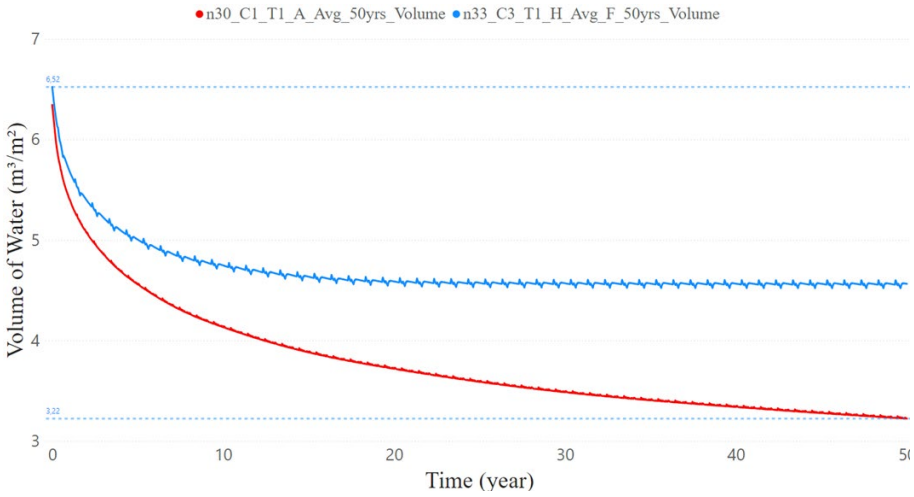

Figure 9: Volume of water of the entire system for base case – 50 years simulation

Cover material C2 and C3

The cover material was modified to C2 and C3, to evaluate the impact of different soil-water characteristic curves (SWCCs). The system shows that C3 provides superior performance, maintaining a higher degree of saturation as a result of a higher AEV (Figure 10). Consequently, C3 was used in the subsequent subsections.

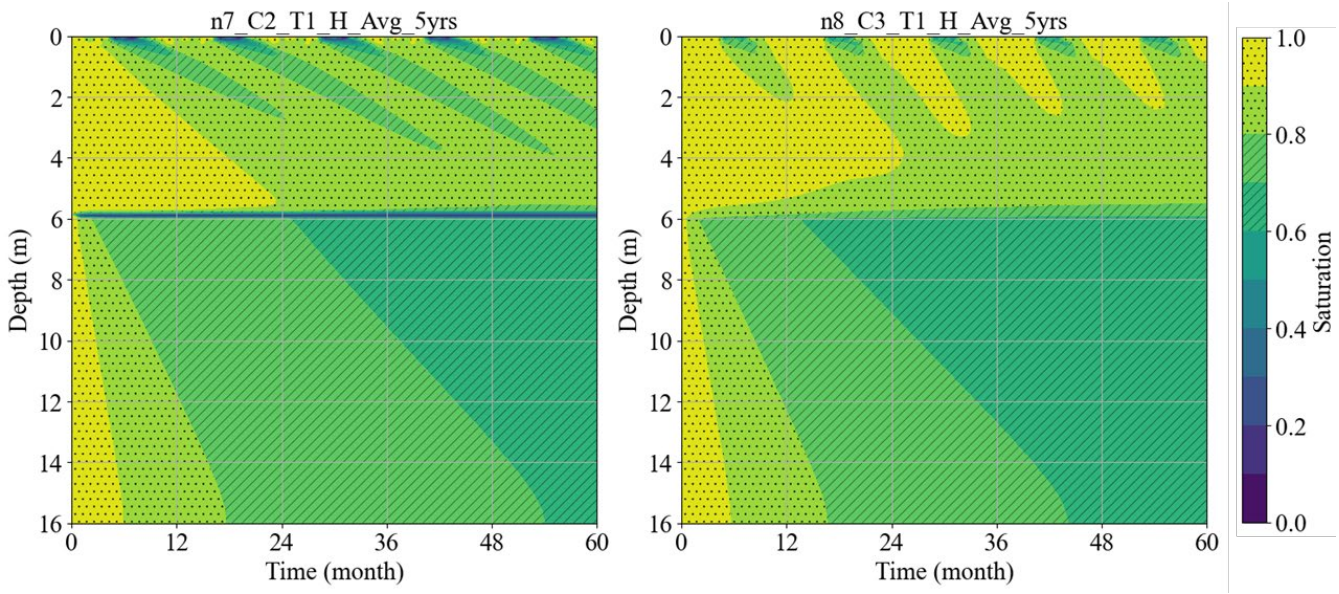

Figure 10: Saturation profile for cover materials C2 (left) and C3 (right)

Climate sensitivity analyses

Daily precipitation values were applied for the base case over 6-hour daily periods. In this section, 2 and 24-hour periods of precipitation were considered. Figure 11 shows that when precipitation is considered throughout an entire day, the degree of saturation increases considerably.

Given that the cold humid climate selection experiences a frozen period of more than 150 days (daily temperature below 0°C), a dry frozen scenario was included as a sensitivity case (Figure 12). The frozen period was assumed to occur between November and March, while the unfrozen period was assumed to occur between April and October. No precipitation was applied during the frozen period; instead, the precipitation quantity was totaled as the volume of water available during the freshet. This volume was then uniformly applied over the April period to emulate the freshet at the beginning of the unfrozen period. Snow losses due to wind and sublimation were estimated at 20%. The precipitation event in April was simply added to the freshet flux over a 14-day period. Freeze-thaw cycles impacted cover performance, potentially failing objectives due to the lack of infiltration during winter.

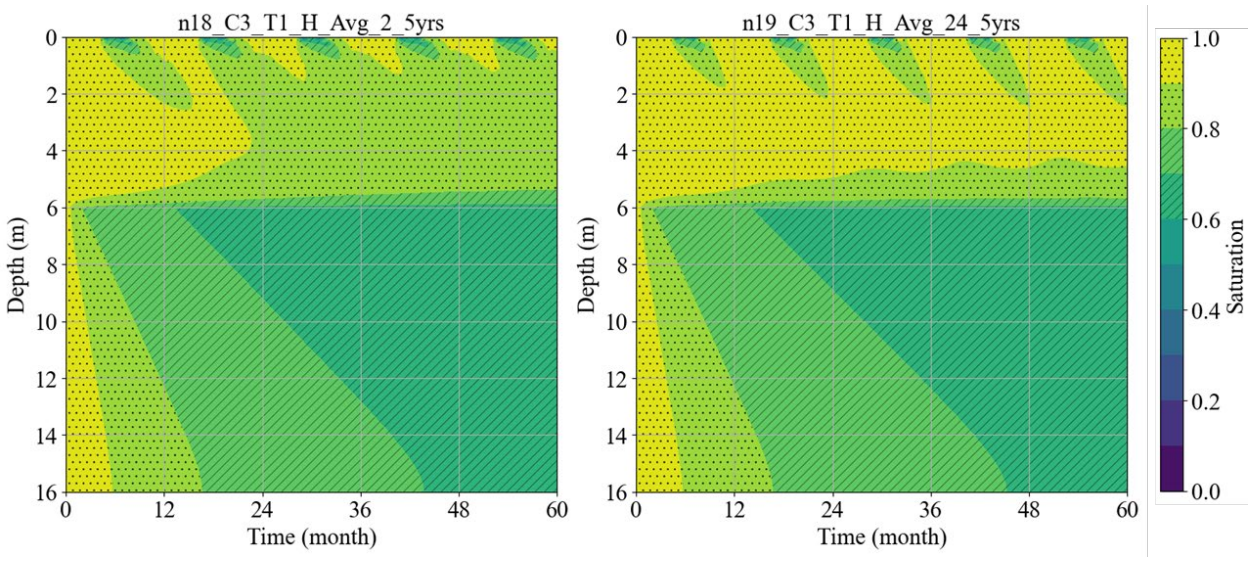

Figure 11: Saturation profile for daily precipitation with 2 hours (left) and 24 hours (right)

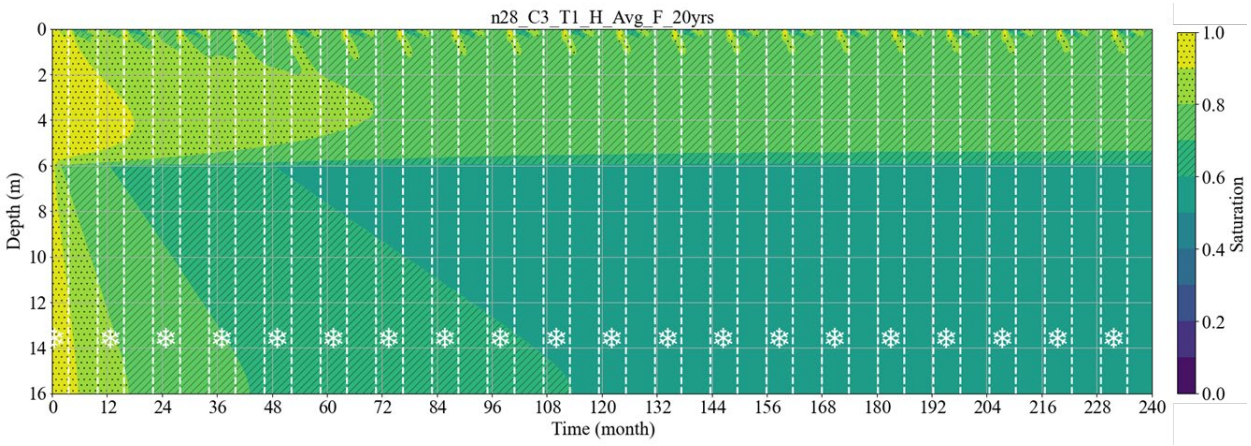

Figure 12: Saturation profile considering freeze periods of 150 days

Permeability sensitivity analyses

While maintaining the SWCC as considered, the saturated hydraulic conductivity of the cover layer was adjusted to vary between 1.00e-10 and 1.00e-6 m/s (Figure 13). The lower hydraulic conductivity maintains a higher saturation in the cover.

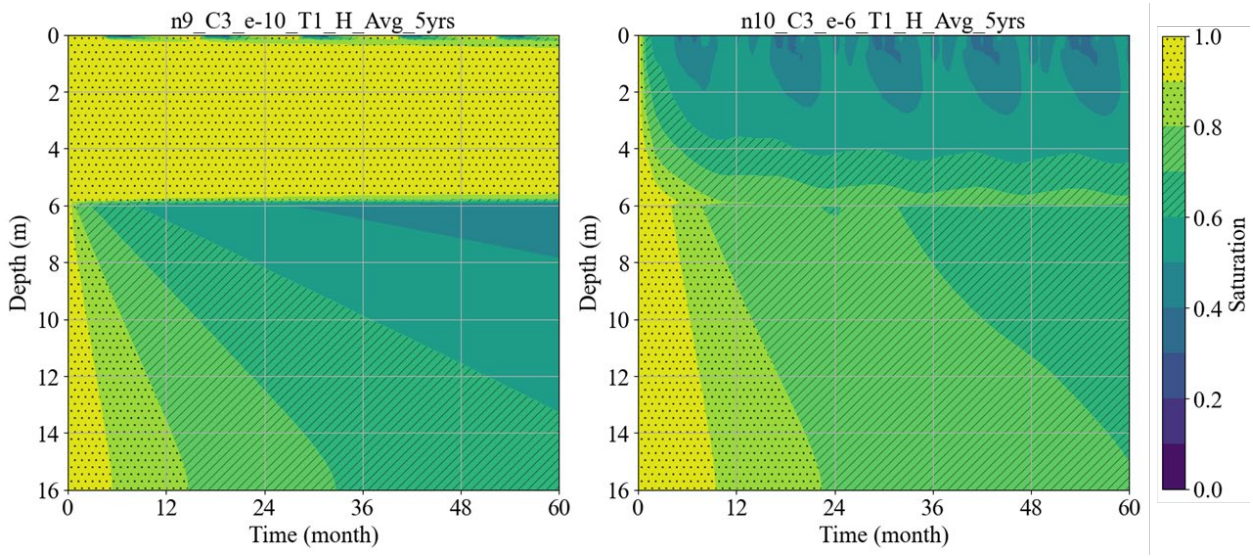

Figure 13: Saturation profile lower (left) and higher (right) Ks

Cover: thin layer of the best-performing material sensitivity analyses

A scenario featuring the best-performing cover material, C3, 2-meters, over the C1 material, which is about 4 meters, is presented (Figure 14).

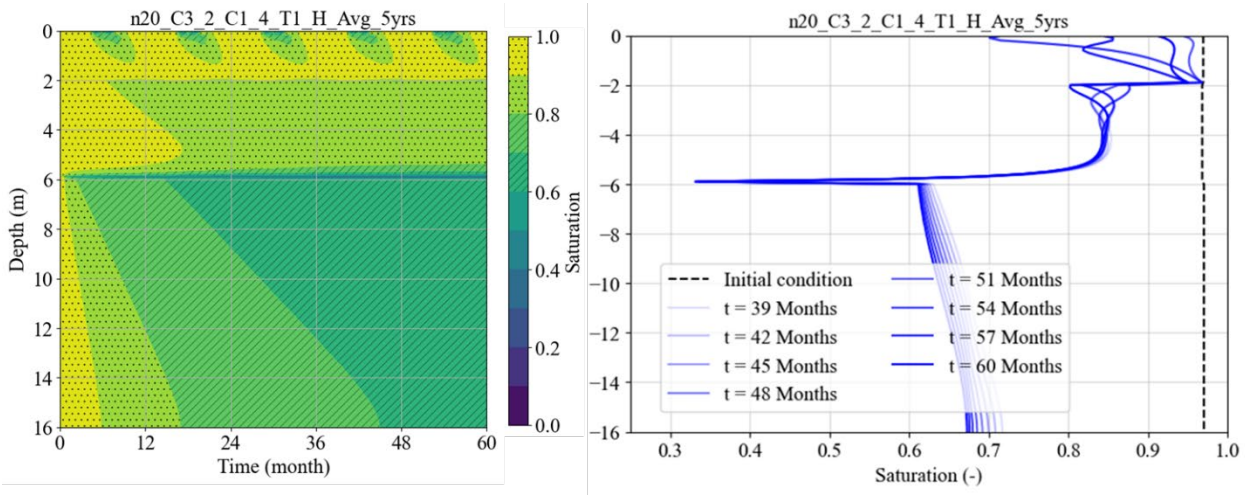

Figure 14: Saturation profile 2-meters C3 over 4-meters C1

Discussion

In this exercise the properties of the cover material were modified to assess the cover performance and find the optimal solutions (e.g., decrease hydraulic conductivity and increase moisture retention). For the engineering design there are several methods that can be considered to meet these requirements with the available non-acid generating tailing's materials, such as compaction, cycloning, material mixing, etcetera. Proper construction practices and rigorous quality control are crucial for the long-term performance of cover systems. Issues like the thickness of growth media, compaction, material placement, and construction schedules must be managed meticulously to prevent negative impacts on the cover's effectiveness and durability, as highlighted in MEND (2004).

The hydraulic properties of soils used in water balance covers can change over time (Benson, 2009), and the magnitude of these changes is closely related to the as-built condition of the cover system. Understanding these temporal changes is crucial for accurately predicting the long-term performance of cover systems in controlling water infiltration and oxygen ingress. In the analysis presented in this paper, properties were considered constant.

Finally, the modeling presented herein was restricted to vertical flow due to the use of Hydrus-1D. It did not include horizontal flow. This limitation could become important in terrain with sloping topography, as this could promote lateral flow under certain conditions.

Conclusion

An automated modeling tool that integrates Hydrus-1D, Python and Power BI was developed to model the degree of saturation for a TSF cover example. The automated process facilitates the execution of multiple scenarios, sensitivity analyses, comparisons, and modifications to cover configurations.

The cover example demonstrated a workflow for designing and modeling a proposed cover system aimed at limiting rates of oxygen ingress into the underlying mine waste materials. Key findings identified within the cover example included:

- Daily climate values have a significant impact on the cover's performance. From the base cover example, the humid scenario achieves good performance in less than 5 years, while the arid scenario did not meet the design criteria and failed to reach a quasi-steady state even after 50 years of simulation.
- An active zone, where a quasi-steady state was reached, can be observed in the base case humid scenario. This suggests that instrumentation and control may be needed only in that zone.

- Among all the cover materials, material number three demonstrated the best performance due to its higher AEV. If this material is not available on-site, a two-layer cover profile can be achieved with a highly saturated cover at the top to minimize the volume of material needed.
- The daily precipitation period had a significant impact on the profile, and well-defined and precise climate data is important for understanding the impact of climate variations on cover performance.
- If the climate includes long periods of temperatures below 0°C, it is important to consider freeze and thaw cycles, as these can affect the cover's behavior and performance, potentially falling below the required objectives due to the lack of infiltration during winter.
- A cover layer with a saturated hydraulic conductivity value not close to or lower than 1.00e-08 m/s may significantly decrease saturation levels, leading to increased infiltration and rates of oxygen transport through the cover.

The Vibro-consolidation Technique for Tailings Management and Dam Decommissioning Works

Gustavo Marçal de Sousa, Vale S.A., Brazil
Ana Torres, Vale S.A./UFOP, Brazil
Felipe Moraes Russo, Vale S.A., Brazil
Lucio Schiavon Yamamoto, Vale S.A./USP, Brazil

Abstract

Reservoir management and the search for tailings dam decharacterization solutions have become challenges that the Brazilian mining industry has to face nowadays. Based on a saturated sandy soil consolidation proposition, a promising alternative to such issues has arisen: in-situ mechanical consolidation. In particular, a technique referred to as vibro-consolidation, which consists of applying load and vibration to the tailings layer, thus forcing particles to be rearranged through tailings consolidation and expelling water up to the surface in a localized fashion, by using potentially efficient equipment for the disposed tailings particle size range, whose undersize percentage through 200 mesh sieve (0.075 mm) is not over 70%.

Thus, this work aims to introduce an experiment to contribute to new technologies aimed at assisting tailings management and/or dam decharacterization processes by applying the vibro-consolidation process, through the simulation of tailings reclamation operations from the reservoir of an iron ore tailings dam within the area referred to as Iron Quadrangle in the state of Minas Gerais, Brazil. The research uses an experimental methodology, with tests based on the proposition of a dam mining method, on an industrial scale, focusing on the vibro-consolidation technique. By applying the proposed mining methodology, enhanced mining and disposal operations workability and, consequently, geotechnical stability of the mine faces is attained. In addition to applying this technique to dam reservoirs, a promising potential might be to manage tailings in bays, existing reservoirs, and most hydraulic embankments made of iron ore tailings.

Introduction

Mining activities positively impact society by providing raw materials, job generation, state and local tax revenue, and manufacturing products required for the modern human lifestyle. Nevertheless, negative impacts also stem from such activities, and continue to impact the environment even after mining activities are discontinued (Flores and Lima, 2012). Within this context, tailings dams have always been the subject

of discussions on dam break impacts and risks. In general, tailings disposal facilities have a large footprint and demand special attention from project owners.

Currently in Brazil, hydraulic fill embankment dam stability and potential environmental impact have come in for questioning, especially following the dam breaks of Fundão, in 2015 (Carmo et al., 2017; Queiroz et al., 2018), and Brumadinho, in 2019 (Petley, 2020), for which reparation costs may be very high, even more than the costs associated with the original project and its operations.

In this context, dam decommissioning solutions have increasingly become attractive, since they do away with stability risks, as well as required on-site monitoring and periodic follow-up activities by the project owner. As recommended by Muir et al. (2005), these projects should preferably be designed by considering solutions that generate fewer geotechnical risks associated with factors such as seepage, erosion, and stability, as well as the safety of downstream communities and the minimization of environmental liabilities.

Safe dam decommissioning is a crucial variable for the decision-making process associated with a dam decharacterization or tailings reuse project. The tailings deposited in dams, in most reservoirs, are saturated, with their excavation being rather difficult (Alves, 2015). Even in legacy facilities that have been shut down for several years, there may be saturated horizons that pose risks to mining activities.

Therefore, studies must be developed to develop new technologies to allow for lower-saturation disposal and safe tailings dam mining. Associated with geotechnical designs, pilot tests and investigations, both in-situ and laboratory, are important for defining material properties, which enables safer designs to be developed (Sousa, 2020).

Hence, based on scale tests, this paper aims at assessing the feasibility of the vibro-consolidation technique in a reservoir for simulation of iron ore tailings dam mining, within the Iron Quadrangle region in the state of Minas Gerais, Brazil. Major benefits in geotechnical parameters of tailings are evaluated. The study was based on the vibro-consolidation technique for tailings, underpinned by the proposition of sandy, saturated, and soft soil consolidation, introduced by Esfahanizadeh and Atashband (2012), along with the strip-mining technique proposed in the mine and production plan developed for the pilot dam.

The major outcomes of this work include the development of the methodology and conception of a new piece of equipment whose activity cycle can potentially condition tailings disposed as slurry, which starts performing with the characteristics of materials disposed with moisture content between 20% and 30%, and may later be drained and stacked in definitive or provisional deposits.

Methodology

Production scale test description

The production scale mining test developed to enhance the in-situ vibro-consolidation technique for tailings

was performed in a conventional compacted soil dam, located in the state of Minas Gerais, Brazil, whose reservoir is used for iron ore tailings disposal. Figure 1 shows the area in which the production scale test was performed, characterized by low-consistency saturated and soft tailings.

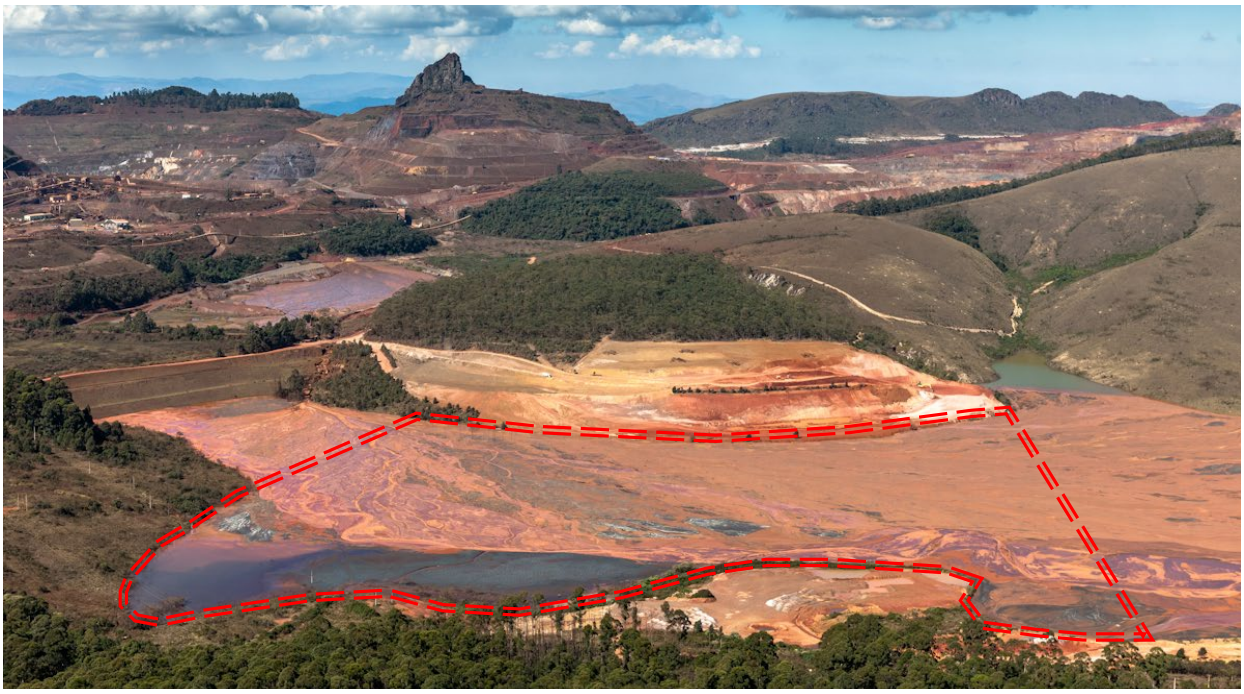

Figure 1: Production scale test area

The tests were performed over a 12-month period, with average monthly output targeted at 360,000m^3. Furthermore, test scheduling considered mine productivity variations due to rainy season months.

Data and discussion

Prior to the test period, the tailings were characterized within the mine development area, with average values obtained for major rates being shown in Tables 1 and 2.

Table 1: Average particle size of tailings disposed at the dam

Sieve	Diameter (mm)	(%) Undersize
10	2,000	95
30	0.590	85
50	0.297	82
100	0.149	80
200	0.075	69
400	0.037	42
500	0.025	38

Table 2: Average values obtained in the characterization tests

Characterization					Permeability
LL (%)	PL (%)	Gs	ρs (g/cm³)	w (%)	K (cm/s)
17	15	3.35	1.85	25.7	$9{,}7 \times 10^{-4}$

In-situ tailings were saturated and similar to soft soil, which resulted in unstable excavation slopes, thus requiring engineering solutions to ensure stability for mining activities to commence, as well as the use of special equipment for previous consolidation. Thus, activities were performed by applying standardized methodology comprising tailings consolidation, excavation, and disposal cycles. Excavations were performed in ranges, with 3-meter-high benches, in order to simulate strip mining of the reservoir with maximum 6-meter-deep excavation. This was obtained with bearing layer reclamation or direct advancement to a maximum 3-meter depth underneath the bearing layer threshold, provided that a 5-meter support meter was maintained, with a 45° slope, as shown in Figure 2.

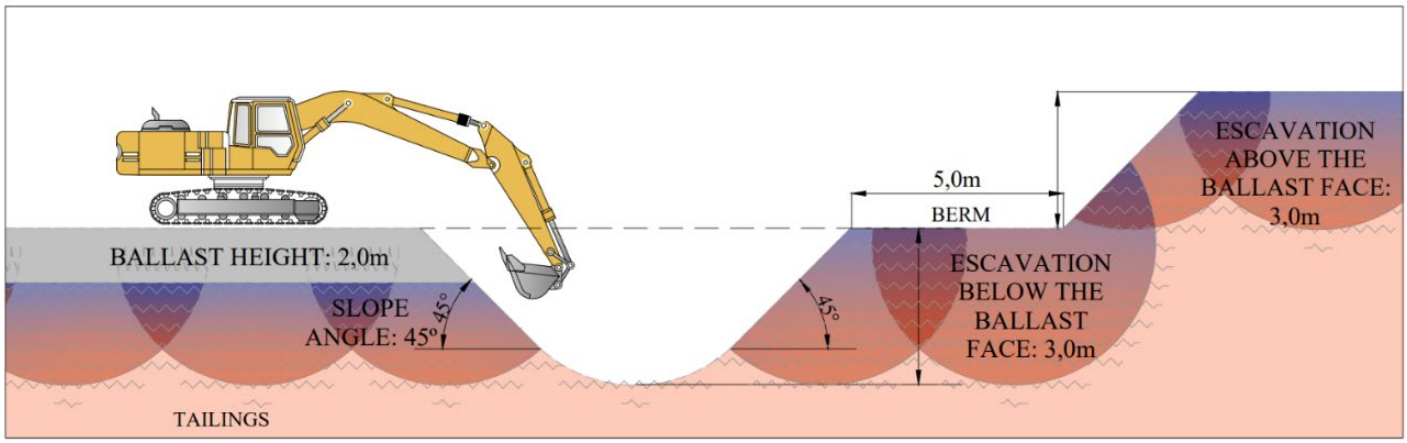

Figure 2: Operational detail of mining involving bearing layer/advancement down to a 6-meter depth

This allowed partial or total mining of a tailings reservoir, even under saturated conditions. Subsequently, the high moisture content of tailings was the challenge to be faced for material spreading, compaction, and haulage operations to be carried out, as a high moisture content might hinder haul trucks (35 tonnes) from being fully loaded.

Therefore, the tailings vibro-consolidation stage was implemented (the focus of this paper), by applying common earthworks equipment and adapting existing equipment, as shown in Figure 3, so as to enhance mining and disposal operations workability and, consequently, the geotechnical stability of mining faces.

(a) (b) (c) (d)

Figure 3: Main equipment used: (a) high-output long reach excavator (45 tonnes, 1.90 m³ bucket); (b) pump excavator suitable for pumping water and solids (20 tonnes); (c) amphibious excavator used for tailings consolidation (20 tonnes; (d) vibrating plate compactor adapted for vibro-consolidation (35 tonnes)

Mechanical consolidation proposition, vibro-consolidation, consists of applying load and/or vibration to the tailings layer, thus forcing particles to rearrange themselves by softening tailings and expelling water up to the surface in a localized fashion, followed by soil mass volume reduction. A consolidation settlement is then attained, similarly to what is proposed by Esfahanizadeh and Atashband (2012). The activity was supported by equipment potentially effective for the particle size range of the tailings disposed in the reservoir.

The test was performed over a 364-day monitoring period, with 3 daily eight-hour shifts, 7 days a week. The 12-month period has allowed for operations performance to be assessed under both dry and wet weather conditions, with hardships imposed by climate conditions to this type of operation being duly mapped out. Figures 4 and 5 (on the next page) depict the operational sequencing performed during the test in the consolidation and excavation stages.

Removed material from trial excavation were disposed of in a provisional deposit, in 2-meter-thick layers (maximum), ascending fashion, with 10-meter-high benches, 5-meter operational berms, and an angle between berms of 22° (2.5:1). An area of approximately 300,000 m^2, divided into 7 sub-areas, was prepared. In each sub-area, a 30-day cycle (minimum) was planned, comprising placement, drying, spreading, and compaction stages. A minimum 95% Normal Proctor compaction, with layer top, middle, and base checks, was set as a release criterion for the placement of each subsequent layer.

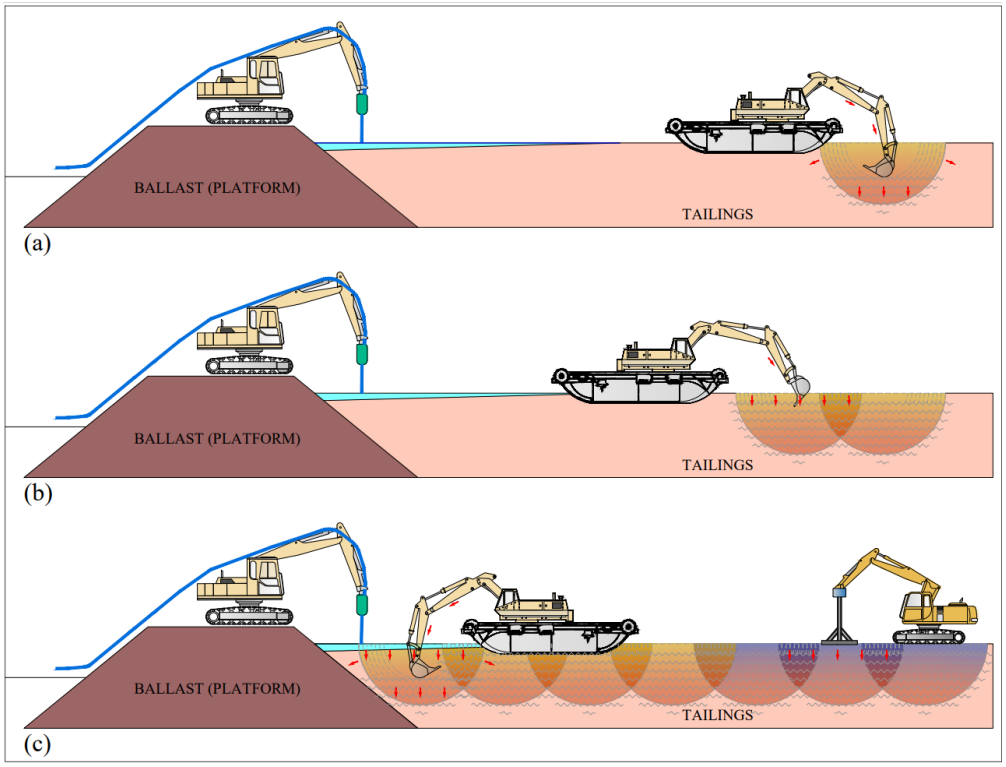

Figure 4: Vibro-consolidation execution sequence: (a) initial upward agitation at a 3-m depth by an amphibious excavator; (b) process completion up to the surface with 5 m x 5 m grid advancement; (c) employment of vibrating plate compactor for better efficiency in a 3 m x 3 m grid

Results

Production scale results: production scale mining – application of vibro-consolidation technique

Due to the provisional character of excavations and to the adoption of highly restrictive geometries regarding height, and in order to cut down on potential dam break damages, a minimum Factor of Safety (FoS) of 1.15 was set for excavation slope sizing, calculated with scenarios simulating undrained conditions, where shear-induced pore pressures originating from stress relief actions during test mine stages would act. With the adoption of in-situ consolidation, tailings were considered to assume a thoroughly drained behavior, thus significantly improving safety conditions when compared to areas where the technique had not been applied.

Provided that it is appropriately executed, the geometry proposed for the test could ensure Factors of Safety (FoS) previously associated with the geotechnical stability of excavation slopes, as shown in Table 3, based on in-situ parameters.

Table 3: Geotechnical parameters and factors of safety for production scale testing

Scenario	Parameter				FoS	
	ϕ' (°)	ϕ' (°)	ru	Su (kPa)		
σ'Effective	29	–	0.40	–	1.21	(1)
σTotal	–	20	–	–	1.16	(1)
Su	–	–	–	0.23σ'v	1.15	(1)
σ'Effective	29	–	–	–	1.37	(2)

(1) Normal in-situ condition; (2) Inclusion of the vibro-consolidation stage

Figure 6 shows the tailings vibro-consolidation stage, which allowed for enhanced mining and disposal operations workability.

(a) (b)

Figure 6: Mechanical consolidation: (a) vibrating plate compactor; (b) amphibious excavator

In fact, the amphibious excavator and the vibrating plate compactor employed in the test produced good results, cutting down on the average moisture content of the tailings disposed in the embankment from 25.7% to 20.6%, thus significantly changing its consistency and improving productivity rates in all mining stages.

The best efficiency of the equipment employed for mechanical consolidation and dewatering of tailings, which allowed for a reduction of the previously shown moisture content, fell within the particle size range shown in Figure 7 (Zone B). Out of this range, in its lower bound (Zone A), dewatering is slow, and the outcome is not always satisfactory. When tailings are off their upper bound (Zone C), their consistency and moisture allow for direct load to be applied, without the consolidation process being required. Particle size variations observed occur due to hydraulic segregation of tailings particles at various mine points.

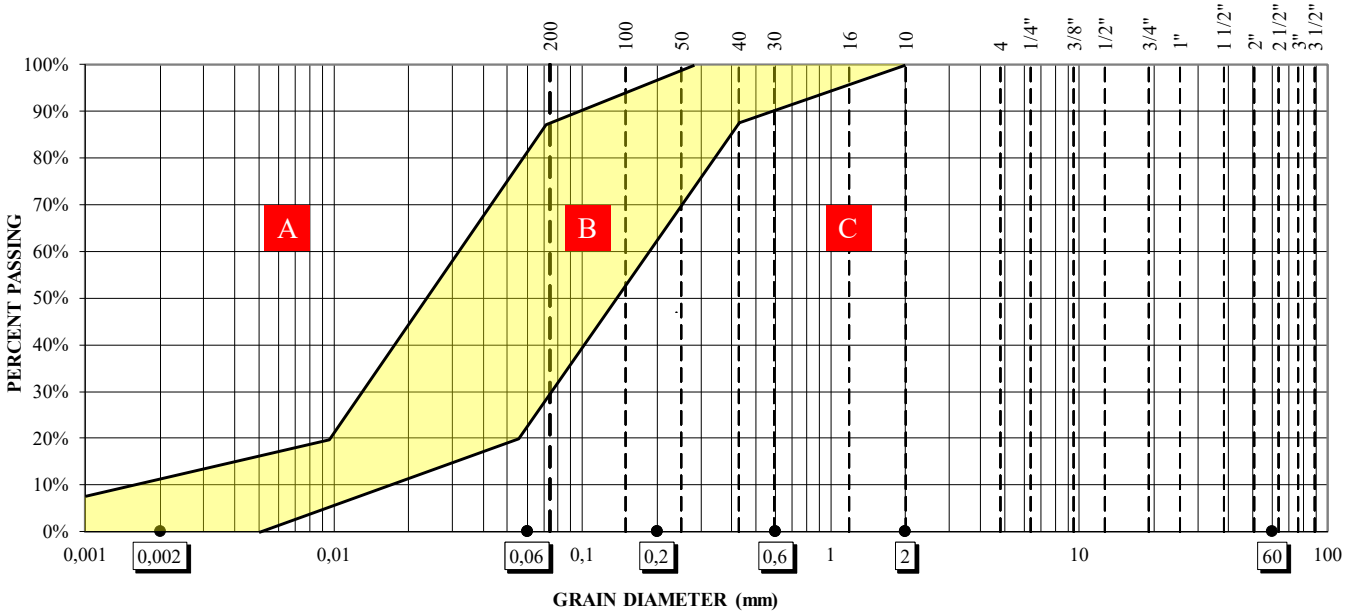

Figure 7: Efficiency of vibro-consolidation with application of the equipment described for production-scale mining test

The mining operation was standardized in average 30-day cycles from filling, rest, vibro-consolidation, and mining, as shown in Figure 8. Figure 9 shows some of these stages.

Figure 8: Management cycle through mining

Figure 9a shows the stratified structure resulting from hydraulic segregation in the particles of the tailings deposited in the reservoir. Figure 9b shows depositional layer break following vibro-consolidation, with formation of a dense and uniform horizon, where stratified layers are no longer observed.

(a) (b)

Figure 9: Various aspects of mining in the same area:
(a) before consolidation process; (b) after consolidation process

Including the vibro-consolidation stage before tailings mining has significantly improved the operational conditions, both at excavation faces and at offloading points in the deposit, thus allowing the area to be released for a new disposal cycle within the 30-day drying cycle and ensuring an exceptional stacking condition. Table 4 shows the average of random sampling for moisture content and dry apparent specific mass, carried out at mining faces and in the permitted deposit close to the dam.

Table 4: Average moisture and dry apparent specific mass values for production scale test

Collection point	avg-w (%)	avg-ρs (g/cm³)	Number of tests
Mine	20.60	1.920	43
Offloading pad	18.90	1.954	57
After 30 days	12.64	1.976	16

For moisture contents around 20%, removal to the deposit was easier, thus allowing the haul truck to be directly loaded and a dump box (haul bed) to be fully filled up. Following operations standardization, a moisture content threshold of 23% was set for mining to avoid collapses and maintain the operational condition of the deposit. Above this value, mine face operations were halted, and the material was reworked with the application of vibro-densification until it fell within the reference moisture content. Table 5 summarizes test scheduling and execution and highlights the productivity rate attained, as well as the average values measured for physical availability of tested equipment.

Table 5: Summary of production scale test performed

Period	Worked hours		Volume (m³)		Accumulated precipitation (mm)
	Estimated	Actual	Estimated	Actual	
March 2017 to May 2017	1,330	1,254	526	547.32	143.80
June 2017 to August 2017	1,710	1,672	944	1007.35	30.3
September 2017 to November 2017	1,140	1,425	870	920.60	410.7
December 2017 to February 2018	1,045	1,140	700	343.905	704.1

Even though worked days were more than estimated, the productivity rate obtained in the test was 7.8% below, which reflects the fact that the physical availability of equipment was below expectations in some months, once fleet sizing had forecasted an average productivity rate of 8,300 m^3/day. Such productivity expectation was only attained or surpassed under ideal operational conditions, i.e., without any interferences or excessive equipment breakdown.

Tested earthworks equipment has proven to be appropriate for fine tailings excavation, with approximately 70% 200 mesh sieve undersize (0.075 mm), and high specific grain mass (Gs = 3.31 g/cm^3), with productivity peaks above expectations attained. The operation is extremely sensitive to rainfall, with varying downtime due to precipitation volume.

Strength gain in the vibro-densification process

Strength gain with the application of the vibro-consolidation process was assessed by CPTu tests in a specific portion of the test area, both before and after the process, by using only the amphibious excavator to handle the material. Figure 10 shows the results before and after the use of the amphibious excavator, respectively, for a reference depth of 3 m. Tests have evidenced tip resistance gains close to or higher than

100% increment from baseline data down to a depth of 2 m. From this point downward, no significant strength gain has been evidenced.

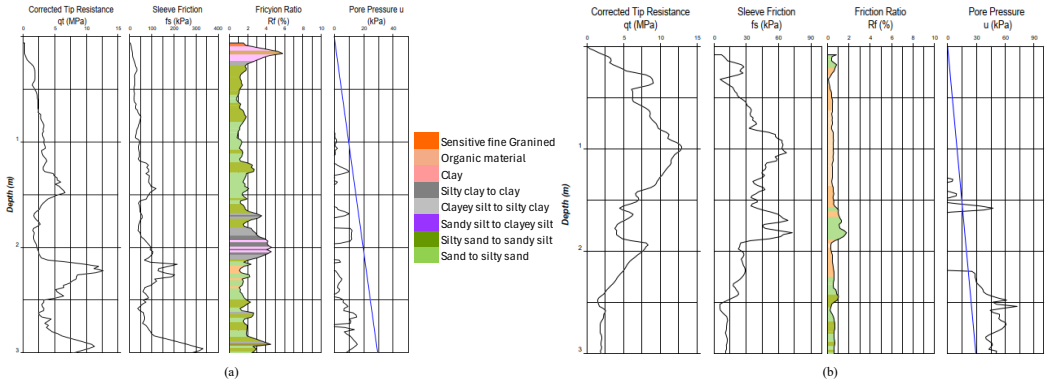

Figure 10: Test carried out: (a) before and (b) after vibro-consolidation

Also, upon observing SBTn classification abacus for soils, based on CPT tests (modified from Robertson, 1990), dispersion of results is reduced and migration of ranges 3, 4, and 5 of clays, silty clays, and clayey silts to ranges 6, 7, and 8 of clayey silts, sandy silts, and silty sands can be observed. As for pore pressure generation, in spite of the low values recorded in both tests, the generation over the first 2 m following vibro-consolidation might be considered null, which stands for gains in the stability condition, in addition to enhanced material workability.

Initially, process efficiency was expected to reach a depth of at least 3 m, which did not occur as per the test performed. One of the major reasons for this is that the amphibious excavator boom and size limited the conditioning to a maximum depth of 2 m and, even if a complementary stage with the vibrating plate excavator had been performed, initial strength gain would hinder applied energy from being transmitted beyond the previously consolidated depth.

Therefore, a proposition to overcome such constraint and reach the expected 3 m would be the fabrication of a hybrid piece of equipment, representing a mix of an amphibious excavator and a vibrating plate excavator, as shown in Figure 11. This would allow for an increase in vibro-consolidation process efficiency, as well as reaching the expected 3 m depth and working anywhere within the reservoir, in a thoroughly autonomous way.

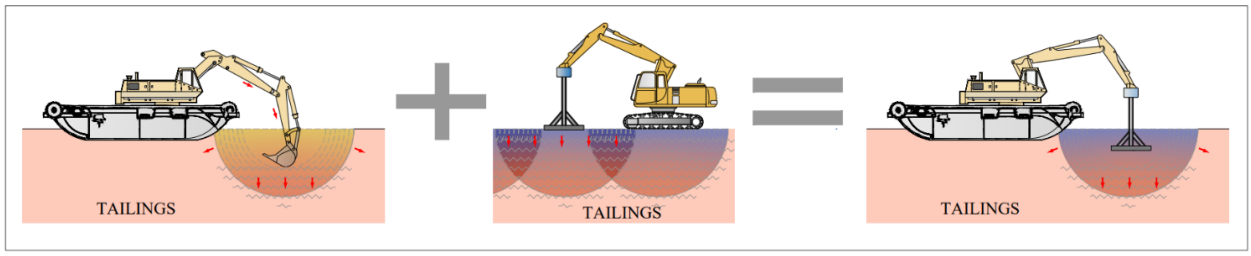

Figure 11: Proposal for the development of a new piece of equipment called amphibious plate

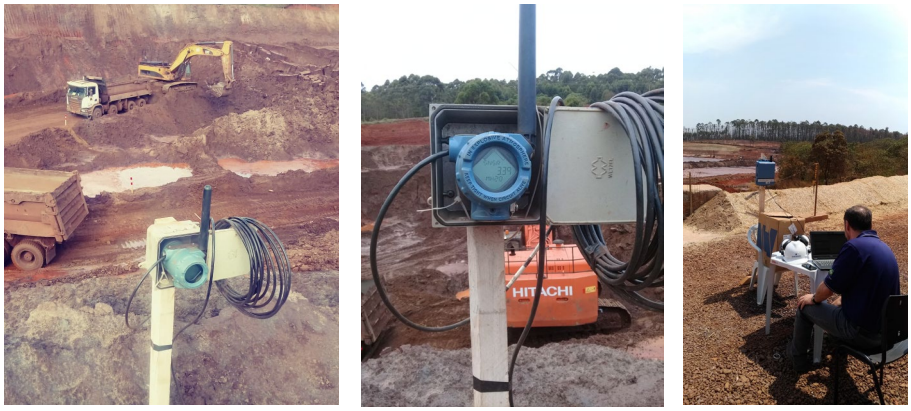

Vibration and pore pressure monitoring

During test performance, vibro-consolidation and excavation operations were monitored with vibration and pore pressure measurements at a fixed location 20 m away from the operations. Vibrations were measured from the surface by Micromate engineering seismographs, manufactured by Instatel (Figure 12), while pore pressure was measured at a 5.5 m depth by an electric piezometer manufactured by Emerson Measurement Instrumentation (Figure 14).

(a) (b) (c)

Figure 12: Vibration monitoring during operations cycle:
(a) geophone installation; (b) equipment display; (c) data acquisition

(a) (b) (c)

Figure 13: Pore pressure monitoring during operations cycles:
(a) position in relation to site; (b) equipment display; (c) remote data acquisition

Average results obtained are shown in Tables 6 and 7 below.

Table 6: Summary of production scale test performed

Reference	Parameter			
	Resulting Particle Velocity – VpR (mm/s)	Particle Displacement (mm)		Acceleration (g)
Average Value	0.2296	0.2296	0.0041	0.0057

Table 7: Summary of production scale test performed

Reference	Pore pressure (kPa)		
	Initial Phase	Vibro-consolidation Phase	Excavation Phase
Average Value	48.05	44.23	34.71

Vibration measurement records were not very significant, being close to the natural ground condition. As for pore pressures, a decrease in vibro-consolidation and excavation phases was observed against the initial condition. Records assessment allows for classification of the operational cycle applied in the test with localized interferences and without any relevance towards overall stability. A potential vibration-induced liquefaction due to the application of the technique would not be of any relevance either.

Disposal in a transitional storage facility

The excavation material was hauled and disposed of at a storage facility 3 km away from the dam, in an area duly permitted for tailings and waste disposal, as shown in Figure 14. Following excavated tailings spreading at the storage facility, with no rainfall, quick moisture loss was clear to see, even with no internal drainage element underneath tailings. Nonetheless, the best operational results were observed 30 days after material placement.

(a) (b) (c)

Figure 14: Transitional storage facility: (a) placement; (b) spreading; (c) compaction

Table 8 shows the average values obtained in the compaction control performed by random sampling after test completion, in 1 m deep trenches.

Table 8: Compaction control after test completion (average values)

Woptimum (%)	ρsmax (g/cm³)	Compaction degree (%)	Number of samples
11.6	2.180	100.2	9

The average Compaction Degree (CD) for the sampling points reached values above 100% of the Proctor test energy. This was a characteristic of the material when dry compacted, below the optimum moisture. Adopting the geometry previously described, along with the construction cycle, has ensured geotechnical stability to stacking, providing flexibility to potential mining aiming at management or decommissioning, and allowing for intermediate storage facilities to be established between the mine face and the processing plant.

Conclusion

Tailings harvesting is quite a recent approach in Brazil, with few cases having been described in literature, almost always focusing on the treatment process to be applied to disposed tailings, with mining methodology and geotechnical safety matters not being approached for this type of operation. Hence the required previous tests with equipment to provide elements to allow for a coherent technical assessment, with appropriate mining method selection to inform the development of a production plan aiming at technical and economic feasibility analyses, as recommended by Muir et al. (2005).

The results obtained from the trial using tailings vibro-consolidation technique enhancement showed that mechanized tailings excavation is a technically feasible alternative, with potential for handling large volumes of tailings. Vibration generation during excavations was moderate, with low magnitudes, in a localized fashion, only close to mine faces. Along these lines, when mining is a decommissioning solution, eliminating a tailings dam can be very worthwhile for the project owner.

Design criteria presented were specifically determined to be applied during the test phase. Upon progressing to a final design, new specific technical and economic assessments are crucial for project owner's decision-making on associated risks, so as to ensure total geotechnical safety, thus preventing accidents during excavation phases. Less daring geometries should be designed, so as to ensure higher factors of safety than the ones considered for the test.

It is noteworthy that a possible liquefaction induced by vibration to be potentially triggered by the use of the technique is punctual and has proven to be of little relevance to global stability, however, studies monitoring vibrations and additional pore pressures are ongoing, associated with representative numerical models for a complete validation of the technique applied to hydraulic landfills.

Reclamation of tailings disposed in dams stands for a clear alternative to closure, decommissioning, and/or management, which may be feasible, provided that it is well studied and developed. For this purpose,

six stages are required: Reservoir characterization; qualitative and quantitative tailings modeling; mine plan development; definition of process route/disposal location; operationalized layout; and performance of production scale tests.

All the development described in this paper is for academic purposes, aiming at contributing to the development of dam mining project engineering at a conceptual level, for each project has its own specific features, in addition to legal and environmental requirements, with direct application of results not being recommended.

Acknowledgments

The authors would especially like to thank Vale for its financial support to the project and for allowing the use and dissemination of test results, as well as the Federal University of Ouro Preto – UFOP, represented by NUGEO, for its partnership in technological development focused on sustainable mining.

Design, Construction, Monitoring and Numerical Modeling of Large-scale Field Trials: Assessing Cover Performance for Reclamation Method Selection

Karine Sylvain, WSP Canada Inc., Canada
Marie-Lin Breard Lanoix, WSP Canada Inc., Canada

Abstract

The selection of the reclamation method for tailings storage facilities (TSF) can pose significant challenges, necessitating innovative approaches to its comprehensive evaluation. Four large-scale field cells were constructed at Canadian Malartic Mine (Quebec, Canada) to address specific considerations for selection of the reclamation method, particularly in terms of the constructability and performance of the covers. Each cell was instrumented with a dense system of hydrogeological and oxygen probes. Two meteorological stations were installed to record local climate conditions. The index properties of the cover materials were used to estimate the hydrogeological properties. Field data, comprising thorough monitoring of climate conditions and hydrogeological evolution, were integrated into a 2D transient numerical model in SEEP/w.

This paper presents the methodology and the calibration results of the numerical model of one low permeability cover cell. The numerical model calibration involved the estimation of the spatial distribution of the material properties such as porosity, hydraulic conductivity, and the water retention curve. The calibrated results were consistent with observed field data, highlighting the reliability of the numerical model when combined with extensive monitoring and characterization to accurately represent the complex hydrogeological dynamics in the multi-layer covers. This case study demonstrates the capacity of a numerical model to effectively represent the hydrological evolution of the covers, and how large-scale field trials combined with comprehensive data can enhance confidence in the selection of the reclamation method.

Introduction

One of the main challenges of the mining industry is the long-term management of the tailings storage facilities (TSF) in terms of geochemical stability. Tailings can contain sulfide minerals which, when exposed to atmospheric oxygen and water, can react to generate acid mine drainage (AMD) which is characterized by acidic pH, high concentrations of sulfates and metal(oid)s (Blowes et al., 2014). One of

the primary objectives of mine site reclamation is to prevent AMD in the long-term (Aubertin et al., 2016). Typically, reclamation methods to prevent AMD are based on inhibiting oxidation reactions by limiting the concentration of one of the reactants of the oxidation reaction: water, oxygen or sulfides (Aubertin et al., 2016). The selection of the method depends primarily on the water balance and climate of the mine site but also the topography and natural material availability near the site (Bussière and Guittonny, 2021). For example, under humid and temperate climates, such as encountered in Quebec, Canada, oxygen exclusion is one of the most effective reclamation methods (SKR, 1989). The diffusion of oxygen in water is significantly lower than in air, which can inhibit the oxidation reaction (Yanful, 1993; Nicholson et al., 1989). Consequently, in a saturated porous medium, oxygen diffusion is limited, which can inhibit the oxidation reaction (Mbonimpa et al., 2003). This can be achieved by maintaining the tailings in a high degree of saturation by maintaining an elevated water table position combined with a monolayer cover or using multi-layered cover such as cover with capillary barrier effects (CCBE).

Selecting the most appropriate method for a mine site involves extensive studies which imply thorough analysis of site-specific conditions. For example, Aubertin et al. (2002) outlined eight major key steps for designing the reclamation method, as demonstrated in a case involving a CCBE : 1) Comprehensive characterization of mine waste and cover constitutive material, 2) Gathering climatic and environment data, 3) Preliminary evaluation study, 4) Numerical modeling, 5) Laboratory physical modeling, 6) In-situ test plots, 7) Final design selection and the 8) construction and long-term monitoring.

This conference paper describes both the methodology and the integration of the results of large-scale field trials and 2D numerical simulations, which are key steps leading to the final selection of the reclamation method. Particularly, this case study demonstrates the numerical model ability to represent field conditions, while highlighting the importance of large-scale field trials and extensive data that can lead to a greater confidence in the selection of the reclamation method, guiding towards the selection of the final design.

Site and large-scale field trials description

Site overview

The Canadian Malartic (CM) mine site owned by Agnico Eagle Mines (AEM) is one of Canada's largest open-pit gold mines. It is located in the northwest of Quebec Province, in the Abitibi region. The operation began in 2011 in the CM pit, which was mined until 2023. The operation is still ongoing with the Barnat pit and the Odyssey underground sector. Since 2011, the mine has produced thickened tailings, mainly potential acid-generating (PAG) tailings, which have been stored in a TSF constructed over an abandoned tailings facility (East Malartic). The actual TSF is now composed of seven deposition cells confined by starter embankments raised by the upstream method and the waste rock pile to the North. Over the years,

the perimeter TSF berms were raised at an overall slope between 10H:1V to 20H:1V, except for the recent confining structures. which are made of a single embankment with 2H:1V to 3H:1V slopes. Each upstream raise is 2 m high and composed of waste rocks and a separation of geotextile fabric. In 2024, the TSF has almost reached its full capacity with the tailings deposition moving along in the CM pit.

Large-scale field trials configuration

The CM mine has conducted several studies over the years in preparation for the TSF closure. Among them was the design of four large-scale field trials constructed directly on the TSF to address the constructability and performance of the reclamation methods (see Figure 1). The location was selected to evaluate the hydrogeological cover performance on both waste rocks upstream raises and tailings plateau. Each cell was built on an area that was approximately 250 m long by 15 m wide, and was isolated on each side by low permeability material. Two cells were constructed with covers with capillary barrier effects (CCBE), to reduce oxygen fluxes through the tailings, while the other two cells consisted of low permeability covers designed to limit water percolation into the tailings and promote runoff. Each cell was instrumented with a dense system of hydrogeological (e.g., volumetric water content and suction) and oxygen probes at different locations and depths. A total of approximately 1,200 probes were installed as water-collecting systems to measure runoff and water flow through specific layers of the covers (e.g., Parshall flume and water flow meter). Volumetric water content probes were initially calibrated in a laboratory.

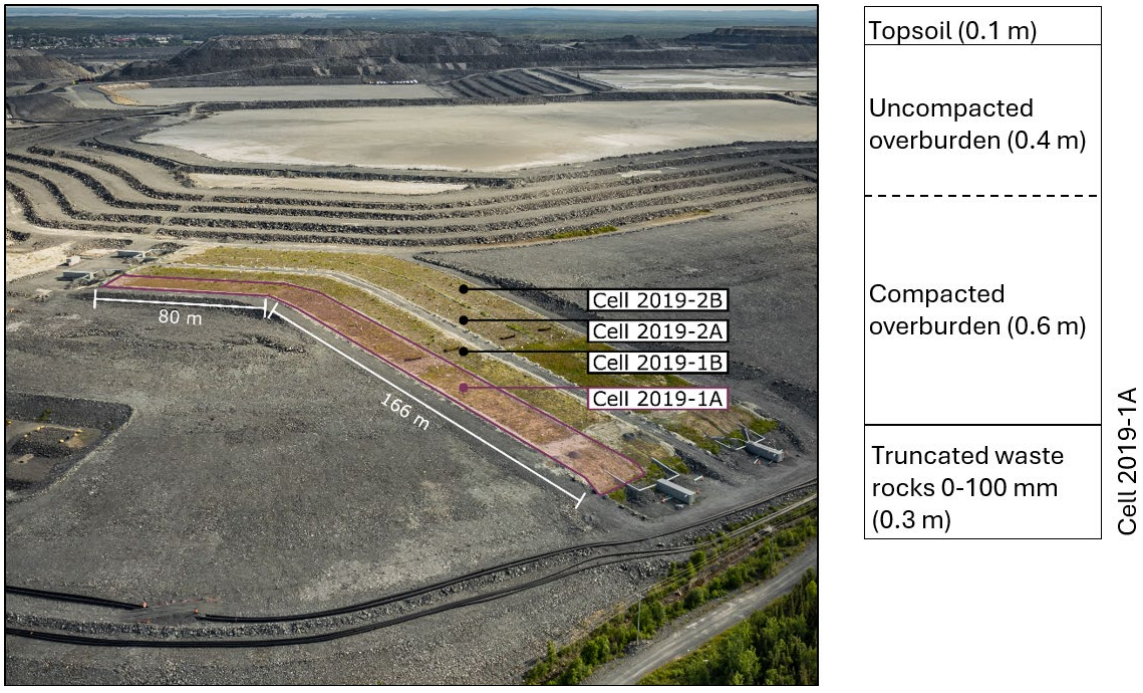

Figure 1: Large-scale field reclamation cover trials at the Canadian Malartic Mine. The field cell 2019-1A (purple) was selected for this study

Specifically, the field cell 2019-1A was selected for this study due to the similarity of the actual cover geometry considered by the mine. The cover configuration from top to bottom of the 2019-1A cell consists of 0.1 m of uncompacted topsoil, 0.4 m of uncompacted overburden, 0.6 m of compacted overburden, and 0.3 m of truncated waste rocks (e.g., particle grain size between 0 mm and 100 mm). On the plateau, an additional waste rock layer (pit run) is present between the transition waste rocks layer (0-100 mm) and the existing tailings for trafficability during the construction. On the downstream slope, the upstream raises have been first reprofiled with a continuous slope of 10H:1V and an intermediate horizontal section.

Methodology

Cover materials properties

In-situ and index laboratory testing has been performed to characterize the different cover materials during the construction of the large-scale field trials. The range of porosity was estimated, with the in-situ density measured with the nuclear densimeter and the sand cone method, based on the specific gravity (G_s) obtained in the laboratory.

A total of 20 samples of the overburden soil were collected to perform particle size distribution tests according to BNQ 2501-025, and 5 samples were collected to perform Atterberg limits tests. The overburden was classified as a clayey silt to silty clay (CL-ML) to a clayey silt (CL). The hydraulic conductivity was obtained on the field using a Guelph permeameter and compared to predictive methods such as the Kozeny-Carman model (KC; Chapuis and Aubertin, 2003), the modified KC (KCM; Mbonimpa et al., 2002) and Chapuis (Chapuis, 2012). The estimated hydraulic conductivities of the overburden varied between 8E-11 m/s and 9E- 07 m/s. The water retention curve (WRC) was predicted using the Modified Kovacs model (MK; Aubertin et al., 2002) and compared to the in-situ WRC expressed using the van Genuchten (1980) equation and the field suction and volumetric water content (VWC) measured with instruments (Figure 2a), which included hysteresis phenomena (not presented here). The permeability functions were calculated from the WRC using the van Genuchten model (Figure 2b). The heterogeneity of the overburden properties was simplified for numerical purpose in four sets of parameters associated with their locations (plateau [PL] vs. slope [SL]), and the compaction (uncompacted layer vs. compacted layer).

The particle size distribution (PSD) of the waste rocks (0-100 mm) was obtained in laboratory for 6 samples and the result showed little variability between them. The index properties were used to estimate the hydraulic conductivity using the Shepherd model (1989), KCM, KC, and Chapuis. The WRC and the permeability function were obtained using the Fredlund et al. (1994) model, which is more accurate for coarser material such as waste rocks. The hydrogeological properties of the uncompacted topsoil were estimated using field porosity and the laboratory G_s.

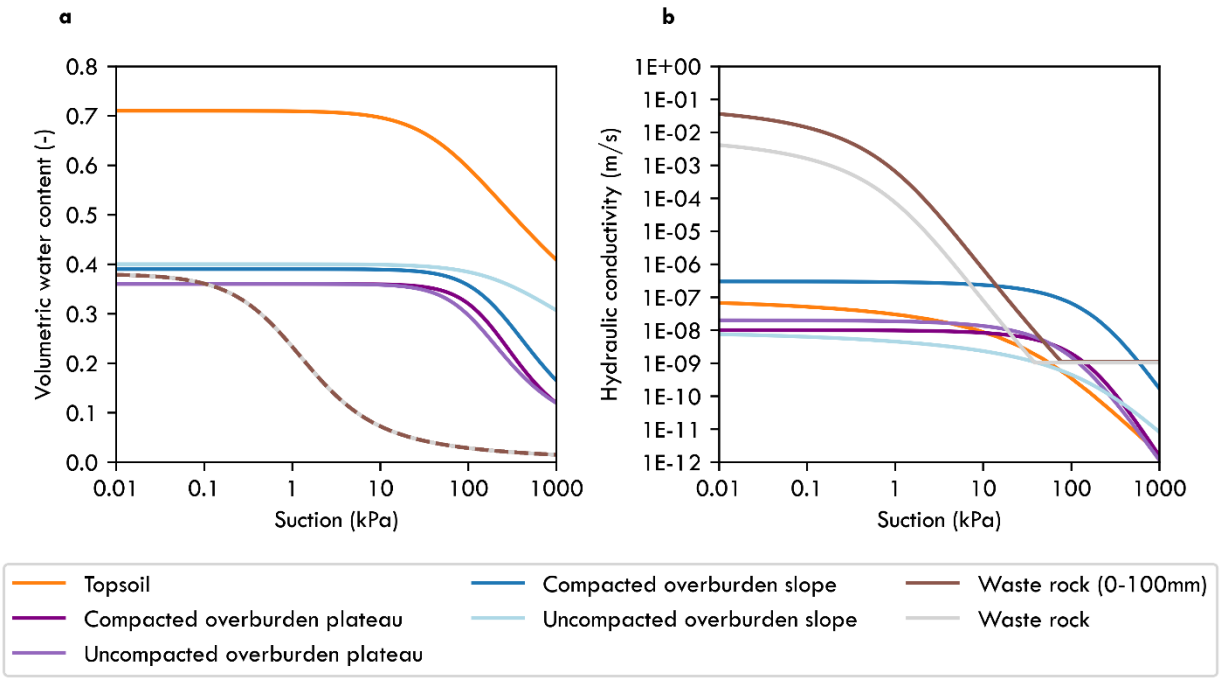

Figure 2: WRC and permeability functions of the cover materials applied in the numerical model

Climate data

The CM mine is located approximately 20 km from the town of Val-d'Or, where meteorological stations have been acquiring data since 1951. Between 1951 and 2023, the mean annual temperature is 1.6°C. The hottest month is July, with a mean temperature of 17.4°C, and the coolest month is January with a mean temperature of -16.6°C. Generally, the temperature is above 0°C around mid-April to early November. The mean annual total precipitation for the same period (i.e., 1951 to 2023) was 908 mm, with a minimum of 704 mm in 2021 and a maximum of 1,183 mm in 1979.

Specifically, the CM mine had installed two meteorological stations on the large-scale field trial area, one on the plateau and another on the slope. These two meteorological stations were in operation since July 2018, monitoring the local climate conditions (e.g., precipitations, temperature, relative humidity, solar radiation, and wind speed), including measurements of snow heights during winter to capture snowmelt infiltration and its contribution to the water balance. The measurement period used for the calibration of the numerical model corresponds to the first year of monitoring, from October 1, 2020, to September 30, 2021. The model integrated the relative humidity, the air temperature, the precipitation, the wind speed, the snow cover thickness, and the solar radiation (Figure 3). The solar radiation was estimated in the numerical model based on the latitude of the site (48.1°) and the albedo was assumed as a constant value of 0.3, due to a lack of solar radiation data over the monitored period.

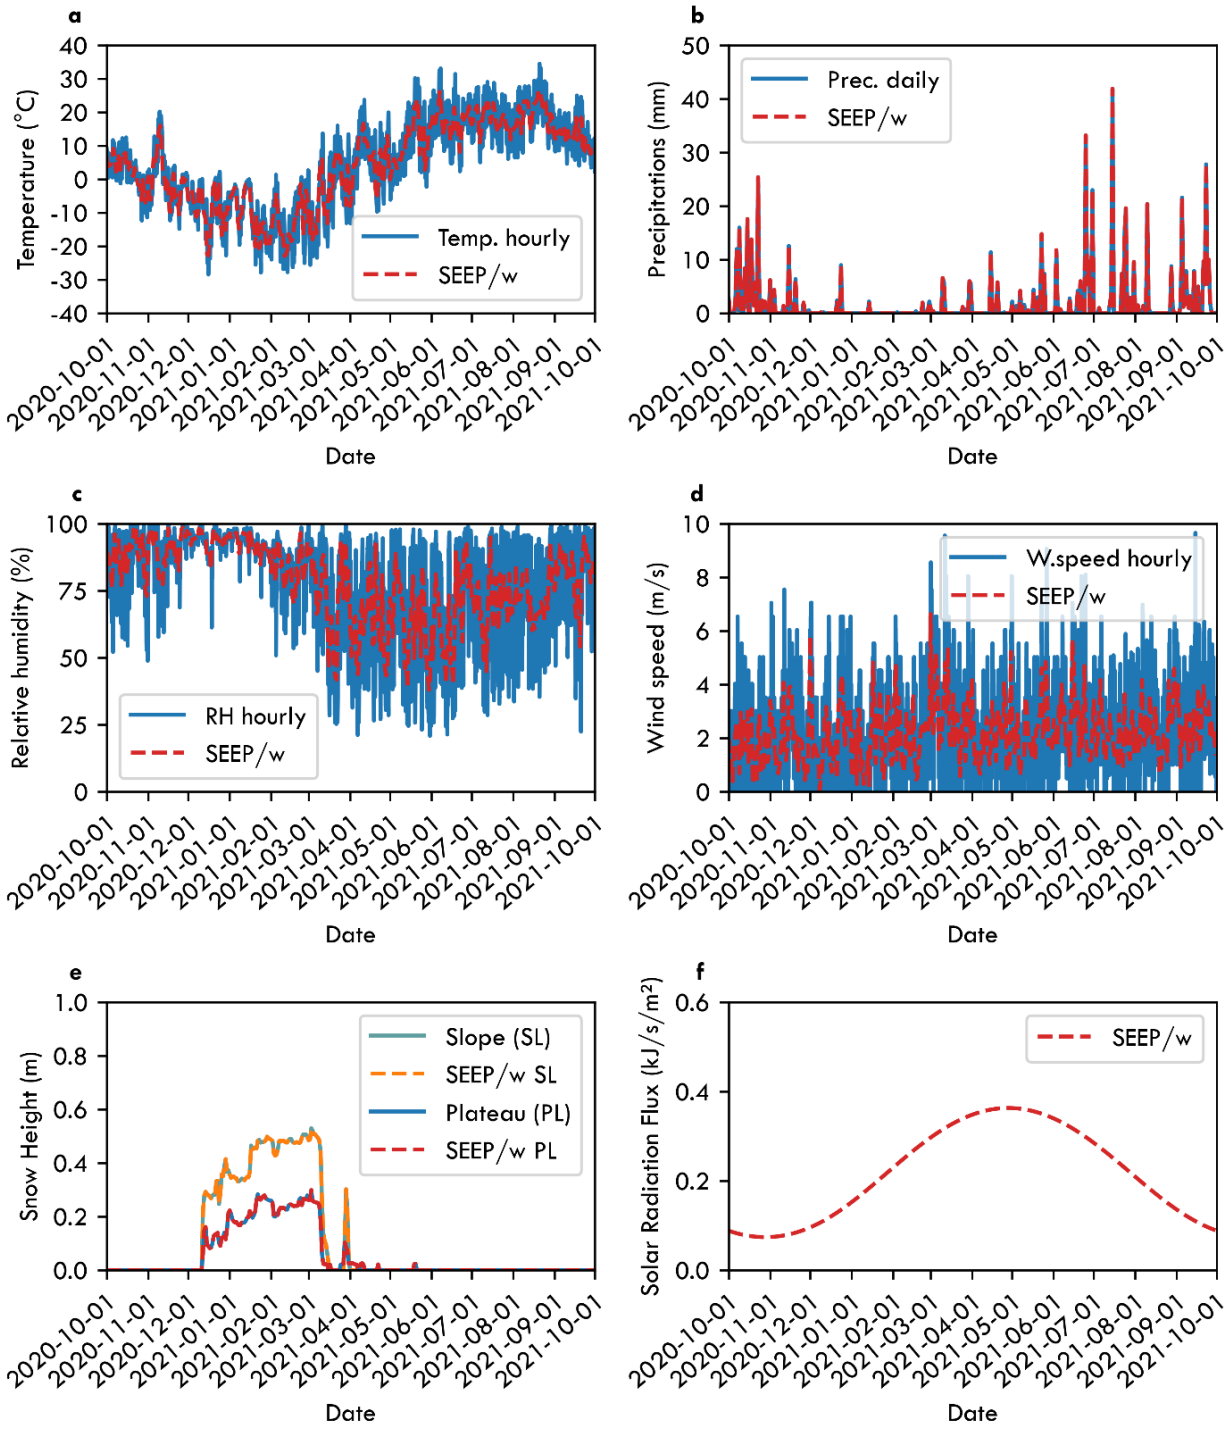

Figure 3: Climate from the weather stations (solid line) and the input parameters in the numerical model SEEP/w (dashed line) for a) Temperature (°C), b) Precipitation (mm), c) Relative humidity (%), d) Wind speed (m/s) e) Snow height (m) of the slope (SL) and the plateau (PL) f) Solar radiation approximated in the numerical model from the latitude (kJ/s/m²)

Numerical model methodology

The numerical analyses of the large field trials were performed using the finite element software SEEP/w (GeoStudio, 2023). The geometry of the model was represented by a 2D configuration and showed a 740 m-long cross-section in the large-scale field trial sector intercepting the initial toe berm, the different upstream raises, and the tailings surface. The cover configuration of the 2019-1A cell was built with the functionality of a Surface Layer to generate a fine discretization near the surface, with a resolution varying between 0.05 m and 0.07 m. The regions below the cover were built using quadrilateral and triangular elements, with an element edge length between 1 m and 5 m. Adjustments of the under-relaxation criteria due to the non-linearity of the input functions (e.g., particularly waste rocks and Land-Climate Interaction [LCI] conditions) were applied in the model by changing the initial rate of the under-relaxation criteria at 0.65 and reducing the minimum rate at 0.01. The numerical modeling approach for this study was selected to optimize the convergence and the time calculation.

The validation of the numerical model was performed by simulating the first year of data acquisition (i.e., before vegetation establishment, except for the lower portion of the slope) and comparing the temporal numerical VWC results with the VWC measured by the instruments at a similar elevation (e.g., daily time step). More specifically, three criteria were selected to choose the probes for the calibration of the numerical model: 1) similarity of the particle grain size distribution; and 2) the porosity (maximum variation of ± 0.02) between the in-situ and the modeled material; and 3) the raw data range used for the probe calibration in laboratory compared with the range measured by the instruments on the field. The modeled material properties were adjusted iteratively, based on the range of values obtained in the laboratory. The validation was based on the fit between the numerical results and the measured VWC using the Root Mean Square Error (RMSE) and the Mean Absolute Error (MAE), in addition to qualitative observations of the general behavior of the VWC (e.g., the increase of the VWC after a rainfall event followed by the rate of desaturation).

The verification of the numerical stability was performed in a four-year cycle to confirm that the initial steady state parameters did not influence the response of the transient model using the LCI boundary condition. The water balance result was similar in the second, third, and fourth year of simulation. The long-term behavior of the cover was modeled using the cumulative net infiltration of the second year and applied to a steady state model coupled with the transient model. The 2019-1A cover was also modeled on two other cross-sections of the CM TSF to verify the influence of the upstream raises geometry and the impact of the waste rock pile directly in contact with the tailings (not presented in this paper).

Results

Numerical validation of the VWC on the plateau and the slope

The numerical validations were performed for the unfrozen period from June to October, because minimal variations in VWC were observed. Such an approach is used in comparative studies (Pabst et al., 2017; Éthier et al., 2018). Simulated VWC fluctuations correlated with the seasonal variations and followed the same general trends of the field for the plateau (see Figure 4). For example, the simulated VWC of the topsoil (orange dashed lines) at a depth of 7 cm on the plateau at station PL-S1 increased after a rainfall and subsequently decreased due to drainage and evaporation, which is consistent with field VWC fluctuations. However, the VWC of the field was more varied due to the greater field porosity measurements. The RMSE and MAE were respectively 0.06 and 0.05 for the topsoil. Furthermore, the overburden layers (purple dashed lines) also had a good correlation with the field measurements. For example, the RMSE and MAE were both equal to 0.01 for the probes at a depth of 91 cm, with SEEP/w result and the field VWC at 90 cm. The maximum RMSE and MAE calculated for the compacted and uncompacted overburden were 0.05 for station PL-S1 on the plateau.

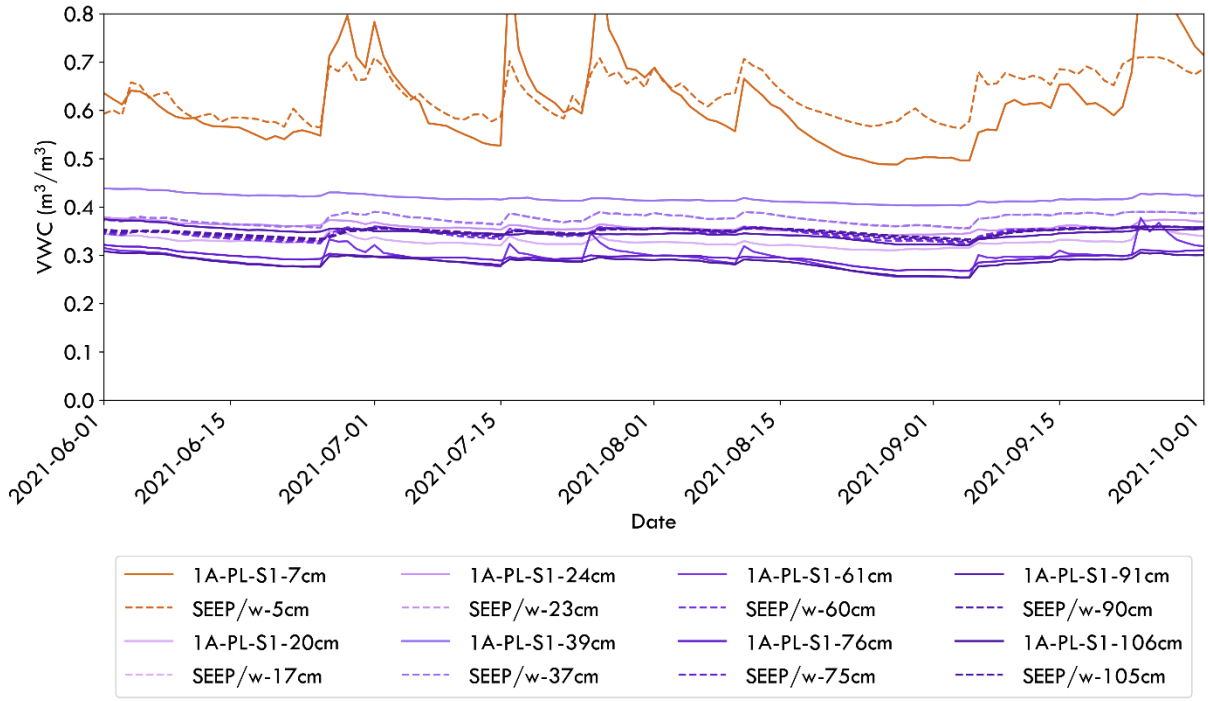

Figure 4: Evolution of the volumetric water content of the cover materials after winter. The dashed lines present the SEEP/w results, and the continuous lines present the results of the probes on the plateau (PL) at the station PL-S1

The results at the upper part of the slope at the station SL-S1 were also well represented by the numerical model (Figure 5). For example, after a rainfall, the VWC of the topsoil (orange lines) increased

substantially, followed by a decrease due to drainage and evaporation. The VWC of the overburden (blue lines) had the lowest amplitude, and the RMSE and MAE were lower than 0.05.

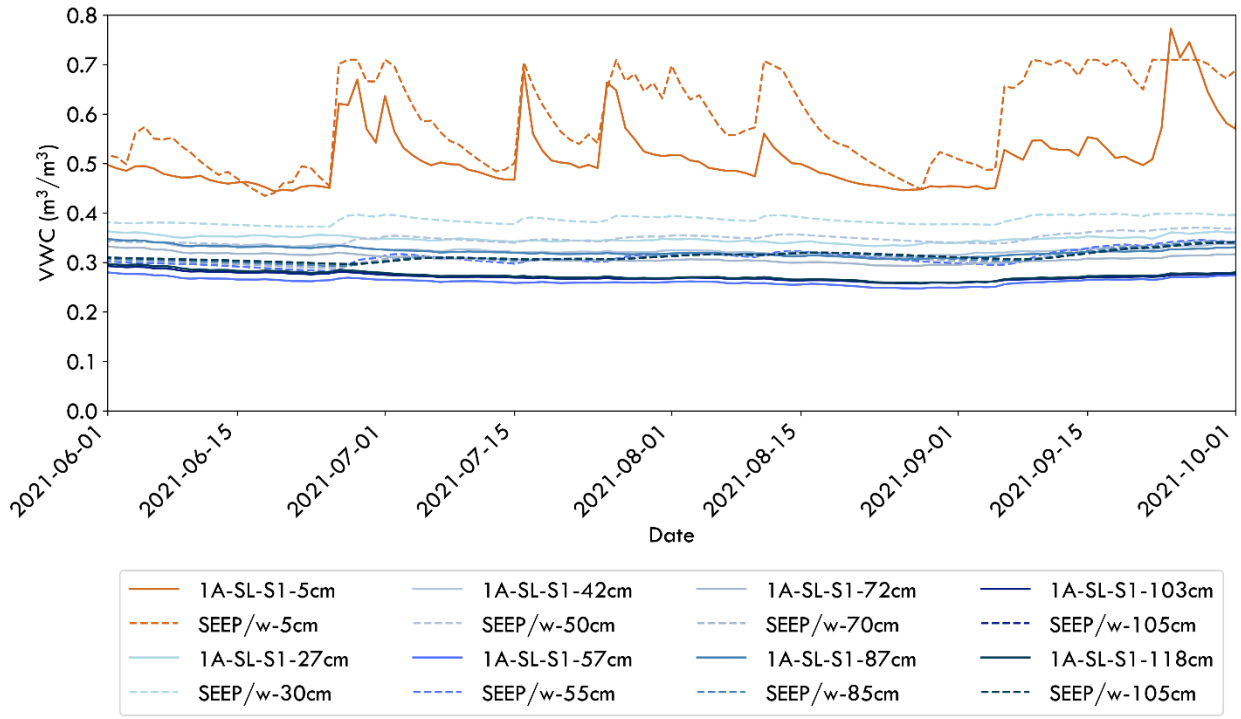

Figure 5: Evolution of the volumetric water content of the cover materials after winter. The dashed lines present the SEEP/w results, and the solid lines present the results of the probes on the upper part of the slope (SL) at the station SL-S1

The transient simulation was able to represent the general behavior of the VWC for the instrument stations and the probes on the plateau, along the upper and middle portion of the slope. The model was therefore considered representative of the field conditions and was validated for further analysis of the hydrogeological behavior of the cover system.

Water balance estimation

The water balance of a one-year cycle was analyzed to understand the influence of the cover configuration 2019-1A compared to a scenario without cover, which was considered as the reference case representing the actual state for the same cross-section (Table 1). For both scenarios, the vegetation aspect was not simulated. It was assumed that the vegetation would have the same influence on both water balance results and thus are only reliable for comparison. The addition of the 2019-1A cover on this TSF sector reduced the net infiltration, decreasing from 215 mm/y to 140 mm/y on the plateau and 255 mm/y to 55 mm/y on the slope. The runoff portion increased with the cover placement and the reprofiled slope. For both scenarios, the actual evaporation was similar, varying between 50% and 60%. The numerical results showed the effectiveness of the cover in reducing infiltration into the TSF.

Table 1: Water balance estimation (SEEP/w)

Model	Location	Net infiltration (mm/y)	Net Infiltration (%)	Runoff (%)	Actual evaporation (%)
Reference case (without cover)	Plateau	215	32	10	58
	Slope before reprofiling	255	39	1	60
2019-1A cover configuration	Plateau	140	23	22	55
	Slope reprofiled 10H:1V	55	10	40	50

Cover performance over the long term

The long-term behavior of the cover was modeled using the cumulative net infiltration of the second year (e.g., 140 mm/y on the plateau and the intermediate plateau and 55 mm/y on the slopes) and applied to a steady state model coupled with the transient model. The degree of saturation (S_r) in the center of the compacted overburden layer (continuous lines) and the uncompacted overburden layer (dashed lines) were represented for two time steps: end of July (orange lines) and for the steady state (blue lines; Figure 6). The compacted and uncompacted overburden layers maintain the same S_r on the plateau (e.g., 99% at the steady state and approximately 92% at the end of July). The compacted layer desaturated on the slope portions to reach a minimum S_r of 94% at the steady state and 80% at the end of July. The results are compared to S_r of 85%, representing the threshold value where the oxygen diffusion is significantly reduced (Collin and Rasmuson 1987; Aubertin et al., 2002). In the case of the 2019-1A cover, oxygen reduction was not part of the cover design criteria, but its evaluation was used to understand the hydrogeological behavior along the cross-section and the impact of the slope sections.

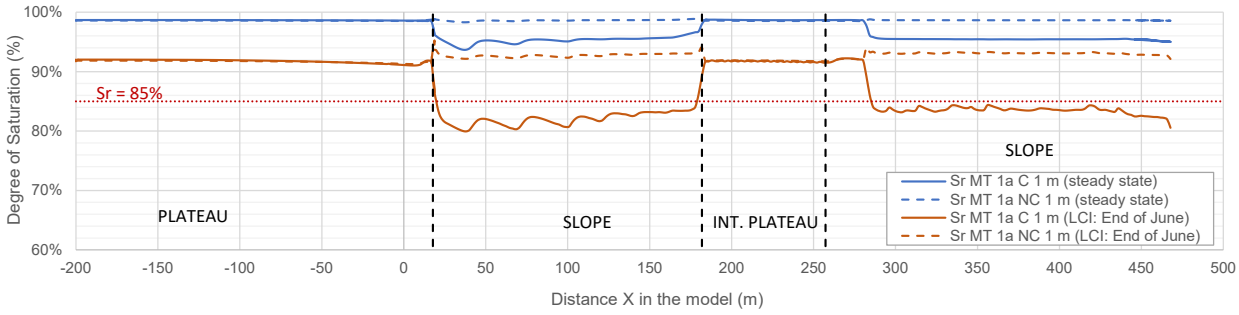

Figure 6: Degree of saturation of the uncompacted and compacted overburden layer at the end of June and in steady state condition

Discussion

Model calibration involved estimating the spatial distribution of the material properties, and the simplifications were required to manage feasibility while maintaining model accuracy. Field data included

numerous probes to capture variations in VWC, of which some disparity in porosity and behavior was observed within a given layer. The mean porosities of each layer were used in the simulation, which could explain the main difference in the field VWC data and the simulations. The manufacturer's calibration of the probes was also a specific validation criterion, and the measurement range was specifically addressed when selecting the probes for numerical validation. The WRC and permeability functions of the waste rocks were typically steep. Therefore, the permeability function was cut at 1E-09 m/s to ensure convergence of the numerical model, which implied that no capillary break between the overburden and the waste rocks was simulated.

The instrumentation stations located on the lower portion of the slope were not considered for the numerical calibration as vegetation had grown and only barren soil was simulated. VWC measurements in this sector were influenced by the vegetation during the unfrozen period. Vegetation establishment can significantly modify the water balance in cover systems (Yves-Dady et al., 2018). For example, vegetation can intercept rainwater and limit erosion (Zhang et al., 2022). Vegetation can also increase infiltration and significantly increase evapotranspiration rates, which can reduce deep percolation (Nicholls et al., 2019). Finally, vegetation can modify the soil albedo, which has a direct influence on radiation and therefore on evaporation. The impact of the vegetation establishment will be evaluated in further studies.

Conclusion

Selecting the most appropriate method for TSF closure involves extensive studies, and might consider site-specific conditions such as climate, material availability, geometry, and social aspect. This case study presented the methodology used to integrate the CM large-scale field trial data (probe results and meteorological in-situ data) to calibrate a 2D transient numerical model using SEEP/w. The material properties of the numerical model were adjusted using the index laboratory results and the in-situ WRC. The modeled material properties were adjusted iteratively based on the fit between the numerical results and the measured VWC using the RMSE and the MAE, in addition to qualitative observations such as the general behavior of the VWC and the hydrogeological properties ranges. The correlation between the general behavior of the VWC measured and simulated demonstrates the numerical model's ability to represent field conditions. At this stage, the numerical results were used to compare different cover configurations, layer thicknesses, and TSF geometry. In further studies, it is planned to better understand the influence of the vegetation, as well as the impact of climate change on the cover performance.

Acknowledgements

The authors would like to acknowledge the contribution of Canadian Malartic's Agnico Eagle Mines personnel for the large-scale trials and their support. The authors also acknowledge the contribution of their

WSP colleagues, particularly Vincent Martin and Myriam Roy, who directly contributed to the numerical simulation work.

Kidston Hydro Electric Power: Re-purposing an Abandoned Mine

Malcolm Barker, GHD, Australia
Tony Ford, Genex, Australia
Peter Gaylard, Construction Joint Venture (John Holland & McConnell Dowell), Australia

Abstract

Hydroelectric power using pump storage is one of the significant renewable energy sources for Australia. The Kidston Hydro Electric Power (HEP) project provides a first for Australia in the use of a disused mine to provide both the storage capacity and the head to develop a scheme with 250 MW capacity.

.The scheme comprises an upper storage, Wises Dam, with two vertical shafts leading to the underground powerhouse discharging into the lower Eldridge pit, creating a head of over 200 m for the power generation. Pumping back to the upper storage is achieved using the turbines with solar and grid power.

The Wises Dam was constructed using waste rockfill from the mine excavation with a high-density polyethylene (HDPE) liner for the water barrier. Considerable review of the foundation conditions, including the use of a 3D leapfrog model, was required for the evaluation of the foundation depths for the HDPE plinth and the underground tunnels and powerhouse. Construction techniques for the Wises Dam liner preparation were challenging and the contractor made significant contributions to the design changes, which improved the constructability and sustainability of the works.

The Wises storage dam is now complete and the underground power station is progressing with expected power production commencing in 2025. This paper presents information on the scheme and some of the design and construction challenges from the perspectives of the Owner, Construction Joint Venture and Designer.

Introduction

The Kidston project is a 250 MW pumped storage hydro scheme located in far north Queensland on the site of the old Kidston gold mine. Gold has been mined at or near the site intermittently from 1907 up to 2001, when the mine was closed. The project incorporates the use of the two existing mining pits, Wises and Eldridge, which are shown in Figure 1 and Figure 2.

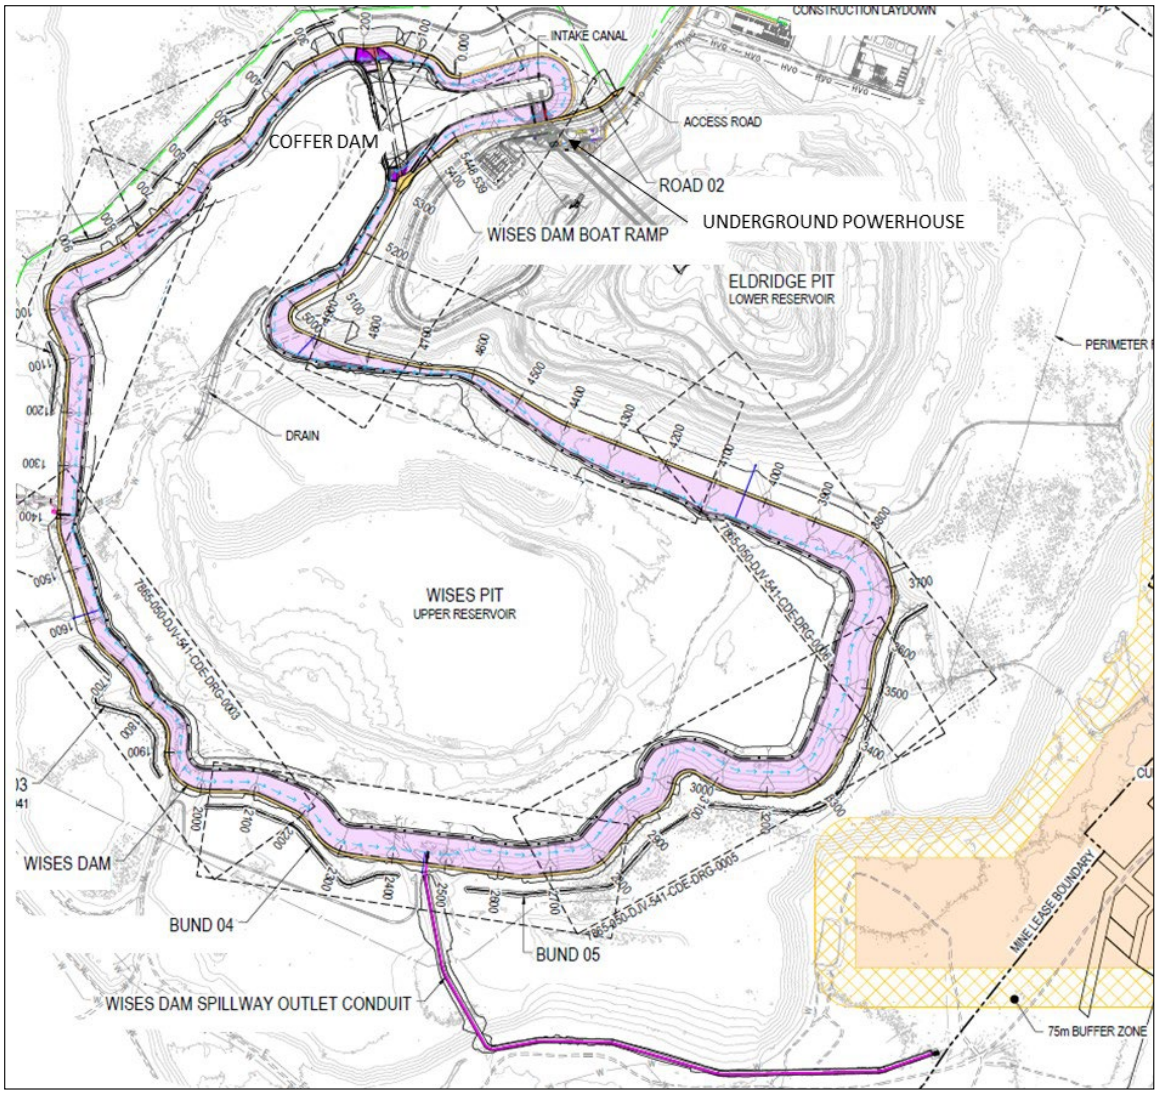

Figure 1: Project layout

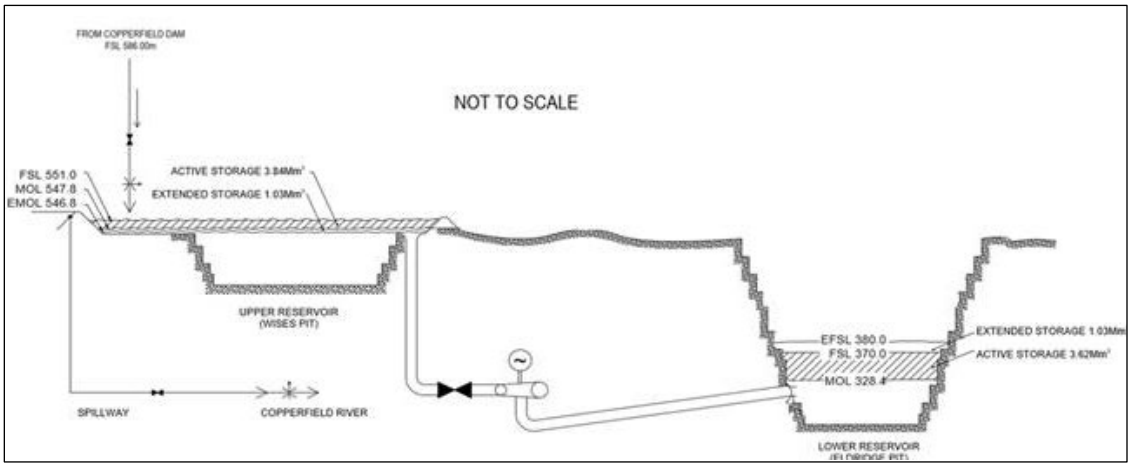

Figure 2: Project section (CJV water management plan)

Due to the historic nature of the site and the contamination from the old mining activity, seepage water from the waste rockfill area is collected from the surrounding area and pumped back into Wises Dam to prevent contamination of the environment. The Copperfield Dam, located about 20 km south of the mine, was constructed for water supply to the mine, and the existing pipeline will be used to provide makeup water where necessary. The nearby Copperfield River can accept spillway flows from the Wises storage in conditions where release is allowed by the regulating authority.

Figure 2 shows the schematic of the pumped hydro scheme, which has the underground powerhouse and tailrace into Eldridge pit connected to Wises Dam via two vertical lined morning glory shafts. The available head for power generation varies and is in the order of 200 m.

Wises Dam design

The Wises Dam has been designed as a waste rockfill embankment from the mine excavation with a 2 mm thick high-density Polyethylene (HDPE) liner for the water barrier. The design concept for the dam was based on the principles for a concrete-faced rockfill design in accordance with the International Commission on Large Dams (ICOLD) Bulletin 174.

The design was a joint venture between GHD and Mott Macdonald with the construction being completed by the McConnell Dowell John Holland Joint Venture for the client Genex. The dam, as shown in Figures 1 to 4, includes the following major components:

- Upper reservoir Wises Dam
- Inlet channel to the two vertical shafts for the pump/generator turbine units
- Rockfill embankment with cement stabilized crusher dust surface for the HDPE membrane
- HDPE upstream membrane with geotextile underlay
- Excavated cut-off trench with concrete plinth for liner locking down
- Pipe spillway including inlet with inclined slide gate, pipeline to valve control pit and Copperfield River discharge structure
- Inlet pipeline from Copperfield Dam
- Coffer Dam for early works pumping of Eldridge water into Wises Dam

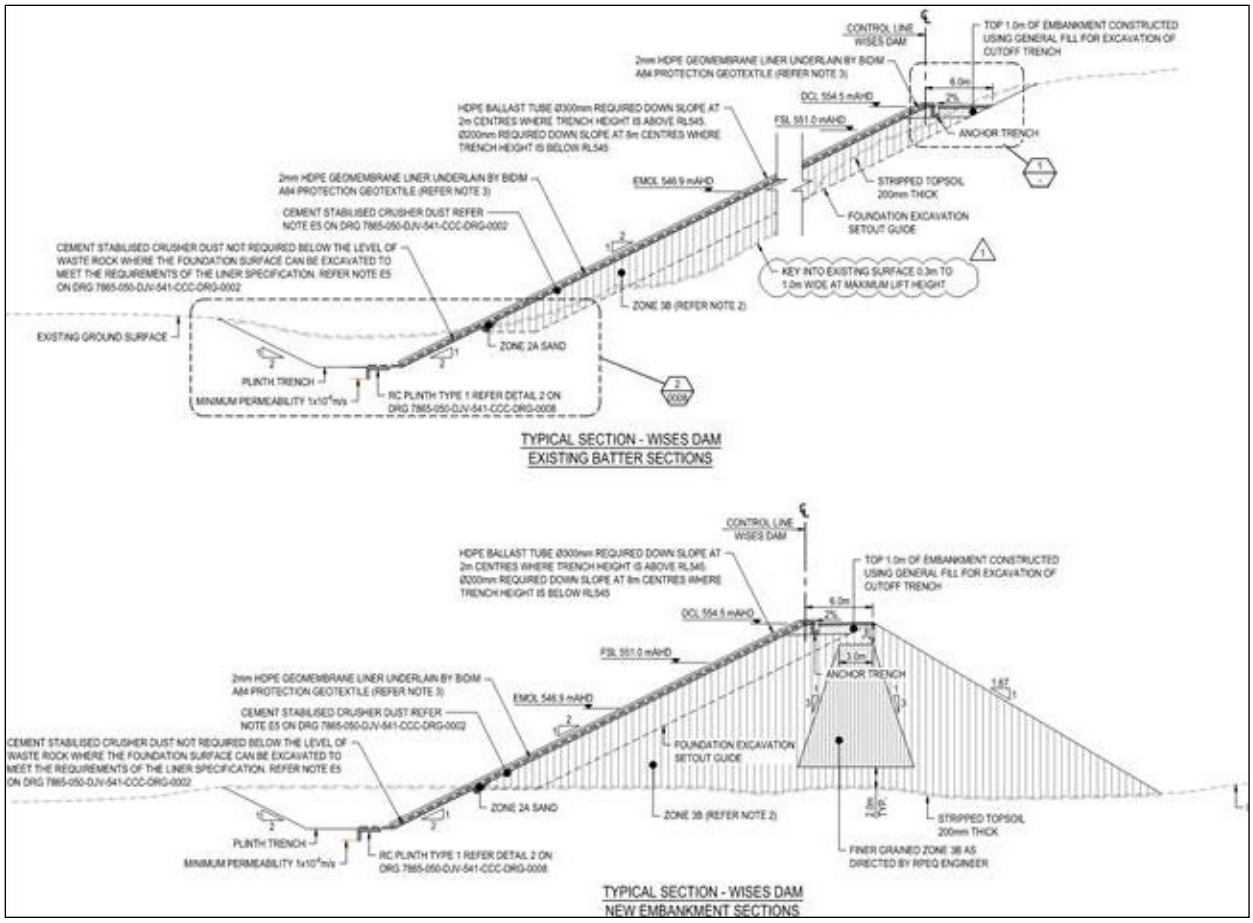

Figure 3: Embankment cross-sections

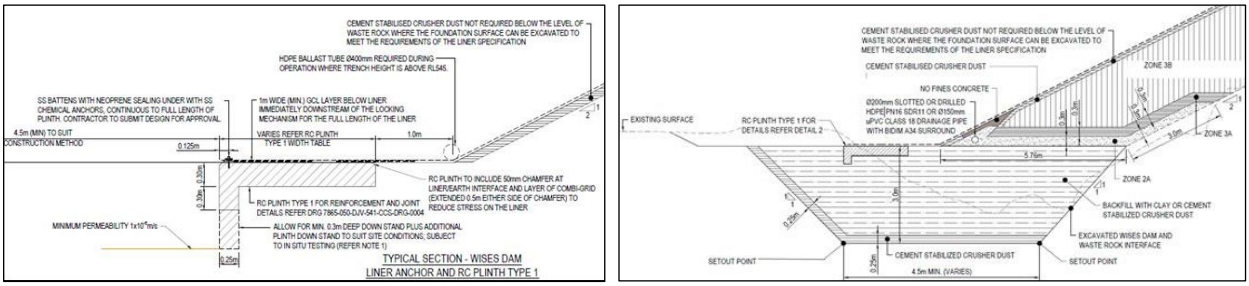

Figure 4: Plinth details. Left: rock foundation. Right: embankment plug excavate and replace

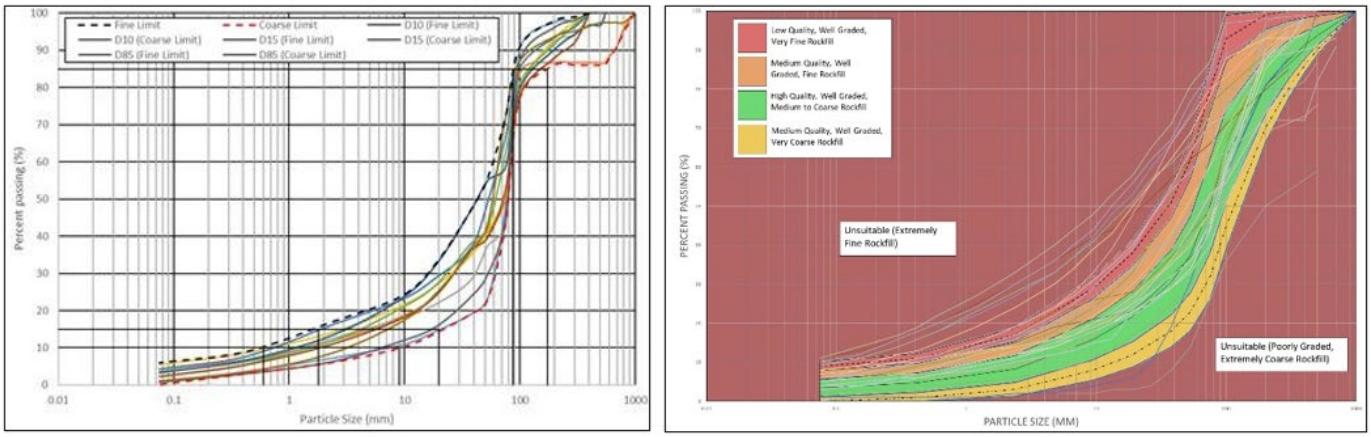

Figure 5: Zone 3B particle size distribution (Entura, 2017) left and as built right

Foundation

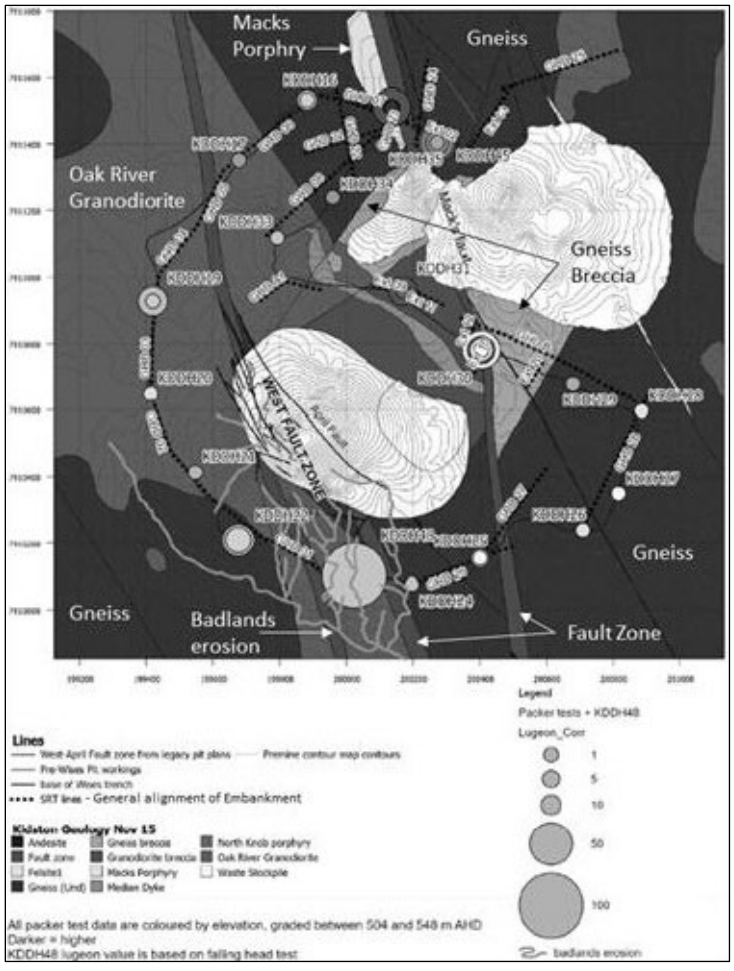

Figure 6: Geological plan at 490 m AHD level – with BH packer test permeability data

As shown in Figure 6, the bedrock beneath Wises Dam and the intake channel have been significantly affected by large-scale NNW striking faults. These are:

- Macks Fault – passing through the pillar of rock between Wises and Eldridge pits and through the intake channel.
- West Fault (zone) – passing through the western side of Wises pit and under the proposed embankment dam at two locations.
- April Fault – a "splay" off the West Fault that defines the eastern edge of the West Fault Zone and passes beneath the southern section of the embankment dam footprint.

Pre-mining topographic contour mapping showed that the now-buried topography exhibited "badlands" style erosion of the residual soil in the area where the West Fault Zone is projected to pass beneath the dam, as annotated in Figure 6.

At the time of writing this document, the filling of Wises Dam was complete. Excessive losses from the system through the "badlands" had not occurred; however, seepage loss is occurring through the foundation and liner seepage control system, which is either being pumped back into the Wises Dam from the southern areas or is flowing directly back into Eldrige pit from the northern embankment area.

Key challenges

Contractor's perspective

From a Contractor's perspective, some key challenges included the following.

Availability of geotechnical data to inform the contract price

- Geophysics are excellent for FEED studies and reference designs; however, in entering into a contract it would be better for both Contractor and Principal to have a greater level of certainty in the geotechnical data used as the basis for pricing. This would include:
    - Boreholes to at least 10 m below proposed foundation level, on the proposed alignment at about 250 m – 500 m centers. At Kidston this would have been 16 holes and only ~600 – 750 m of drilling. A very small investment to manage a risk that had implications 10 to 20 times the cost of the investigation.
    - Cut-volume increased ~40% due to the limit of accuracy on the geophysical data that was relied upon.

Materials testing

- Availability (source) of Zone 2a, 3a, 3b materials must be proven by test data at a rate of about 1 test per 250,000m^3 of proposed borrow.
- As depicted in Figures 7 and 8, the single biggest challenge was the suitability of mine waste as rock-fill.

One of the earliest reports that informed the Wises Dam design and its construction methodology was the 2017 document "Kidston Pumped Storage Project Bankable Feasibility Study – Geotechnical Report – Part B – Interpretive, Entura-B398A" provided by the Principal. It described the waste rock found onsite as "relatively consistent" and usable as for a rockfill dam embankment

On this basis the Contractor prepared the detailed design, methodology, and sequence as illustrated below, noting and observing that this method was efficient and at this stage works would be done in a timely manner without any impact to the project schedule.

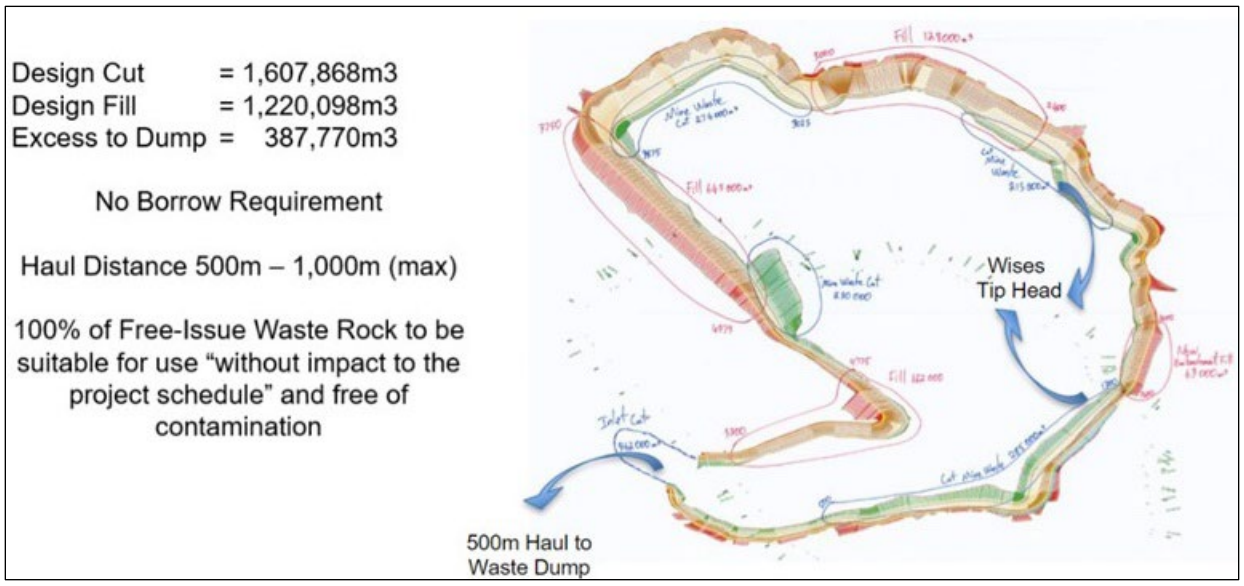

Figure 7: Planned cut-fill plan

Once significant quantities of the materials were identified as unsuitable and contaminated, the Contractor needed to revise their methodology, resulting in significant time and cost impacts due to:

- Increased haulage distances
- 387,770 m^3 of material planned to be dumped to waste stockpile increased over 400% to 1,566,576 m^3
- 1,153,134 m^3 needed to be sourced from borrow pits outside of the Wises Dam footprint – not contemplated at time of contract signing.

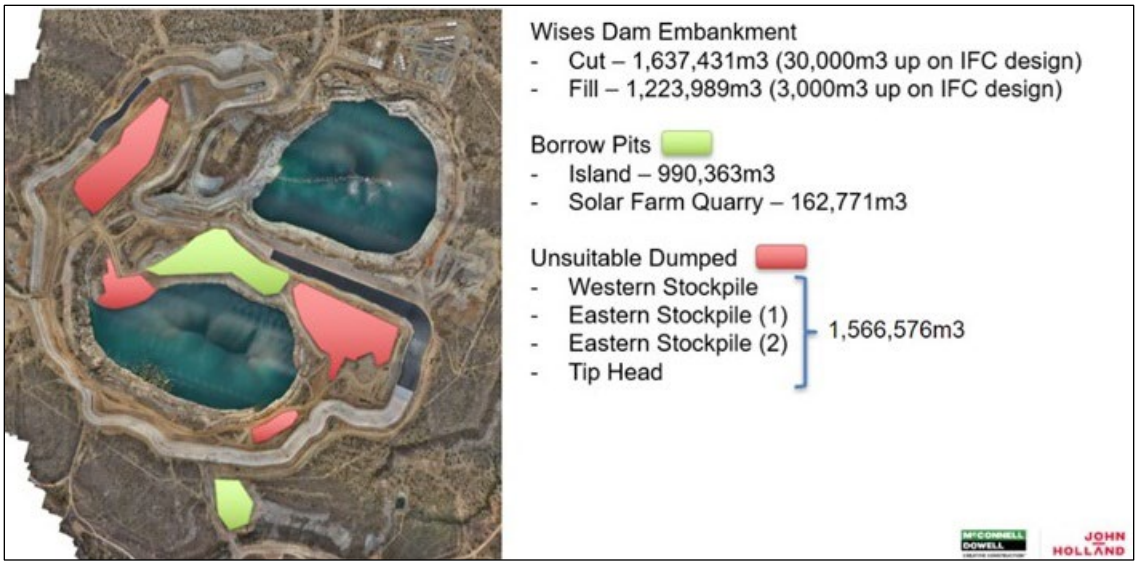

Figure 8: Revised cut-fill plan

- Rockfill grading curves. The concept design grading curves for mine waste were unrepresentative of what was actually encountered, as shown in Figure 9. Notwithstanding this, the densities and permeabilities achieved were in compliance with the design requirements.

Figure 9: Poorly graded rockfill (left) and well graded rockfill (right)

- Safety in design vs. cost
    - Batter slope of 2:1 was used for the HDPE slope to reduce costs. This steep slope presented significant construction safety risks that were very difficult and very complex to manage.
    - Dam crests must address safety in construction
        - Edge protection bunds/barriers
        - Width for heavy plant to pass if the embankment is any longer than ~500 m

Owner's perspective (Genex, 2023)

Embankment placement

To ensure settlement of the embankment, material was controlled and a minimum density of 1,950 kg/m^3 was initially specified, but was increased to 2,100 kg/m^3. This density was achieved. The grading of the rockfill needed to comply with a grading limit specification to ensure a reasonably well graded material was utilized to ensure compaction requirements were achieved, but did not contain too many fines as to reduce the permeability of the material, noting that it was required to be free draining. A trial embankment section (on permanent works) was undertaken to ensure a method specification for compaction was understood based on layer placement height and number of passes of specific machinery and quantity of water added. Increased testing frequency was adopted during the trial embankment section.

A key challenge was ensuring material and placement compliance was achieved consistently, which is very much a function of the construction team and machinery operators. In practice, this really meant that the operator loading dump trucks with rockfill material had significant control over what types of materials were being loaded at any one time to blend rock types for achieving material compliance. Initially this was very much a learning curve with testing to confirm compliance.

To expedite the process and reduce risk, a materials ready reckoner was prepared by the engineering team for the operators to refer to in terms of material compliance expectations. This involved a simple sheet, together with photographs of types of suitable rockfill blends. The importance of achieving rock fill material compliance was communicated and workshopped with the construction team and operators so that the whole dam construction team understood its importance. Once implemented, the level of rework for ensuring compliance is drastically reduced.

The rockfill compaction was achieved using only a bulldozer pushing the material into place and tracking over the material in lifts up to 1 m depth. The challenge of achieving the required density and rockfill grading confirmed the importance of undertaking a trial embankment for the purpose of developing a method specification for material placement and the implementation of a materials compliance ready reckoner to allow the operators to better determine in the field the material to be selected for utilization.

Seepage collection pipe

A seepage collection pipe is located within the rockfill material below the dam liner, to collect any leakage that may find its way through the HDPE liner and underneath the concrete cut-off plinth.

The installation of the seepage pipe and backfill details were developed in joint consultation between the design and construction team. Upon initial installation, it was observed that a better, faster and safer way for installation could be achieved. This involved modification to the pipe backfill configuration without

any lessening of design intent. The ability of the design and construction teams to work together post-design enabled this solution to be worked through and ultimately adopted.

The lesson learned relates to the ongoing design and construction interface during both the design and construction phases to ensure constructability improvements, ensuring a better, faster and safer outcome is continuously promoted, and if economically viable, then adopted.

Material preparation under the liner

The original design specified a select fill layer that was to be placed and compacted in layers to the upstream face of the rockfill material, against which the HDPE with underlying geofabric was to be placed. The challenge was that the specification of such a layer is common for HDPE-lined structures, but has had constructability issues (if the main embankment is unable to be constructed using similar materials), and there is a risk of rework due to erosion, should rain occur and the face is not protected with the liner.

A crushing and screening plant was established for the production of road base materials and concrete aggregates using the material found in the existing waste stockpiles. As part of the crushing process, a fines byproduct was produced providing a relatively consistent fines gravel (i.e. <5 mm in size). The percentage of manufactured product to byproduct waste fines was approximately a 70 to 30 split respectively. As such, a considerable quantity of waste fine material was available.

An alternate cement screed product was developed by the CJV in consultation with the designer using the waste fines to produce a low slump cementitious material that could be applied to the upstream dam face. This was an environmentally friendly solution as it used waste material, which would otherwise have a limited use, for the balance of the works, and provided a rain-resistant surface.

The installation of the cement screed utilized a combination of two long reach excavators working in tandem, as shown in Figure 10, with one excavator taking the product from the concrete truck and placing the cement screed on the dam face and roughly spreading it to level using a normal mud bucket attachment, while the other excavator smoothed out the screed to a final finish utilizing a project-developed customized screed attachment. With the excavators having a finite reach for placement, the screed was installed in sections as the dam embankment was placed to final level.

The challenge of providing a founding layer for the HDPE appropriate to the field conditions was solved by investigating opportunities for reuse of materials onsite to provide a product that satisfied design requirements/intent and also provided a protective surface to completed works in the event of wet weather. The design/construction interface and out of the box thinking enabled this solution to progress.

Figure 10: Placement of cement screed

HDPE liner placement

The upstream face of the entire dam is lined with a 2 mm high density polyethylene (HDPE) liner membrane with underlying geofabric to provide cushioning. The liner is secured under a trench backfilled with stabilized backfill on the dam crest, secured at the bottom with a stainless-steel fixing and battening system, and affixed to the reinforced concrete plinth. While this is a proven anchoring system, care was needed to ensure that the liner was secured at a relatively neutral temperature (prior to being filled with water) to ensure that the expansion and contraction of the liner remained within certain limits and did not pull away from the fixings. Some areas of the liner were up to 70 m long, resulting in considerable movement up and down the slope during the day and night.

Individual rolls of HDPE are seam welded together to ensure a continuous liner membrane. Each seam was tested onsite, together with off-site testing undertaken on HDPE liner samples that were cut from the HDPE rolls.

The lesson learned for the HDPE liner is that it is important to have the early engagement of subject matter experts to ensure that the liner specification is fit for purpose and that it achieves the specified 30-year design life.

Transfer of water from Eldridge pit to Wises Dam

Wises Dam was filled using water existing within Eldridge pit. This was achieved with a one-off transfer of water, using a bespoke pumping system comprising six 3.3 KV x 850 kW electric pumps, mounted on a pontoon structure. In total, approximately 28 GL of water needed to be pumped. The dewatering pumping station was designed to provide a flow rate ranging from 1,700 L/s to 1,250 L/s at the lowest level in Eldridge pit (where the pumping head is greatest), where the dewatering will allow access to the tail race tunnel portal. This is approximately 200 m of water level that was to be pumped into Wises Dam over a planned period of approximately 200 days under continuous operation.

The pumping system was designed, manufactured, installed, and commissioned by a panel of international suppliers and experts. Overall, the system has functioned well to date. Initial concerns about high bearing temperatures were overcome with the replacement of a larger bearing arrangement. This downtime did not impact the overall program.

The pontoon that houses the pumps and motors is put into position by three winches that can locate the pontoon within Eldridge pit. This was fundamental to being able to control the position of the pontoon, as the water level dropped in order for the pontoon to be navigated away from known features in the pit, which are remnant haul roads and platforms from mining operations.

Figure 11: Dewatering system from Eldridge pit to Wises Dam

Overcoming the challenge of the Eldridge pit dewatering was achieved by the integral commitment by all involved. All were committed to input their respective expertise into the design, manufacture, installation and commissioning phases for a successful outcome.

The challenge now evident is that there is excess water in Eldridge pit and Genex is using four misters to evaporate the water in order to lower the level by a further 40 m, after pumping into Wise Dam to a level of 1.3 m below the dam crest level. This level is above the peak expected water level allowing for the Probable Maximum Flood and is, in effect, providing a full “first fill test.”

Consultant’s perspective

What was originally planned and what was built provided significant challenges for the design team, including the following.

Foundation – depth; permeability; seepage

The concept level design assumed a relatively shallow founding depth for the concrete plinth. However, on investigation using test pitting, additional seismic traversing and Leapfrog 3D foundation modeling, it was

evident that the founding depths were quite variable and significantly lower than the concept design.

The challenge was identifying the foundation level that would provide adequate foundation strength for the concrete plinth, while having sufficiently low permeability to reduce seepage losses through the highly weathered granodiorite foundation rock to an acceptable level.

The geotechnical investigation scope incorporated a series of permeability tests targeting the overlying residual soils and extremely weathered rock mass. These tests included:

- Laboratory constant head permeability and oedometer permeability tests.
- In-situ soak-away falling head permeability tests in excavated test pits.
- In-situ Bill Cromer permeameter constant head permeability tests completed every 100 m along the plinth foundation level, with additional holes as needed in areas suspected of having a higher permeability. Figure 12 shows a Cromer (Cromer, 2015) permeameter test on material, similar to the founding level for the plinth.

Figure 12: Cromer permeameter test (Cromer, 2015)

The suitable cut-off trench level for the Wises Dam embankment methodology following the observation of low permeability testing results (<1 x 10-6 m/s) was the natural surface. To determine the natural variability of the cut-off trench (natural surface) depth between investigation locations the pre-mining survey was used as the benchmark. Observation of the variance between the pre-mine surface contours and the available borehole waste rock/natural interface was used to develop a statistical analysis of the natural surface level. The variance was plotted on a normal distribution plot at various additional depths to the pre-mine contour and a depth of the pre-mine contour plus 1.5 m additional excavation was

found to be suitable for founding the plinth. This depth was found to be very close to the final levels achieved during the construction.

Embankment – materials and quantity

The challenges described above in the owners' section were faced by the designers when ensuring that the material was of sufficient quality to ensure minimal deformation, while at the same time achieving the required permeability to ensure that there was no buildup of pore pressure within the rockfill.

Lining – material type; placement

The lining material was selected on the basis of the lowest cost suitable for the purpose. A challenge for the placement was the slope of the face at 2H:1V, which required the use of ropes for all personnel working on the face to smooth the cement stabilized crusher dust. The placement of the facing material using the long reach excavators, while achieving an overall satisfactory slope, resulted in a lot of hand labor being required to smooth out irregularities in order to achieve a maximum step of 10 mm in the facing, so as to prevent overstressing of the HDPE, potentially leading to failure.

Plinth length – jointing

The reinforcement for the liner plinth was sized based on the requirement to eliminate transverse joints, thereby minimizing seepage risks and simplifying construction with the removal of waterstops within the cutoff. The reinforcement design was performed in accordance with CIRIA C766, adopting full end restraint. N24 longitudinal bars were required at 150 mm centers to control crack widths to less than 0.3 mm. Nominal N16 bars at 200 mm centers were provided in the transverse direction. This reinforcement arrangement proved to be effective.

Drainage system

The drainage system initially considered was to have a collection pipe at the base of the slope downstream of the plinth with sumps at the low points along the plinth, in order to pump any seepage water back into the Wises Dam. This was subsequently replaced by a gravity system to avoid pumping costs, resulting in a system that would not relieve seepage flowing through the foundation below the plinth, where the water is now flowing into the seepage collection ponds surrounding the waste stockpiles.

Wises pit and waste rock interface

The sloping cut-off trench and RC plinth methodology proposed across Wises Dam was unsuitable for a portion of the embankment where the existing Wises pit (backfilled with mine waste rock) encroached on the Eldridge/Wises pit walls. The cut-off trench would be founded within the mine waste rock. Given the 1:2 (V:H) slope, it would continually extend outwards from the near vertical Wises pit walls.

Several solutions were considered but were ultimately rejected, in part due to the significant costs associated with each option. A summary of the options and the factors impacting feasibility are included in Table 1.

Table 1: A summary of the options and the factors impacting feasibility

Options	Key infeasibility factors
Modified dam/embankment designs	
Roller Compacted Concrete (RCC) dam body	Extreme cost of construction and challenges associated with connecting from and to the existing embankment design within the reduced footprint.
Conventional Vibrated Concrete (CVC) retaining wall	Must be an impermeable concrete structure including complex water stops that are required to tie into the impermeable foundation and HDPE liner.
Existing embankment designs with foundation improvement	
Zone 1A clay blanket	Granite belt geomorphology resulting in less than 1 m of residual soils across the site.
CVC blanket	Thermal and differential cracking due to the thickness of >3 m.
RCC blanket	High ambient air temperatures (>40 degrees) and insufficient volume (5,000 m^3) to introduce an additional material type with associated testing.

The foundation improvement using removal and replacement of the waste rock interface with a clay bentonite plug was determined to be the preferred solution. This uses an impermeable material (<1 x 10-7 m/s) tying into the low permeability XW rock target foundation material and forming a horizontal blanket overlying the mine waste rock. Details of this solution are shown in Figure 4.

Conclusion

The Kidston Hydro Electric Power (HEP) project provides a first for Australia in the use of a disused mine to provide both the storage capacity and the head to develop a scheme with 250 MW capacity.

The design and construction of the Wises Dam encountered a number of challenges, which were addressed with practical solutions. These included the following:

- Variable foundation conditions that were unavoidable due to the position of previous mining pits.
- Buried natural surfaces beneath meters of permeable mine waste rock.
- Variable mine waste rock deposits requiring careful adaption of the plinth design using the bentonite treated fill “plug.”
- Compaction of rockfill using bulldozer without vibration.
- Use of a continuous reinforced concrete plinth of 6,180 m, which has achieved the required maximum crack size of 0.3 mm.
- Rockfill face screeding using cement stabilized crusher dust for placement of the HDPE.

- Water transfer from Eldridge pit into Wises Dam.

Some of the challenges were expensive, but this has not prevented the CJV from continuing to provide a high-quality product for the hydropower generation.

Abstract

Mine waste facilities reclamation and acid mine drainage (AMD) prevention usually involve the construction of cover systems on tailings impoundments, requiring significant amounts of materials with specific hydro-geotechnical properties. However, if materials are unavailable locally, their extraction and transportation cause environmental and financial impacts. For legacy or closed mine sites, oxidation processes of sulfidic minerals may have already generated AMD and can make the reclamation more sensitive to geochemical conditions. Tailings valorization in cover systems can reduce environmental impacts and costs. However, using reactive tailings may require a treatment to prevent metal leaching. Among treatments, cement-based solidification/stabilization may effectively improve hydrogeotechnical properties and reduce contamination potential. Stabilized tailings could be used to create a surface layer with low water permeability on tailings storage facilities.

This research evaluated the effectiveness of adding Portland-Limestone (GUL) cement and slag-based cement at 5% or 7% binder dosages on the unconfined compressive strength (UCS), hydraulic conductivity, and oxygen consumption (OC) of cemented tailings pastes. Fresh filtered tailings provided from two active mines (samples R1 and L1) currently in operation in Québec and weathered tailings provided from an inactive closed mine (sample M1) located in Abitibi-Temiscamingue were tested. The experiment results showed that for tailings R1 and L1, slag-based cement was more effective than GUL in reducing hydraulic conductivity and increasing UCS. However, for tailings L1, a significant loss of strength was observed after 28 days of curing. One reason could be the oxidation of sulfidic minerals as observed during OC tests,

leading to a decrease in the pH of the cement matrix and dissolution of the cement hydrates. For tailings M1, with a paste pH value of 2.58, GUL was the most effective binder. However, adding 5% of lime kiln dust, as an alkaline additive, in the slag-based cement resulted in higher short-term mechanical strength.

Introduction

The mining industry produces large quantities of solid wastes, particularly waste rock and tailings, which must be stored in a manner that assures their long-term physical and chemical stability. Indeed, many geotechnical and environmental challenges are associated with mining waste storage areas. One of the main environmental challenges is the generation of acid mine drainage (AMD). AMD occurs when sulfidic minerals oxidize in atmospheric conditions (Aubertin et al., 2002). Tailings storage facilities (TSF) closure and reclamation methods have been developed to control water infiltration and/or oxygen diffusion in waste storage facilities, via cover systems built on TSF. More details are presented in the literature (Aubertin et al., 2002, 2016; Bussière et al., 2005; Bussière and Guittonny, 2021). Generally, covers require significant amounts of natural materials with specific hydro-geotechnical properties. However, access to sufficient quantities of adequate materials can be problematic, especially for large TSF or remote sites. For legacy or closed mine sites, oxidation processes of sulfidic minerals may have already generated AMD and can make the reclamation more sensitive to geochemical conditions. Indeed, on these sites, water quality can be highly contaminated with metal/metalloids, and a high concentration of Fe^{3+} in pore water can oxidize sulfidic minerals. Despite the application of reclamation methods, oxidation reactions can be difficult to stop. In this case, TSF reclamation must both prevent new contamination, by limiting water or oxygen infiltration, and treat previous contamination (Bussière et al., 2005).

To reduce the quantities of borrowed natural material and/or transportation over long distances for the construction of cover systems, valorization of in-situ mine tailings can be done. However, tailings do not always have adequate hydrogeotechnical properties. Moreover, for reactive tailings, a treatment is required to prevent AMD and metal leaching. Among treatments, cement-based solidification/stabilization (S/S) may effectively improve hydrogeotechnical properties, reduce the reactivity potential of sulfides and limit contamination by stabilizing metals and metalloids in non-soluble compounds. Cement-based S/S processes are widely used in the mine backfill industry (hydraulic fill, rockfill and cemented paste backfill). In previous studies, low-carbon cements have shown great potential for stabilizing oxidized and reactive tailings. Binder hydration creates a low-permeability cementitious matrix, in which contaminants are encapsulated, preventing leaching and pollutants from moving. The reactive surface of tailings is also reduced (Deschamps et al., 2006). The efficiency of cement-based S/S treatment depends on the binder hydration processes, controlled by intrinsic and extrinsic parameters, and on the geochemical stability of cement hydrates. Among intrinsic parameters, a significant sulfidic minerals content can harm the integrity

of the matrix, if oxidation of sulfidic minerals happens, resulting in a sulfate attack. Sulfate attack is a process due to the formation and expansion of secondary minerals, leading to cracking, strength loss, and disintegration of the matrix (Benzaazoua et al., 2002).

Cement-based S/S treatment could improve hydro-geotechnical properties and reduce the contamination potential of hazardous tailings, prior to their valorization. However, there is a lack of experience in using cemented tailings pastes as cover materials. In addition, a surface layer made of such materials will be exposed to atmospheric conditions. Limiting sulfidic oxidation could therefore be a real challenge.

So, the objective of the current research is to assess the feasibility of the valorization of cemented tailings pastes in cover systems. In this study, Portland-Limestone (GUL) cement and slag-based cement were used to solidify and stabilize tailings from three different mine sites (two active and one inactive). The unconfined compressive strength, (UCS), the saturated hydraulic conductivity (k_{sat}), and the oxygen consumption (OC) of the cemented tailings prepared with 5% or 7% binder content were evaluated to obtain the most appropriate binder and binder dosage. UCS and k_{sat} were used in this study as the first indicators of cement hydrate formation that favor contaminant stabilization. OC was used as an indicator of sulfide mineral passivation.

Methodology

Materials

In this study, three different tailings were used to prepare cemented tailings pastes. Fresh filtered tailings were taken from Raglan Mine (R1) and LaRonde Mine (L1), two operating mine sites located in the north of Quebec and in Abitibi-Temiscamingue (A.-T.), respectively. Weathered tailings were sampled from Manitou (M1), an inactive closed mine site in A.-T. After transferring the tailings to the laboratory, samples of all materials were homogenized using a spade to avoid, as much as possible, heterogeneities in the chemical and mineralogical properties. Reactive tailings R1 and L1 were submerged in water before being sealed in plastic containers to prevent oxidation. Weathered tailings M1 were oven-dried at 60°C and sieved to remove coarse fractions over 450 µm before carrying out the homogenization, characterization, and preparation processes. Porland-Limestone (GUL) cement and a blend of 20 wt.% of GU cement and 80 wt.% of ground granulated blast furnace slag (Slag) (20GU/80Slag) were used as the main binding agents. A mixture of 20GU/80Slag and lime kiln dust as an alkaline additive (5 wt.%) was also used as a binding agent. Deionized water was used for the preparation of cemented tailings paste samples to eliminate the effects of water chemistry on cemented tailings behavior.

Methods

Physical, mineralogical, chemical, and hydrogeological characterizations

The specific gravity (Gs) of tailings was measured using a Micrometrics helium pycnometer (Ultrapyc 1200e, Quantachrome Instruments). Tailings particle size distribution (PSD) was analyzed using a laser diffraction particle size analyzer (Malvern Mastersizer S3000, Malvern Panalytical, Canada).

The mineralogical composition of tailings was semi-quantified with X-ray diffractometry (XRD) using a Bruker AXS D8 Advance X-ray diffractometer. Identification of mineral species was carried out using DIFFRAC.EVA software (version 5.2.0.3) and their quantification was done by Rietveld-TOPAS software (version 4.2).

The paste pH of tailings was analyzed using a pH meter, after adding 5 ml of deionized water to 10 g of tailings. The interstitial water in the tailings was diluted with deionized water and collected by vacuum pumping. The chemical composition of interstitial water was then analyzed by ICP-AES on the liquid samples acidified with 2% HNO_3.

The k_{sat} of tailings was estimated using the model developed by Mbonimpa et al. (2002a). k_{sat} was evaluated using a rigid-wall compaction-mold permeameter (ASTM-D5856-95, 2002).

Preparation, curing and testing of the cemented tailings paste mixtures

Uniaxial compressive strength (UCS) tests

To use stabilized tailings as cover materials to create a surface layer on a TSF, a minimum UCS of 1 MPa of cemented tailings pastes after 28 days of curing was targeted in this study (Belem et al., 2009). Tailings paste mixtures were prepared with 5 wt.% and 7 wt.% GUL and 20GU/80Slag.

All the tailings paste mixtures were prepared in the laboratory, using these steps:

Half of the deionized water was mixed with the binder in a Hobart mixer bowl (capacity of 4.8 L) using a hand spatula. The tailings and the remaining water were added progressively to the mixture and mixing continued for up to 5 minutes to achieve a homogeneous paste. Immediately after preparation, the consistency of the cemented tailings pastes was measured by the mini-slump test. The slump test was also used to determine the optimum water requirement for each paste mix by aiming for a slump between 7-8 inches. Water was added to reach the desired consistency.

The cemented tailings paste mixtures were poured into 2 × 4 inches cylindrical plastic molds (50.8 diameter × 101.6 mm height) in a single layer. Molds were drilled to allow drainage. After molding, the cylinders were tapped 25 times using a steel rod with a diameter of 9.53 mm (3/8 in) to expel the air bubbles from the pastes. The prepared drained cylindrical samples were labeled and stored in the laboratory (approximately 60% relative humidity and 22°C) to cure for 3, 7, 14, 28, and 56 days before testing. The

conditions remained unchanged over the curing period to ensure the comparability of tests and to limit the number of influencing factors.

The strength evolution in the pastes was assessed by performing UCS tests on three separate specimens for each recipe. UCS tests were carried out based on the ASTM C39 standard by a computer-controlled mechanical press with a normal loading capacity of 50 kN and a 1 mm/min displacement rate, and the stress-strain data were recorded for each sample. The samples were taken out of molds after 3, 7, 14, 28, and 56 days of curing for UCS testing. The base and top of the cylinders were flattened parallel to the plates of the mechanical press before the UCS tests. The maximum stress value before failure during the compression test was measured. All the measurements were carried out in triplicate and the average values were taken as the final compressive strengths. The UCS test results were used to select the most appropriate binding agent and dosage. After UCS tests, the cemented samples were oven-dried at 90°C to determine the water content. The paste pH was then analyzed using a pH meter after adding 5 mL of deionized water to 10 g of cemented samples.

For the cemented tailings paste samples tested that reached the targeted UCS of 1 MPa after 28 days of curing, new mixtures with the same recipes were prepared for the k_{sat} and OC tests.

Saturated hydraulic conductivity (k_{sat}) tests

Cemented tailings paste mixtures were cast into 4 × 8 inches cylindrical plastic drained molds in three layers. Each layer was tapped 25 times using a steel rod with a diameter of 9.53 mm (3/8 in) to expel the air bubbles from the pastes. Samples were stored in the laboratory under controlled temperature and moisture conditions (22°C and 50% respectively) to cure for 28 and 56 days before testing. The k_{sat} of cemented tailings was evaluated using a flexible-wall mold permeameter (ASTM-D5856-95, 2002).

Oxygen consumption (OC) tests

Oxygen consumption tests were used to determine the sulfide oxidation rates in the tailings and cemented tailings pastes. In OC tests, paste mixtures were poured into drained cylinder molds with dimensions of 5.90 × 1 inches. Samples were stored in the laboratory and cured under controlled temperature and moisture conditions (22°C and 50% respectively) for 3, 7, 14, and 28 days before testing. The cylinder was then closed and sealed for oxygen concentration measurements with an oxygen sensor for a period of two to five hours (Oxygen dipping probe type PSt7, PreSens Precision Sensing GmbH, resolution at 0.01 % O_2 at 1 % O_2 and 0.05 % O_2 at 20.9 % O_2). High oxygen decrease means a high sulfide oxidation rate. To evaluate the effect of binder, OC tests were also performed on control samples (i.e. tailings without binder). For control samples, tailings were poured into cylinder molds with dimensions of 5.90 × 1 inches at a porosity n= 0,45 and a degree of saturation around 50% to favor oxidation conditions.

Results and discussion

The results of the initial characterization of the materials and mechanical strength, hydraulic conductivity and oxygen consumption of cemented tailings pastes samples are presented in this section.

Physical, mineralogical and chemical characterization

The physical properties are presented in Table 1. The G_s values of fresh tailings R1 and L1 were higher than the oxidized tailings M1: 3.05 for both R1 and L1, and 2.72 for M1. Figure 1 depicts the cumulative PSD of the tailings, and some commonly used indicators associated with PSD are presented in Table 1. The PSD values showed that 45% of tailings R1 and L1 are less than 20 µm in diameter. 90% of tailings R1 and tailings L1 are less than 120 µm and 100 µm in diameter, respectively. Tailings M1 showed a coarser PSD than the other tailings. The D_{50} and D_{90}, which correspond to 50% and 90% passing on the cumulative particle-size distribution curve, were 51 µm and 382 µm, respectively.

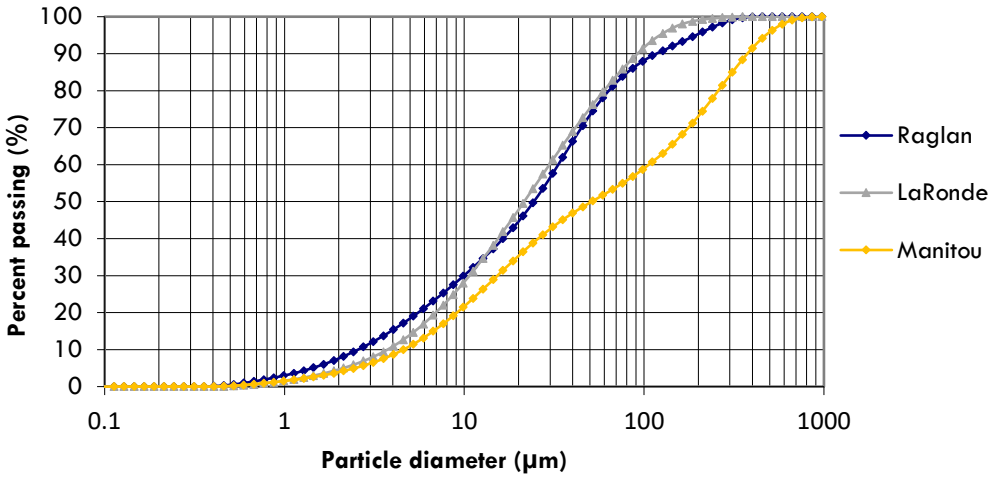

Figure 1: Particle size distribution of the studied tailings samples

Table 1: Physical characteristics of the tailings samples

Parameter	D_{50}	D_{90}	$Cu=D_{60}/D_{10}$	$Cc = D_{30}^2/(D_{60}*D_{10})$	$U = (D_{90}-D_{10})/D_{50}$	G_s
Unit	(µm)	(µm)	(-)	(-)	(-)	(kg/m³)
Raglan R1	24.3	117	13.01	1.16	4.71	3,055
LaRonde L1	21.5	92	7.99	1.03	4.11	3,052
Manitou M1	50.8	382	23.14	0.48	7.43	2,721

The mineralogical composition of tailings samples is presented in Table 2. For fresh reactive tailings R1 and L1, sulfide contents (mainly pyrrhotite for R1 and pyrite for L1) were 20.3 wt.% and 14.9 wt.% for

R1 and L1, whereas carbonate contents were 0.9 wt.% and 2.8 wt.% for R1 and L1, respectively. Mineralogical compositions of tailings M1 were completely different. Sulfides, carbonates and secondary minerals content were 0.3 wt.%, 0.2 wt.% and 1.5 wt.% respectively.

Table 2: Mineralogical properties of the tailing samples

	Raglan R1	La Ronde L1	Manitou M1
Sulfides	20.3	14.9	0.3
Carbonates	0.9	2.8	0.2
Sulfates	0.0	2.7	1.5
Fe- oxyhydroxides	2.8	0.0	0.1
Others	76.0	79.6	97.9

Table 3 presents the paste pH of the tailings. As fresh tailings, R1 and L1 present a near-neutral paste pH, contrary to M1 oxidized tailings with an acidic paste pH of 2.58, characteristic of AMD production.

Table 3: Paste pH of the tailing samples

	Raglan R1	La Ronde L1	Manitou M1
Paste pH	7.28	6.91	2.58

Hydrogeological properties

The predicted and measured k_{sat} values are shown in Table 4. The measured k_{sat} values for R1 and L1 were 7.49E-8 m/s and 4.52E-8 m/s, respectively. The k_{sat} value for oxidized tailings M1 was 2.53E-7 m/s. The predicted k_{sat} values were within an order of magnitude of the measured values.

Table 4: Measured and predicted saturated hydraulic conductivities k_{sat}

Tailings	Porosity	Predicted k_{sat} (m/s)	Measured k_{sat} (m/s)
Raglan R1	0.42	1.80E-07	7.49E-08
LaRonde L1	0.42	3.10E-07	4.52E-08
Manitou M1	0.42	5.60E-07	2.53E-07

Pore water chemical composition

The pore-water chemical composition of the tailings samples is presented in Table 5.

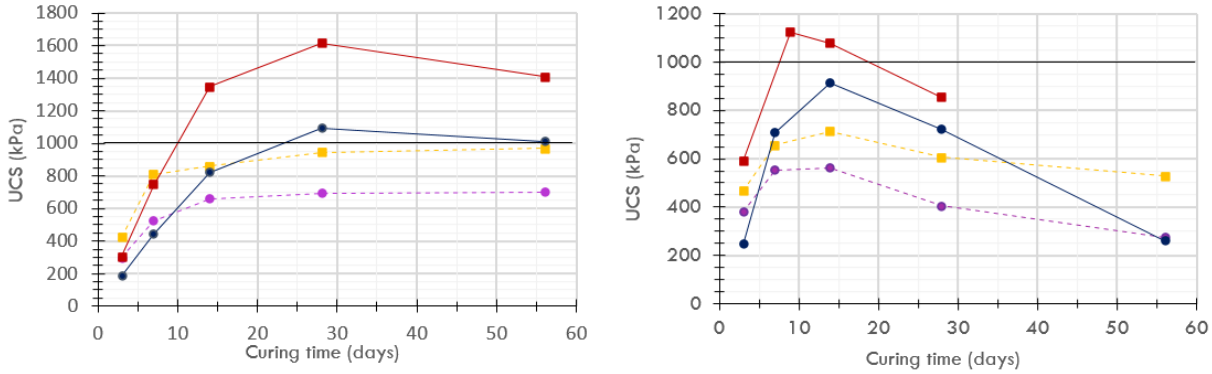

Table 5: Results of the pore-water chemical composition of the tailings samples

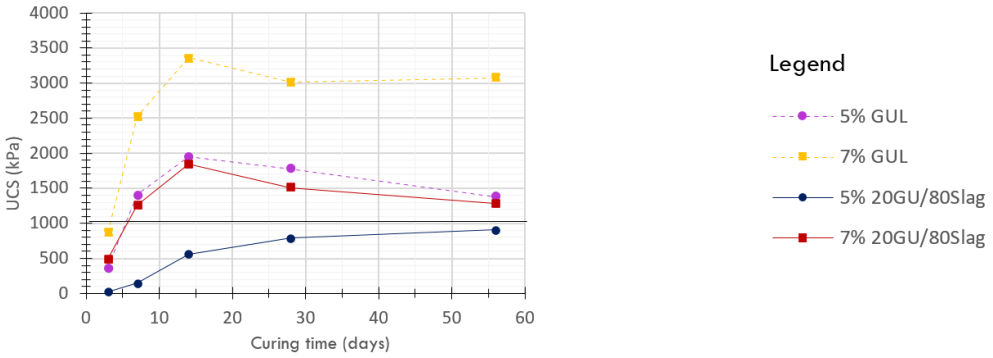
Tailings		Raglan mg/L	LaRonde mg/L	Manitou mg/L
Main pore-water chemical components	Cu	0.158	OQ*	67
	Fe	OQ*	OQ*	125
	Ni	15	OQ*	0
	Pb	OQ*	OQ*	0,23
	Zn	OQ*	0,218	84
Ions sulfates	SO_4^{2-}	11,708	23,528	23,946



*LOQ: limit of quantification

The results show high concentrations of sulfates in the porewater of all tailings samples, especially for L1 and M1. M1 tailings have the highest concentration of Fe, which can be explained by the acidic conditions of the tailings. M1 have also higher concentrations of Cu and Zn.

Figure 2: Results of UCS tests on the cemented tailings samples prepared with GUL cement and slag-based cement (20GU/80Slag)

Figure 2 shows the relationship between uniaxial compressive strength and curing time of the cemented tailings paste samples prepared at 5 wt.% and 7 wt.% binder content using GUL and 20GU/80Slag for each tailings type.

For R1 tailings (Figure 2a), after 28 days, UCS increased significantly with curing age for both binder types and both binder dosages tested. However, samples prepared with GU failed to reach the targeted 28-day UCS of 1 MPa. Only the samples prepared with 20GU/80Slag binder for both binder dosages achieved it. Although a slight decrease in strength was observed after 56 days of curing, the targeted UCS was always achieved. For L1 tailings, Figure 2b shows that after 14 days of curing, UCS increased appreciably with curing age for both binder types and percentages. Slag-based cement gave the best results, probably due to its high sulfate resistance.

However, after 28 days of curing, a significant loss of strength was observed. As the samples were stored unsealed in the laboratory under atmospheric conditions, oxidation of the sulfide minerals must have occurred, leading to a decrease in the pH of the cement matrix and dissolution of the cement hydrates (ettringite, hydrated calcium silicate [C-S-H]) responsible for the strength gain. Paste pH was measured for each sample of L1 tailings prepared with 7% of GUL and 20GU/80Slag at 3, 7, 14, 28, and 56 days of curing. For both recipes, an increase in the paste pH at the beginning of the cement hydration was observed. Indeed, after 3 days of curing, the paste pH was around 11.0 and 10.1 for samples prepared with GUL and 20GU/80Slag binders respectively. Then, it decreased and dropped below 9.5 and 8.5 after 56 days of curing. For tailings M1 (Figure 2c), with an acidic paste pH of 2.44, GUL was the most effective binder. Samples prepared with 5 wt.% and 7 wt.% GUL gave UCS values above the target at 14 days. A slight loss of resistance was observed, but strengths were still superior to 1 MPa. For samples prepared with 20GU/80Slag cement, only 7 wt.% dosage was efficient in reaching the target UCS of 1 MPa. GUL cement was more efficient in rapidly increasing the pH of the cement matrix, which could contribute to the formation and stability of cement hydrates responsible for the strength. Moreover, the coarser particle size of tailings M1 could explain these high UCS values.

To evaluate the effect of the type of binder on strength development, new samples were prepared with M1 tailings and 5 wt.% of 20GU/80Slag cement where 5% of lime kiln dust was added as an alkaline additive. Figure 3 shows the relationship between uniaxial compressive strength and curing time for this alternative recipe. It resulted in higher short-term mechanical strengths, and a UCS of 1 MPa was achieved at 28 days. However, at 56 days of curing, the strength decreased to 950 kPa. The addition of an alkaline material could raise the pH value to a sufficient alkaline level, making cement hydrates more stable.

Cemented tailings saturated hydraulic conductivity results

4a)·Raglan·R1·4b)·LaRonde·L1¶

4c) Manitou M1

Figure 4: Results of saturated hydraulic conductivity tests on the cemented tailings samples prepared with GUL cement and slag-based cement (20GU/80Slag)

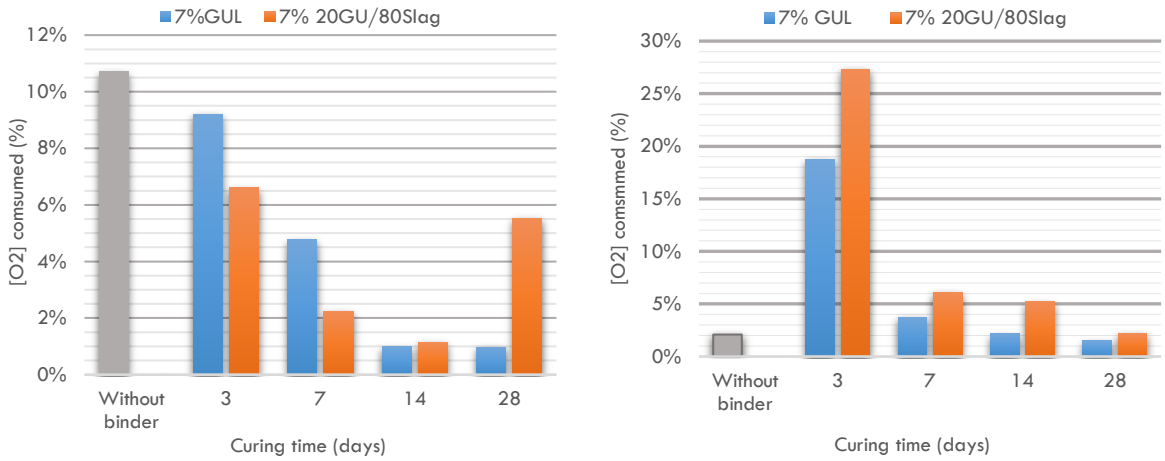
Figure 4 presents the results of saturated hydraulic conductivity tests of cemented tailings pastes samples that reached the targeted 28 days UCS of 1 MPa.

In all cases the results showed a significant reduction of k_{sat} when binder was added to tailings (initial tailings with k_{sat} around 10^{-7} – 10^{-8} m/s). For R1 tailings (Figure 4a), with a binder proportion of 7% GUL, k_{sat} decreased by a factor of approximately 1½ order of magnitude after 28 days of curing. However, it remained superior to 1×10^{-9} m/s. For L1 tailings (Figure 4b), when 7% of 20GU/80Slag cement was added, k_{sat} value of the tailings decreased only by a factor of approximately ½ order of magnitude after 28 days of curing and remained superior to 1×10^{-8} m/s, which does not take into account the hydraulic barrier condition. This slight decrease in k_{sat}, despite the addition of binder, can be explained by the significant loss of strength after 28 days of curing, which suggests a dissolution of the cement hydrates of the matrix and an increase in porosity. For M1 tailings (Figure 4c), a reduction of k_{sat} of between 2½ and 3 orders of magnitude can be observed according to the mixture recipes.

Figure 4c also shows that the binder type and the proportion influence k_{sat} evolution. The GUL cement significantly impacts k_{sat} more than the 20GU/80Slag binder after 28 and 56 days of curing for the same proportion of binder. After 28 days of curing, for 7% binder content, k_{sat} is about ½ an order of magnitude lower than the one with the 20GU/80Slag binder. These results show that the k_{sat} of the samples can be negatively correlated to the UCS values (Figure 2c). The higher the UCS value is, the lower the saturated hydraulic conductivity is. At 28 days of curing, with 5% of GUL, k_{sat} was reduced at a lower amplitude than with 7% GUL, and at 56 days of curing, k_{sat} increased nearly 1 order of magnitude (from 9.8×10^{-10} m/s to 1.1×10^{-8} m/s). A crack was observed along the sample, which represents a preferential flow path for water movement and could explain the higher k_{sat} value.

Cemented tailings oxygen consumption results

The oxygen consumption (OC) tests were performed using an empty space (chamber headspace) of height h of 7.5 cm at the top, and measurements were conducted every minute for 200 minutes and 300 minutes. The percentage of oxygen consumed in the headspace ($[O_2]_{consumed}$) during OC tests is calculated as follows:



$$[O_2]_{consumed} = \frac{C_0 - C_f}{C_0} \times 100 \qquad \text{(Equation 1)}$$

where C_0 and C_f are the oxygen concentrations [ML^{-3} or $molL^{-3}$] at the beginning and the end of the OC tests, respectively.

Figures 5 presents the results of the OC tests for cemented R1 and L1 tailings paste mixtures with a binder proportion of 7% GUL and 7% 20GU/80Slag cement at 3, 7, 14, and 28 days of curing. For tailings R1 (Figure 5a), the addition of binder reduces the oxygen concentration consumed by the tailings in a short

time. Indeed, for the control sample, $[O_2]_{consumed}$ was more than 11% in the 7.5 cm headspace (over a period of 200 minutes); whereas, for both paste mixtures, the oxygen consumed in the top chamber during tests decreased with time and dropped below 1.5% after 14 days of curing. Slag-based cement seems to be more efficient in reducing the oxygen consumed by the oxidation of sulfide minerals than GUL cement. Even if an increase of $[O_2]_{consumed}$ was observed at 28 days of curing with 7% 20GU/80Slag, it remained inferior to the control sample. For tailings L1 (Figure 5b), it was observed that $[O_2]_{consumed}$ by cemented paste mixtures is 9 and 13 times higher than the control sample at 3 days of curing with 7% GUL and 7% 20GU/80Slag cement respectively.

This could be explained by the curing conditions in the laboratory. Indeed, drained unsealed molds were used in the experiment, which favored water drainage and evaporation of the samples. Consequently, the saturated conditions of the paste mixtures were not guaranteed to limit oxygen diffusion through cemented tailings paste during the curing time. After 7 days of curing, the percentage of oxygen consumed in the top chamber during the tests decreased, and a $[O_2]_{consumed}$ in the headspace less than 2% was reached for both mixtures cured at 28 days.

5a) Raglan tailings 5b) LaRonde tailings

Figure 5: O_2 concentration consumed in the chamber headspace during OC tests at 3, 7, 14, and 28 days of curing compared to control sample at 1 day

OC tests were also performed with Manitou tailings (with and without binder). However, for these tests, a total consumption of O_2 less than 1% in the 7.5 cm headspace (over a period up to 5h) was obtained. Manitou tailings can be considered as low-sulfide tailings (0.3% of sulfides) and seemed to not consume the O_2 flux into cemented paste tailings. AMD generation in these tailings is mainly driven by oxidation with ferric ions or dissolution of secondary iron oxyhydroxides (Bussière and Guittonny, 2021).

Conclusion

Based on the results of this study, it can be concluded that:

- The addition of 5% and 7% of binder increased the strength of the tailings paste mixtures and reduced the saturated hydraulic conductivity; however, both targeted UCS > 1 MPa, and k_{sat} < 1E-9 m/s after 28 days of curing were usually achieved with 7% of binder.
- Cemented paste mixtures prepared using 20GU/80Slag cement showed higher strength for tailings having neutral paste pH than the samples prepared with tailings with acidic paste pH; in that case, samples prepared with GUL cement showed higher UCS. However, adding 5% of alkaline additives can increase strength by raising the pH value to a sufficient alkaline level and making cement hydrates more stable.
- One reason for strength reduction in the cemented tailings paste at LaRonde is the dissolution of the cemented hydrates responsible for the strength, due to the oxidation of sulfide minerals during a short curing time, and thus a reduction of the paste pH of the cemented matrix.

TRIM4Post-Mining: Geotechnical Input for Transition Information Modeling for Post-mining Landscapes

Gerald Verbeek, Eijkelkamp North America, USA
Gustavo Hamu, Royal Eijkelkamp, The Netherlands

Abstract

As part of the recent TRIM4 research project, Royal Eijkelkamp performed various soil investigation techniques. The results of these techniques can be used as input for information modeling to support decision making and planning during the transition from mine exploitation to a re-vitalized post-mining landscape. In this paper the use of soil sampling using a sonic drill rig, the Monitoring While Drilling technique (including the use of the obtained results for subsurface characterization), as well as Sonic Cone Penetration Testing (whereby a vibration is superimposed on the standardized downward movement of a cone into the soil) are described as they were applied at the test site for the research project. The emphasis of the descriptions in this paper are the main findings that were reported in the final report of the TRIM4 research project. The paper also summarizes future development work recommended for these techniques.

Introduction

The development of effective solutions to transform mining locations into sites with new perspectives that are socially and economically viable is a fundamental part of responsible post-mining management. To promote an integrated approach for such developments, the European Union initiated the TRIM4Post Mining research project, which focused on Transition Information Modeling for post-mining landscapes. At an active lignite mine in Germany just south of Leipzig, Germany (the United Schleeenhain Coal Mine), a group of companies applied various techniques to generate the required input data for such modeling. Royal Eijkelkamp participated in this effort and contributed by performing various geotechnical techniques, such as soil sampling using sonic drilling, Monitoring While Drilling (MWD) and using the results for geotechnical sub-surface characterization, Sonic Cone Penetration Testing (CPT) to expand the use Standard CPT in challenging soil conditions, and the use of a CPT module to obtain images of the soil profile as the cone was pushed into the soil. The results of the last-mentioned are described in an accompanying paper, while those of the first three are described in this paper.

TRIM4 Research Project

The TRIM4Post-Mining Research Project was a project funded by the European Union that brought together a consortium of European experts from industry and academia to develop an integrated information modeling system, designed to support decision making and planning during the transition from coal exploitation to a revitalized post-mining landscape, enabling infrastructure development for agricultural and industrial utilization, and contributing to the recovery of energy and materials from coal mining dumps.

The basis of this system is a high-resolution spatiotemporal database, utilizing state-of-the-art multi-scale and multi-sensor monitoring technologies, which allow characterization of dynamic processes in mining waste dumps related to timely, dependent deformation and geochemical processes. It integrates efficient methods for operational and post-mining monitoring, comprehensive spatiotemporal data analytics, feature extraction, and predictive modeling; this then allows for the identification of potential contamination areas and the forecasting of geotechnical risks and ground conditions. For the interactive exploration of alternative land-use planning scenarios – in terms of residual risks, technical feasibility, environmental and social impact, and affordability – up-to-date data and models are embedded in an interactive planning system, forming a TRIM – a Transition Information Modeling System. This system is designed to support decision making and planning during the transition from mine exploitation to a re-vitalized post-mining landscape, enabling infrastructure development for agricultural and industrial utilization, and also to contribute to recovering energy and materials from coal mining dumps.

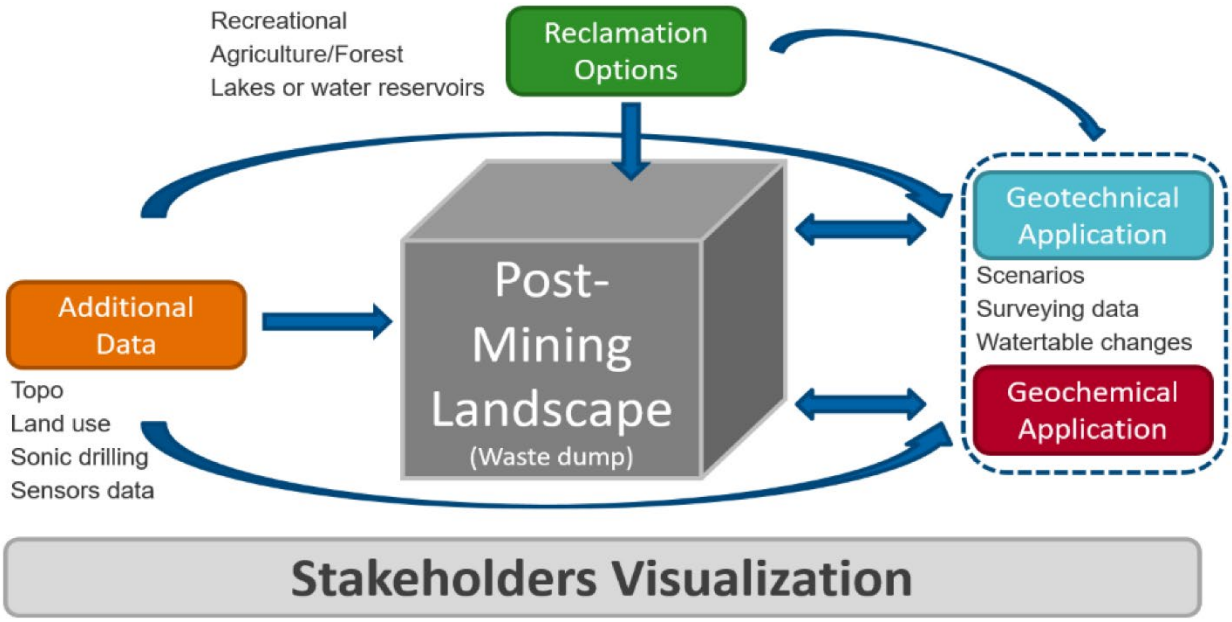

Figure 1: Considerations for the transition from mine exploitation to a revitalized post-mining landscape

Sonic sampling

For the analyses done within the Trim4PostMining project, it was of high importance that high-quality and highly representative drill cores were acquired. Any disturbances in the drill cores have a direct impact on the final test results and thus induce an error in the models that are created. To minimize these disturbances the sonic drilling method was chosen. Sonic drilling is known for its high drilling speeds, high core quality and high representation between drill core and drilled lithology.

The high performance of a sonic rig is due to the motion that a sonic rig applies on the drill string. Besides the more conventional, rotational motion, a vibrational motion is applied to the drill string. This negates the friction forces on the drill string by liquefying the soil at the drill bit and around the drill string. In rock lithology this sonic vibration results in efficient breaking of the rock, also resulting in high penetration rates and clean "cuts" of the rock lithology.

The goals for the sonic sampling campaign within the Trim4PostMining project were the extraction of drill cores to a depth of 50 m (165 ft) at two test locations, with high representativeness and core recovery rates of the drill cores. The drilling crew was able to successfully achieve both goals, and achieve core recovery rates that are seemingly unrealistic compared to conventional drilling recovery rates.

Figure 2: Drill cores acquired during the Schleenhain campaign in May 2022

Table 1: Results of sonic sampling

	Borehole 1	Borehole 2
Reached Depth (m)	50	50
Total Recoverable (m)	40.5	40.6
Total Slurries/Cavities (m)	9.5	9.4
Total Recovered (m)	39.45	40.2
Average Recovery (%)	97.4	99.0

As shown in Table 1, not all layers of the drilled lithology were acquired with sonic drilling as shown in the recovery percentage. During the drilling operation the operator noticed that in some instances the drill string did not encounter any resistance, indicating the presence of groundwater or very loose soils. In these conditions it is impossible to sample effectively as the material is flushed away or will just fall out of the drill string, which makes layers where these conditions exist unrecoverable.

Nonetheless, when viewed overall the recovery percentage of the sonic rig was very high. Also, comparing the drilled cores with the known dump model of the test locations, it was concluded that the drill core were representable for the present lithologies at the post-mining site.

Monitoring while drilling and geotechnics while drilling

The Monitoring While Drilling (MWD) system is a state-of-the-art data acquisition system that plays an increasingly crucial role in the drilling industry. This system logs various physical drilling parameters so as to optimize the performance of a drilling machine and improve the efficiency of the drilling operation by providing the drilling operator with relevant information about rig performance and soil profile.

Table 2: MWD parameters

Measured parameter	Parameter of interest	Presentation unit
Depth	Borehole depth, Relative depth	m, m
Sonic hydraulic pressure	Sonic pressure	Bar
Sonic hydraulic debit	Sonic frequency	Hz
Rotation hydraulic pressure	Torque	Nm
Rotational hydraulic debit	Rotary speed	RPM
Pull up pressure	Pull up pressure	Bar
Pull down pressure	Pull down pressure, Total downward force	Bar, kN
Flushing fluid pressure	Flushing pressure	Bar
Flushing fluid debit	Flushing flow	l/min
Location	Location	Lat, Lon
Inclination X, Y	Drilling angle	deg.
Acceleration	G-force, THD+N[1], True sonic frequency	g, %, Hz
Temperature	Borehole temperature	°C

[1] THD+N stands for total harmonic distortion including noise, which is defined as the power of the harmonics and noise divided by the total signal power. The harmonic power and noise can be calculated by subtracting the fundamental frequency power form the total output power.

Geotechnics While Drilling (GWD) is a feature that extends the MWD system, focusing on the study of subsurface ground conditions and the prediction of soil properties in real time while drilling is in progress. While the MWD system measures input parameters related to the sonic drilling process, the GWD system uses these values to derive interesting mechanical soil properties such as density, porosity, cohesion, frictional angle, etc. In this way, the GWD feature provides valuable information about soil properties in real time and presents it in such a way that it allows for quick assessment of latent conditions.

The analysis of the data obtained at the two test locations showed that various parameters, such as the pulldown pressure, sonic pressure, torque, and rate of penetration, provide valuable insights into the properties of the materials being drilled. The pulldown pressure reflects the total downward force and can indicate the type of rock or soil: softer materials may require a lower pulldown pressure, while harder materials require more. A significant decrease in the rate of penetration may indicate that the drill has encountered a harder layer, while an increase may indicate a softer layer. Additionally, torque is a good indicator of soil cohesion and varies in response to changes in soil friction to maintain a constant rotational speed. Finally, sonic pressure fluctuates in response to changes in soil friction to maintain a constant sonic frequency. The graphs below show an example of how these parameters change with depth.

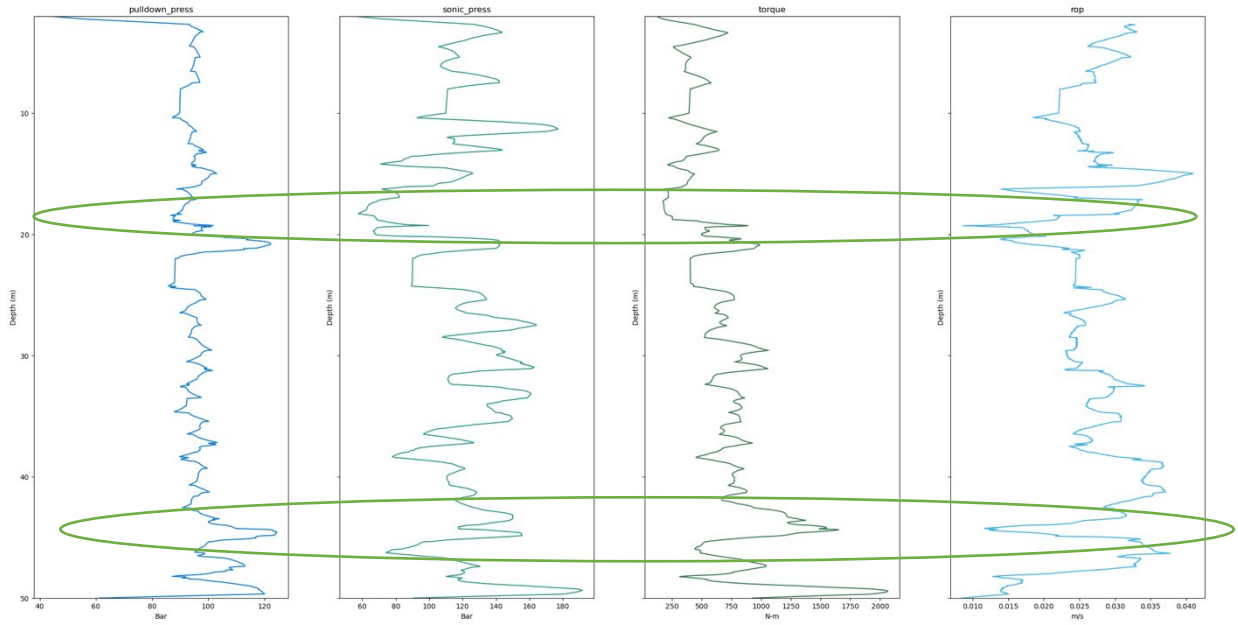

Figure 3: Pulldown pressure, sonic pressure, torque, and rate of penetration vs. depth, with the values at 20 m and 45 m highlighted as they are further discussed in the body of the paper

An intriguing pattern was observed at a depth of approximately 20 meters, where a sharp increase in pulldown pressure, sonic pressure, and torque corresponded with a noticeable drop in the rate of penetration. This demonstrates a clear relationship between the parameters and can be used to infer the characteristics of the subsurface materials being drilled. In this case it can be concluded that at that depth a resistant soil

layer is present, requiring greater pulldown pressure to advance the drill bit, higher sonic pressure to oscillate the drill bit, and increased torque to rotate and steer the drill bit.

A similar trend was observed again at a depth of approximately 45 meters, where pulldown pressure, sonic pressure, and torque displayed an upward trend, corresponding to a decline in the rate of penetration. Conversely, at a depth of approximately 40 meters, an opposite pattern was observed, with the rate of penetration increasing as torque, sonic pressure, and pulldown pressure decreased. This suggests that the soil at this interval offered less resistance to penetration.

At the same locations where the drilling was performed, soil samples were obtained at various depths. These soil samples were analyzed in the laboratory and various soil parameters were correlated with GWD features from the same sampling. This showed a moderate to strong negative correlation between bulk density, dry density, volume loss, constrain modulus low and effective angle, and torque, rate of penetration, and rotational speed. This negative correlation indicates that as these soil properties increased, the torque, rate of penetration, and rotational speed decreased. On the other hand, the constrained modulus and the effective cohesion have a moderate to strong positive correlation with torque, rate of penetration and rotational speed. This suggests that as these soil properties increased, the torque, rate of penetration, and rotational speed also increased.

These correlations were established with minimal geotechnical data and therefore these correlations are indicative only, but they can be used to guide further research and experimentation. Another area of future research should be ranking the MWD parameters listed in Table 2 on their relevance for GWD.

Sonic cone penetration testing

Sonic CPT is an exciting and rapidly developing technique that is reducing early refusals in CPT soundings by carefully applying a vibration, when needed, to the CPT string. The technique actually has a history dating back almost 40 years to 1982, when 1982 Sasaki and Koga reported their work to develop and deploy their vibratory cone, which they used for liquefaction analysis. They compared tip resistance with and without vibration and found that in loose soils the tip resistance was substantially lower in vibratory mode due to the additional excess pore pressure generated, whereas in stiff soils the vibration did not create additional excess pore pressure and the tip resistance was similar.

Royal Eijkelkamp's expertise in sonic drilling technology has allowed us to take this pioneering work much further and develop it into three key areas of application. The first application is to deal with layers of very hard soil above or between layers of softer material. With conventional CPT it is impossible to push through these layers and the test must be terminated. Sometimes destructive drilling will be performed, which is costly and provides no data. However, with Sonic CPT it is often possible to use the vibratory

action to penetrate the hard layer before Standard CPT pushing can be continued in the softer material below.

The second application is that by applying vibration to the CPT rod string, friction between the rods and soil is largely eliminated, allowing a higher percentage of the pushing force to be transferred to the cone, which enables the cone to be pushed deeper into the soil. This is particularly useful in stiff cohesive material, such as London Clay, where almost one ton of pushing force per meter can be required to overcome rod friction. This can also improve the applicability of lower weight CPT rigs, which provide a smaller reaction force.

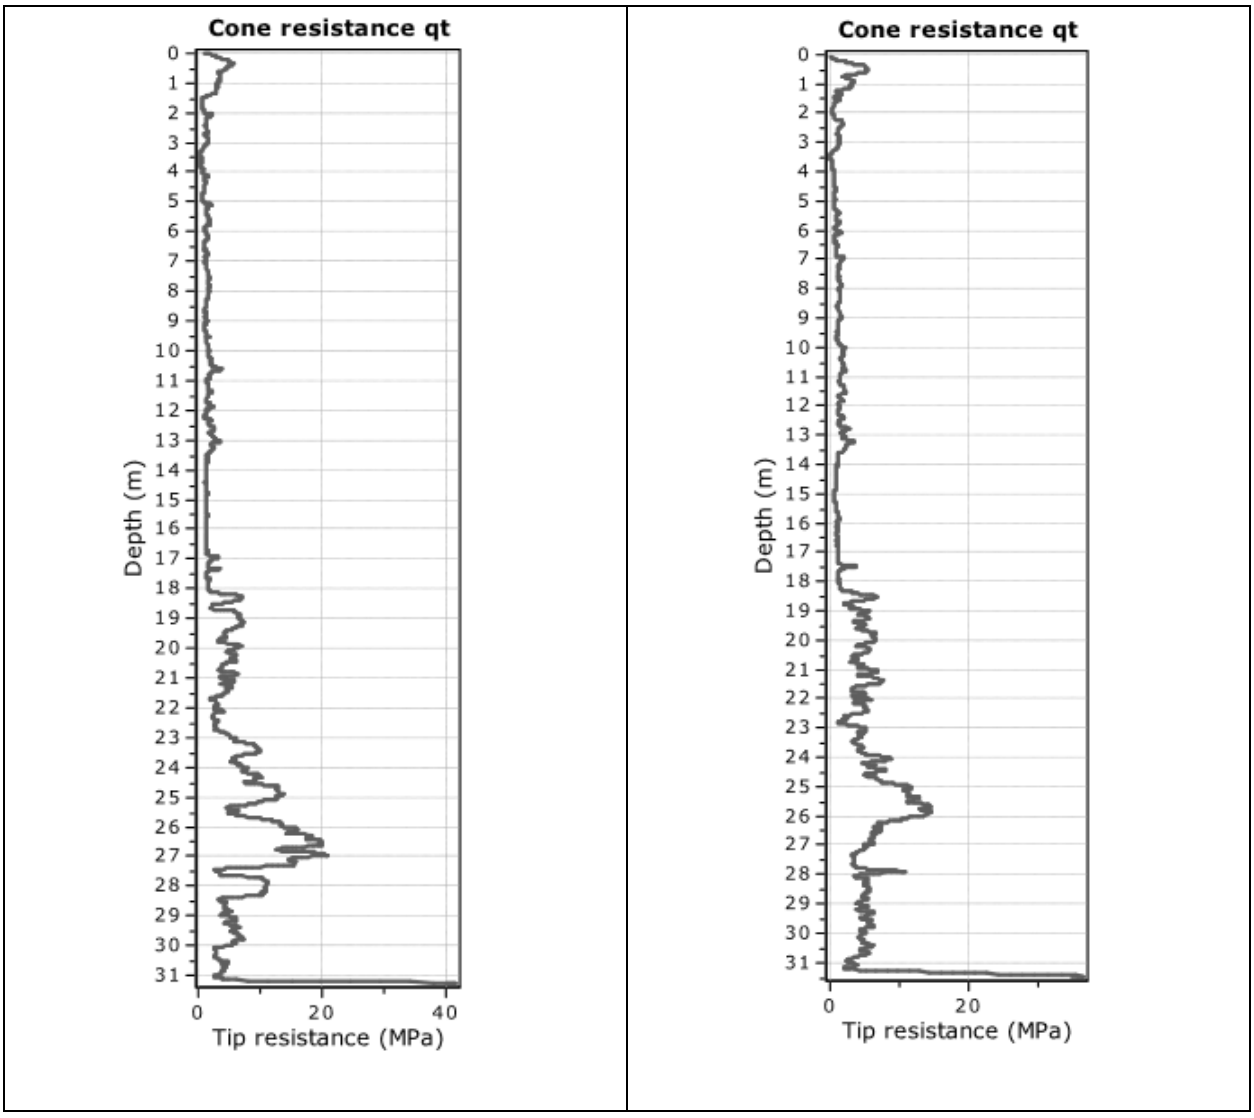

Figure 4: Comparison of tip resistance during Standard CPT (left) and Sonic CPT (right) – location 1

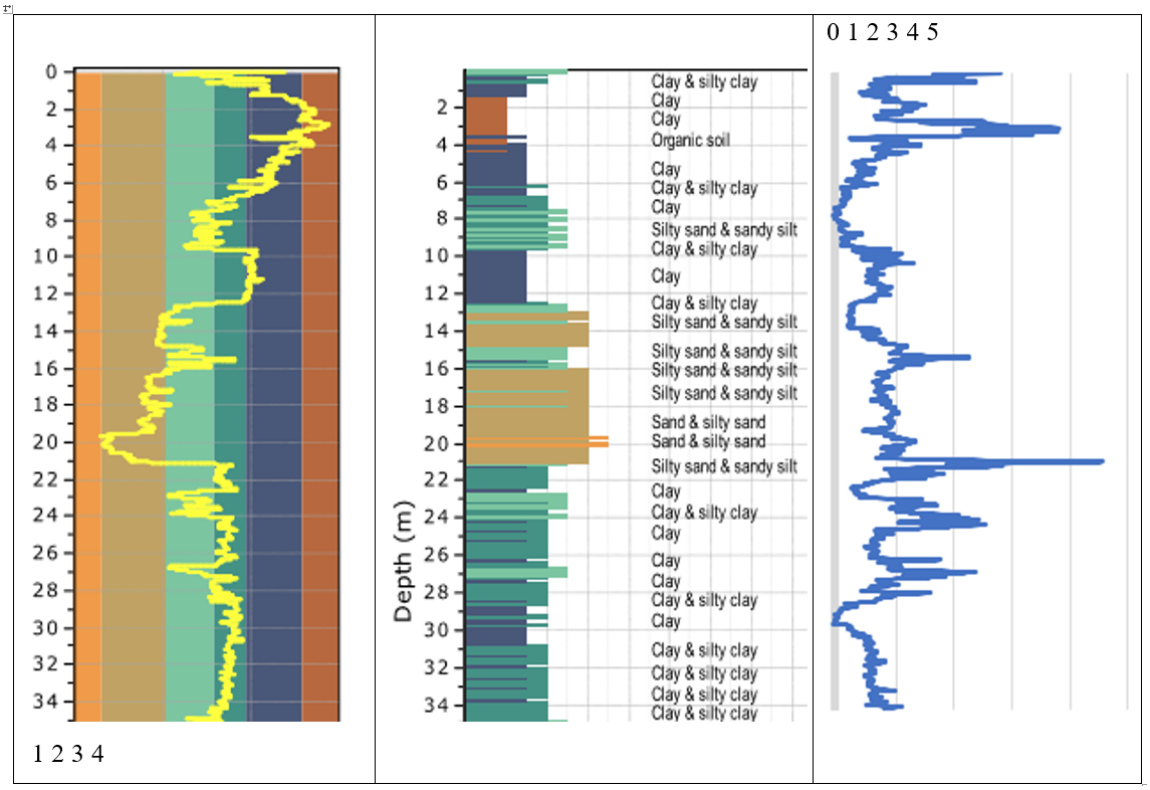
The third application is for producing pile driving simulations for vibratory hammer piling. Standard CPT data has long provided excellent input for impact hammer pile driving simulations, but is less suitable

for piling using a vibratory hammer. With Sonic CPT we can approach or even match the frequency of a vibratory hammer to test the influence of the vibrations on the soil.

For this project, Standard CPT and Sonic CPT were applied side-by-side. Sonic CPT was performed at approximately 100 Hz to assess the impact on the tip resistance. However, as shown in Figure 4, the reduction in the tip resistance was minimal, simply because the soil was largely cohesive. Only in the granular soil layers at depths exceeding 25 m were the tip resistances as expected (especially noticeable at a depth of 26 m), with the maximum value dropping from 21.08 MPa to 14.74 MPa. Unfortunately, it was deemed impossible to penetrate through the stiff sand layer at a depth of 31 m, as at that depth the difference in tip resistance would have been more distinct.



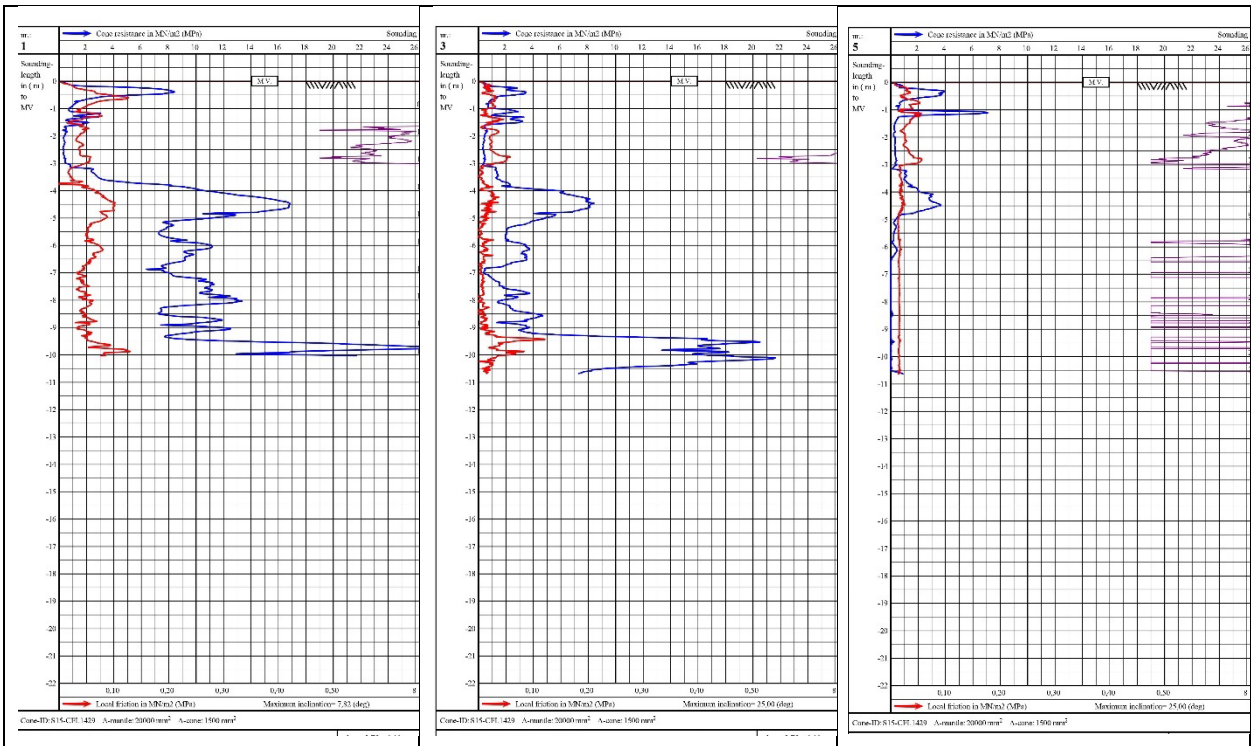


Figure 5: Tip resistance ratio Sonic CPT vs. Standard CPT, location 2, with the soil behavior type index derived from the CPT data on the left

Sonic CPT was also performed at location 2, albeit only to a depth of approximately 35 m. Figure 5 shows the tip resistance ratio between the Sonic CPT and the Standard CPT, with the soil behavior type shown on the left side of the figure. While in most cases the ratio is less than 1, there are many instances where the ratio is (much) higher than 1. At present there is no explanation for these high values, especially since there seems to be no consistency. In Figure 5 the soil behavior type index is shown as well. Initially (to a depth of approximately 16 m) there seems to be some correlation between the tip resistance ratio and the index value, but at greater depths this correlation is completely missing. Obviously more research needs

to be done to allow for a better interpretation of the Sonic CPT data. This is further complicated by the fact that the execution of Sonic CPT introduces a new variable: the frequency of the applied vibration.

Previous testing performed by Royal Eijkelkamp shows that the frequency used has a large impact on the resultant data. As shown in Figure 6, vibrating the cone at 100 Hz greatly reduces the resultant tip resistance (shown in blue), meaning the cone can penetrate harder layers more easily, but the profile does not reflect the profile of the Standard CPT. However, when the frequency is reduced to 50 Hz the shape of the profile resembles the profile of the Standard CPT and is therefore more instructive of the soil conditions. This means that if the objective is simply to make the cone go through stiffer layers (in line with the first two objectives mentioned above) the use of a higher frequency makes perfect sense. If on the other hand the objective is to derive soil parameters from the acquired data, performing Sonic CPT at a lower frequency is essential.

Standard CPT	Sonic CPT – 50 Hz	Sonic CPT – 100 Hz

Figure 6: Comparison of Standard CPT and Sonic CPT (50 Hz and 100 Hz)

Conclusion

As demonstrated during the TRIM4 project, the geotechnical soil investigation techniques described in this paper all belong in the tool box of engineers involved in characterizing mining landscapes. Soil sampling using a sonic drill rig allows for sampling in a wide range of materials, including those found in a mining

landscape, with a very high recovery percentage. The Monitoring While Drilling technique is well established to enhance the drilling efficiency and the drill rig maintenance, but more work is required to use the obtained results for subsurface characterization. The correlations generated during the TRIM4 project provide solid guidance, but before it becomes a routine operation, similar to soil behavior characterization based on the CPT data, more data is required. Finally Sonic Cone Penetration Testing is a well-established technique to minimize refusal, but once again more research is required to correlate the data obtained during Sonic CPT with the soil(behavior) type when it is performed on a stand-alone basis.

Utilization of Novel Electrokinetic Geosynthetics for Stabilization of Ultra-fine Tailings

Nilan Jayasiri, The University of Western Australia, Australia
Andy Fourie, The University of Western Australia, Australia
Cristina Vulpe, The University of Western Australia, Australia

Abstract

Dewatering by means of electroosmosis involves placing a series of electrodes into the ground and applying a potential difference between the electrodes to induce water molecules to move towards the negative electrode from the positive electrode. Despite well documented applications of this technique for improving fine and ultra-fine sediments, the mining industry has yet to embrace this technology at field scale. One of the main impediments is the rapid electrode corrosion of conventional metal electrodes. Severe corrosion of electrodes can hinder the efficiency of this technique over time, which leads to increased energy consumption. The advancement of electrically conductive geosynthetics, also known as electrokinetic geosynthetics (EKGs), presents a significant opportunity to improve the industrial uptake of this technique by replacing conventional metallic electrodes, owing to EKGs vastly superior anti-corrosive properties. The current study investigated the performance of novel EKG electrodes in dewatering ultra-fine tailings using a laboratory-scale experimental approach. The dewatering efficiencies using EKG electrodes were compared with that of conventional metal electrodes (mild steel) by assessing the volume of water expelled, strength gain, end-of-test water content, and energy consumption. The results showed that for dewatering fine, slurried tailings, the novel EKG electrodes proved to be just as effective as their traditional metal counterparts, and usually better, since corrosion effects did not hinder the electroosmosis process. Although the variation in water content between the tests conducted with the two types of electrodes under the same voltage gradients was marginal, the use of EKGs has led to a significant enhancement in undrained shear strength. This constitutes one of the main advantages of utilizing EKGs for treating ultra-fine tailings.

Introduction

Stabilizing slurried, ultra-fine tailings is one of the significant challenges faced by the owners and operators of tailings storage facilities, particularly when it comes to closure and rehabilitation. While there are several conventional practices in the industry to enhance consolidation, these techniques are sometimes only

moderately effective or impractical. Consolidation by means of electroosmosis offers a promising approach for treating slurried tailings. This technique involves placing a series of electrodes into the ground and applying an electrical potential difference between the electrodes to induce water molecules to move toward the negatively charged electrode from the vicinity of the positively charged electrode. When drainage is facilitated at the cathode, consolidation of material takes place in an amount equal to the quantity of water extracted.

One of the abiding factors that has impeded the widespread use of electroosmosis dewatering technique at the field scale is the severe corrosion of metal electrodes. Previous studies have demonstrated that metallic electrodes such as steel, copper, and aluminum are highly prone to corrosion, which negatively impacts efficiency and power consumption, which in turn impacts achieving the required degree of consolidation (Xue et al., 2015). Studies conducted with titanium and gold electrodes have shown little or no corrosion due to the corrosion-resistive properties, but the extremely high cost of these materials makes their usage in large-scale field applications not viable (Loch et al., 2010). In addition, non-metallic electrode types such as graphite have solved the corrosion issue to a considerable extent, although the disadvantages of these include: (1) lesser efficiency and (2) high brittleness (Malekzadeh et al., 2016).

The advancement of electrically conductive geosynthetics, also known as electrokinetic geosynthetics (EKGs), presents a significant opportunity to improve the industrial uptake of this technique by replacing conventional metallic electrodes, owing to EKGs' vastly superior anti-corrosive properties. The current study investigated the performance of novel EKG electrodes in dewatering ultra-fine tailings using a laboratory-scale experimental approach. The dewatering efficiencies using EKG electrodes were compared with those of conventional metal electrodes (mild steel) by assessing the volume of water expelled, strength gain, end-of-test water content, electrochemical changes and energy consumption.

Experimental methodology

Test materials

Commercially available kaolin clay was used to prepare the slurry specimens required for the testing. The basic physicochemical properties of kaolin are summarized in Table 1.

Table 1: Basic physicochemical properties of kaolin

Specific gravity	Liquid limit (%)	Plastic limit (%)	Clay content (%)	Silt content (%)	pH	Conductivity (mS/cm)

Experimental setup

The experiments were carried out using 20 L capacity (380 x 280 x 200 mm) tubs, as shown schematically

in Figure 1. The electrodes utilized in the experiments were composed of either mild steel or EKGs. Both types of electrodes had the same nominal dimensions of 180 × 83 × 3 mm, whereas the weights of mild steel and EKG electrodes were approximately 226 g and 46 g, respectively. While there are various types of EKGs, the specific EKG electrodes used in the study are identical in size to a conventional prefabricated vertical drain but manufactured from electrically conductive polymer. A perforated polyvinyl chloride (PVC) tube encased in nonwoven geotextile facilitated drainage through a small hole at the bottom of the PVC tube, and the drained water was subsequently collected into a measuring cylinder.

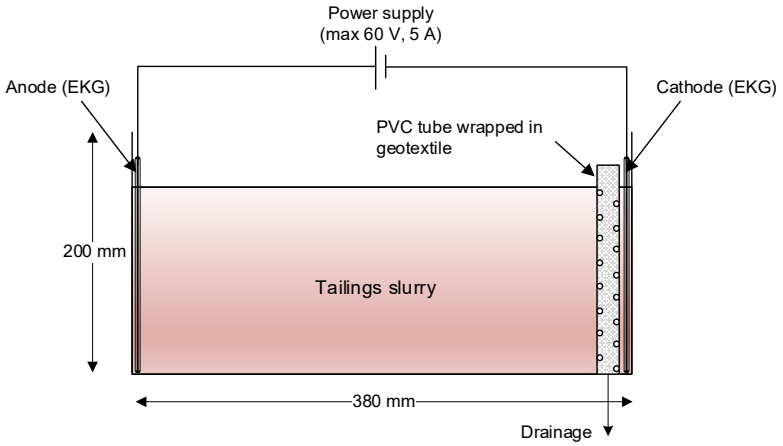

Figure 1: Schematic of the test setup

Test program

The kaolin slurry was prepared by mixing kaolin with deionized water to a water content of 150%. After 24 hours, the slurry was carefully poured into the tub to an initial height of approximately 160 mm. To prevent any moisture loss due to evaporation, the top surface of the tub was covered with clear plastic wrap. The volume of drained water and current were monitored at one-hour intervals, and the tests were terminated once the discharge rate fell below a threshold of 10 ml/hour. Once a test was completed, post-treatment moisture content and undrained shear strength were measured between the electrodes. Details of the test program are provided in Table 2.

Table 2: Details of the testing program

Test designation	Electrode material	Voltage gradient (V/m)	Voltage (V)
SE1	Mild steel	50	19
SE2	Mild steel	100	38
SE3	Mild steel	150	57
EK1	EKG	50	19
EK2	EKG	100	38
EK3	EKG	150	57

Results and discussion

Variation of drainage volume

The temporal variation of cumulative drainage volume for both types of electrode material is depicted in Figure 2a. As can be seen, the final cumulative discharges for tests conducted with EKGs under 150 and 100 V/m voltage gradients were 5.9% and 8.1% higher than those carried out with metal electrodes, respectively. In contrast, when the experiment was carried out at a relatively low voltage gradient (50 V/m), the test with the EKGs (EK1) resulted in an 11.5% lower discharge volume compared to the test with mild steel electrodes. Given that the electrode degradation rate is a function of the amount of electric charge according to Faraday's law, the reason for this behavior could be mainly attributed to the low corrosion rate occurring in the metal electrodes at lower voltage gradients. However, the corrosion effects may start to govern in metal electrodes even at low voltage gradients under field conditions since the dewatering usually extends for prolonged periods (Lockhart and Stickland, 1984).

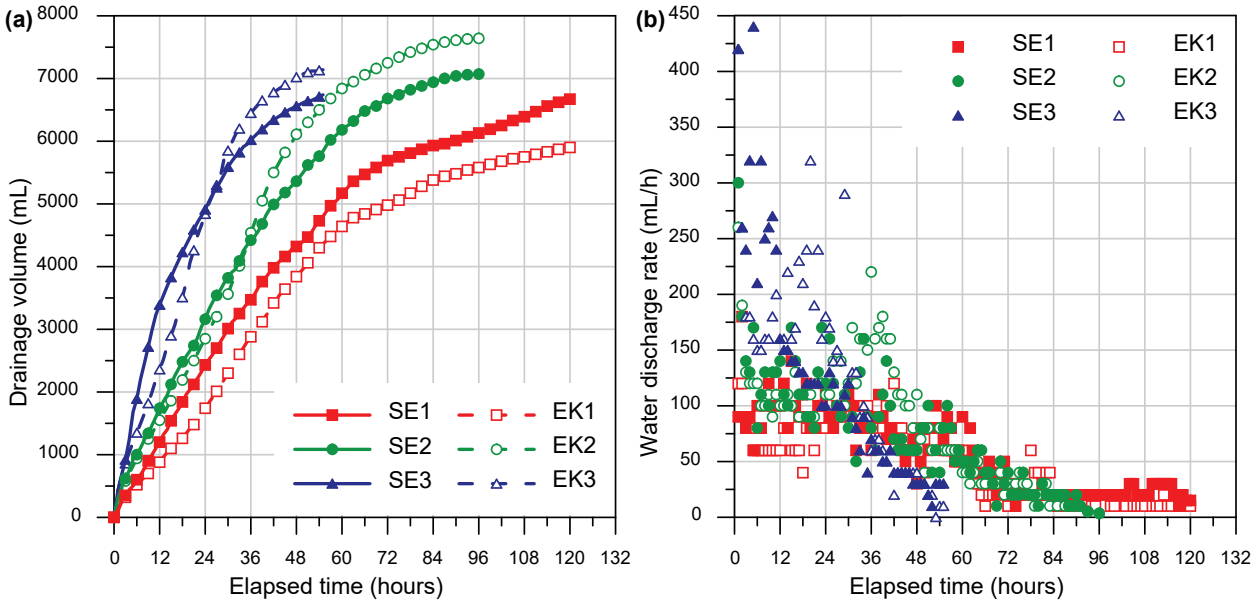

Figure 2: (a) Variation of drainage volume with time; (b) variation of drainage rate with time

It is apparent that the highest voltage gradient resulted in a lower discharge volume than that of the intermediate voltage gradient, regardless of the electrode type. This is predominantly due to the rapid desaturation of material in the vicinity of the anode, with other reasons being (1) loss of contact area between the electrode and soil, (2) electrochemical changes and (3) loss of applied voltage at the electrode interface.

According to Figure 2b, the water discharge rate was relatively constant for a longer time period in tests conducted with EKGs. Although the drainage rate was higher within the first few hours of the experiments with metal electrodes, a progressive declining rate over time can be seen since the early stages

of the tests, particularly for SE2 and SE3. This ever-declining rate is an indication of corrosion occurring at the metal electrodes, which is also reflected by the electric current drawn during the tests, depicted in Figure 3a.

Power consumption

Figure 3a shows that the amount of current drawn was relatively constant for a longer period in tests with EKG at higher voltage gradients, whereas the current tends to drop earlier for the experiments with metal electrodes. Particularly in the case of SE3, the amount of electric current drawn dramatically reduced within the first 12 hours after the commencement of the test, hindering the water discharge rate. This behavior is closely related to the corrosion effects and subsequent voltage loss at the electrode-material interface, which is discussed in the forthcoming sections. Another noteworthy observation pertaining to test EK2 is that after fluctuating around 0.08 A for more than 24 hours, there is a sudden increase in the current drawn, peaking at around 0.16 A. While the prime factor that triggered this spike is not clear, previous studies have shown that changes in ionic concentrations, formation of additional conductive pathways for ion movement within the treated material, and pore structure changes of the material could alter the amount of current drawn during electroosmosis treatment (Liu et al., 2024; Pandey et al., 2024).

The electric current was then used to determine power consumption during the electrically assisted dewatering, and to facilitate comparisons between the tests, the power consumption was interpreted in terms of kWh/dry tonnes of treated material:

$$P = \int_0^t VIdt/W_s$$

where, P is the power consumption, V is the average voltage, I is the average current, t is the treatment time and W_s is the dry weight of the material calculated from the initial solids content.

As depicted in Figure 3b, dewatering with EKG electrodes under 50, 100, and 150 V/m consumed approximately 7.6%, 31.6% and 18.9% more power, respectively, compared to mild steel electrodes under the same voltage gradients. This is mainly because the amount of current drawn during the dewatering process is generally high (resulting from lesser corrosion effects) when EKGs are utilized. Although the power consumption is only marginally higher at the lowest voltage gradient (50 V/m), a noticeable increase in the power consumption can be seen at higher voltage gradients (100 and 150 V/m). However, this can be justified by the higher volume of water extracted using EKGs under 100 and 150 V/m voltage gradients. The currently available power consumption evaluation methods do not account for the degree of treatment achieved. This highlights the necessity for a better measure of power consumption, i.e., an approach that includes changes in material characteristics.

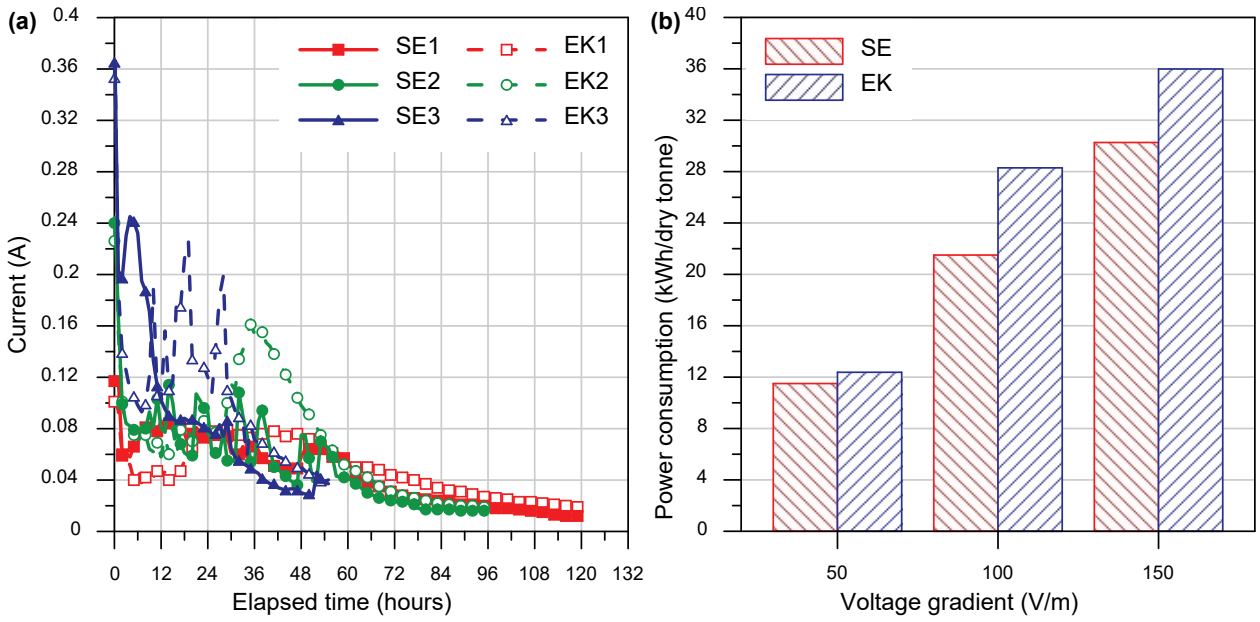

Figure 3: (a) Variation of current drawn with time; (b) power consumption in terms of kWh/dry tonnes of treated material

Electrochemical and corrosion effects

As dewatering progressed using the metal electrodes, the color of the surficial material adjacent to the anode was changed from its initial white to a yellow-brown color. Further investigation at the completion of the tests revealed that similar discoloration was present throughout the material stratum, irrespective of the applied voltage. This is a consequence of anode corrosion and subsequent accumulation of degraded substances in kaolin adjacent to the anode. Application of DC current between the electrodes not only induces the electroosmosis process, but also causes electrochemical reactions to occur adjacent to the electrodes (Mitchell and Soga, 2005). Oxidation will take place at the anode, generating oxygen gas and creating an acid front (due to the reduction in pH) in the vicinity of the anode. If the anode material is reactive (e.g., metal such as mild steel), it could oxidize and release ions into the adjacent soil matrix, causing anode corrosion, as observed in Figure 4a. Similarly, hydrolysis will occur at the cathode, generating hydrogen gas and creating a basic front (due to the increase in pH) in the vicinity of the cathode.

At the end of each test, the weight of the electrodes was recorded to determine the degree of electrode degradation based on the loss of weight during the electroosmosis dewatering. The degrees of anode degradation for the tests with steel electrodes under 50, 100, and 150 V/m voltage gradients were 3.27%, 2.91%, and 2.64%, respectively, whereas for the tests with EKGs, the anode degradation under the same voltage gradients were 0.51%, 0.13%, and 0%, respectively. It is clear that steel anodes undergo corrosion and subsequent degradation due to electrochemical reactions, whereas the EKG-type anodes demonstrated better corrosion resistance. Although the EKG electrodes exhibited minimal signs of corrosion in terms of

the degree of degradation, upon close examination of the electrodes at the conclusion of the tests, some had formed bubbles (smaller than 1 mm in size) on the surfaces of the EKG. Unlike steel electrodes, where corrosion only occurred in areas where the electrode was in contact with the material, the bubbling effect in EKGs was observed beyond those areas, for instance, the section above the material surface horizon. Hence, it is unclear whether the "bubbling" effect is solely due to electrochemical reactions or rather a ramification of applying DC current. Although the polymers do not technically "corrode" as a metallic material (Schweitzer, 2009), it is nevertheless important to further investigate the root cause for this effect as it could compromise the durability of EKGs in long-term field applications.

Regardless of the electrode material, the degree of cathode degradation under all voltage gradients was less than 0.1%, indicating no signs of corrosion as explained by electrochemical theories (Micic et al., 2001). Another noteworthy observation regarding the steel electrodes is the formation of a thin, dark layer in the sections where the electrode is in contact with the material. This is believed to be oxide precipitates resulting from electrochemical reactions. According to Xue et al. (2015), X-ray diffraction tests have revealed that these types of substances present extremely low conductive characteristics. The formation of precipitate films adjacent to electrodes could result in significant potential loss at the soil-electrode interfaces and subsequently lead to a sharp increase in resistivity. No such behavior was observed in EKG electrodes, which may be the reason for the relatively steady water extraction rate during the dewatering process (Figure 2b).

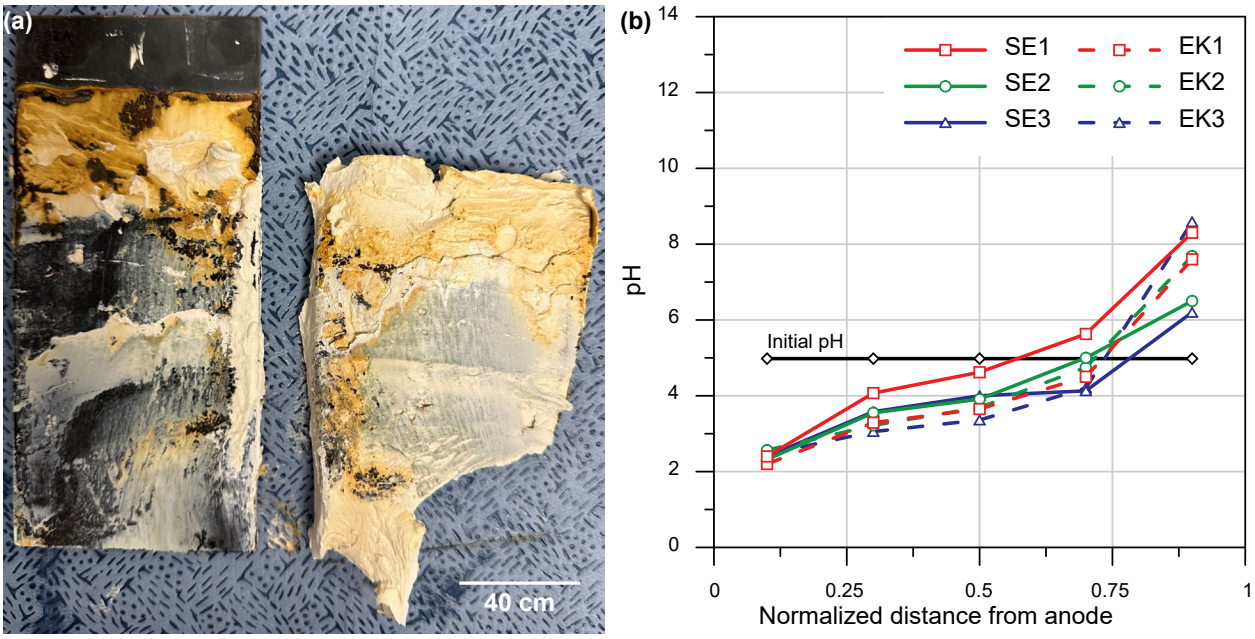

Figure 4: (a) Corrosion observed in anode and adjacent soil at test SE2; (b) variation of pH between the electrodes

Figure 4b shows the pH variation between the electrodes with respect to the normalized distance from the anode (distance to the sampling point from the anode normalized by the distance between electrodes). As expected, the material near the anode exhibited acidic conditions due to hydrogen ion (H^+) release. The pH value of the anodic zone was generally about 2.4, irrespective of the electrode type and the voltage gradient, indicating a twofold decrease from the initial state. In contrast, the pH in the vicinity of the cathode increased due to the release of hydroxide ions (OH^-); nonetheless, the pH values demonstrated considerable variability. The post-treatment pH value of the material near the cathode ranged from 6.2 to 8.6, which is approximately a 50% average increase from the pre-treatment pH. As depicted in Figure 4b, the material away from the electrodes (0.3 – 0.5 normalized distance from the anode) experienced a lesser change in pH. Interestingly, the posttreatment pH of the tailings treated with EKGs was comparable to that of metal electrodes, despite the EKGs being manufactured from non-metallic polymer material.

Variation of water content

The distribution of water content between the anode and cathode is presented in Figure 5. On average, the water content of the slurry reduced approximately 70% from the initial value of 150% due to the electroosmosis treatment. As expected, EK1 has the lowest average reduction in water content (88%) and is 7% higher than the water content obtained from the test with metal electrodes under the same voltage gradient. In contrast, the post-treatment average water contents for tests conducted with EKGs under 150 and 100 V/m voltage gradients are 4.2% and 8.8% lower than those carried out with metal electrodes, respectively. The obtained water content values are generally in line with the extracted water volumes presented in Figure 2. Overall, the results of water content measurements further showed that the EKGs performed slightly better in dewatering compared to metal electrodes at high voltage gradients.

The electroosmosis process causes the water molecules to move toward the cathode from the vicinity of the anode and as a result, the water content at the anode is generally lower than that at the cathode. However, no such variation was found in the present study. According to Figure 5, the water content is generally low at the closest sampling point to the anode, but as the sampling location moves towards the cathode, it starts to increase before starting to decrease again, indicating the highest water content at the section before the halfway point between the electrodes (0.3 – 0.5 normalized distance from the anode). The reason for this behavior could be mainly attributed to the formation of shrinkage cracks perpendicular to the flow path (Figure 6), which subsequently resulted in disrupting the conductivity and electroosmotic flow (Jayasiri et al., 2024). It appears that the shrinkage cracks may have acted as a barrier up to a certain degree, preventing water molecules from passing from the anode section to the cathode. Besides the above, loss of contact area between the electrode and soil cluster due to electrode detachment could also contribute to this peculiar behavior.

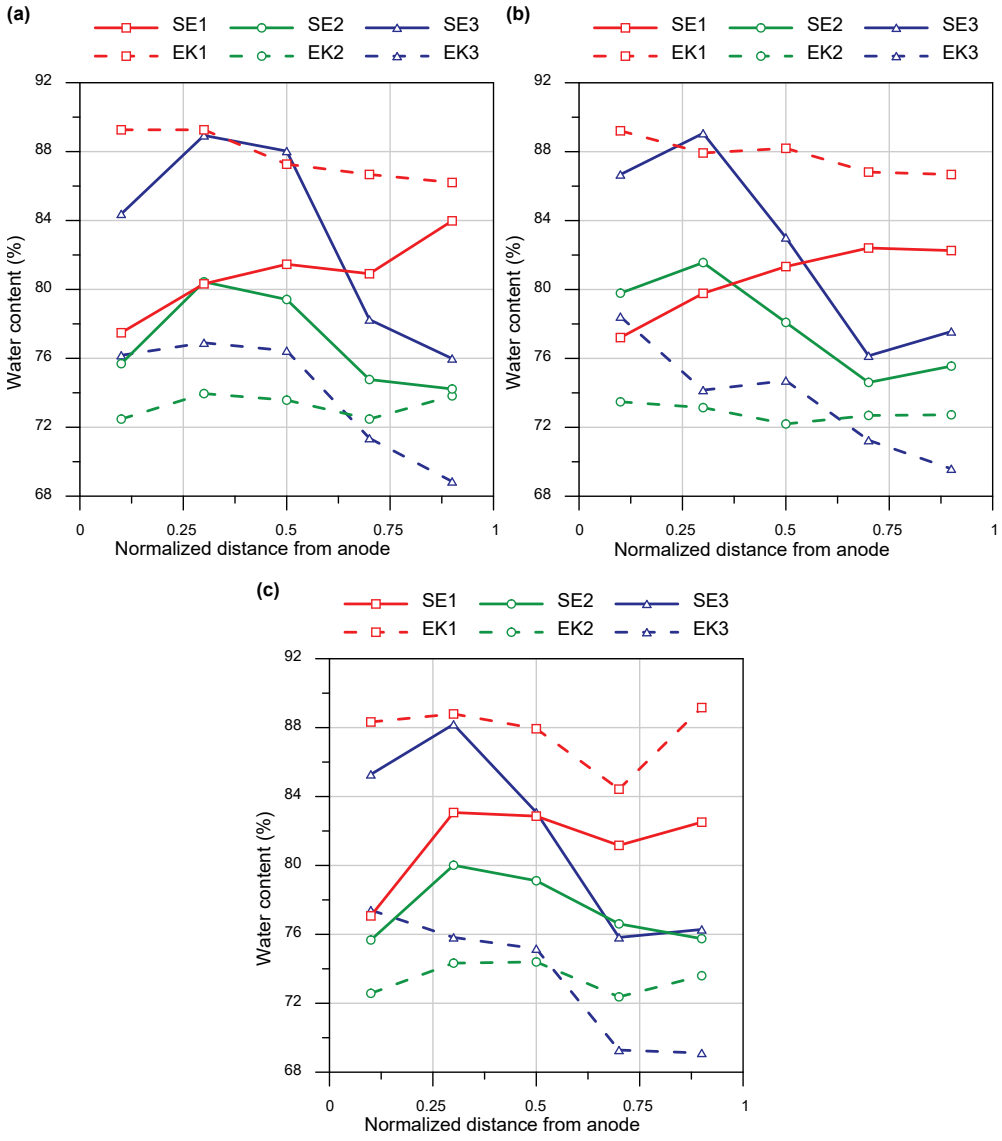

Figure 5: Variation of water content in (a) top layer; (b) mid-depth layer; (c) bottom layer

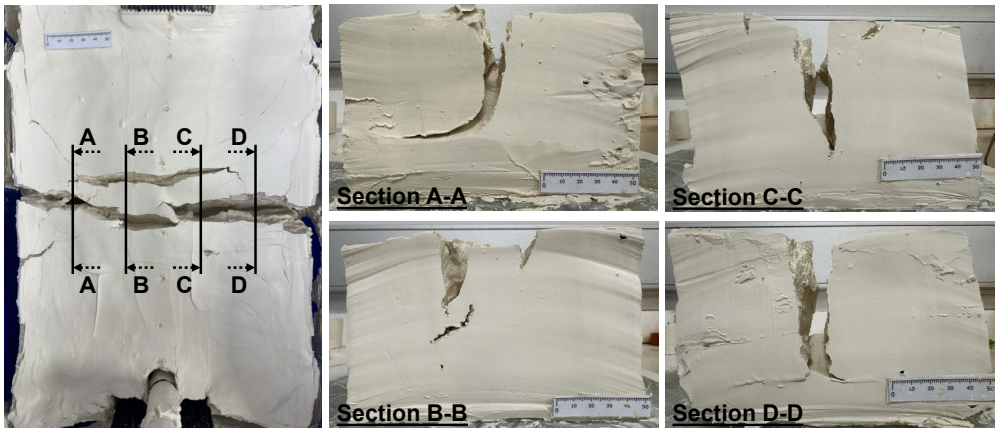

Figure 6: Cross-sections showing the formation of shrinkage cracks in test EK2

Variation of undrained shear strength

Figure 7 depicts the distribution of approximate undrained shear strength between the electrodes. The measured undrained shear strength variation generally agrees with the observed water content trend presented in Figure 5. On average, the electroosmosis treatment enhanced the undrained shear strength of the material by 24 times compared to the pretreatment shear strength of 0.3 kPa. Under the low voltage gradient (50 V/m), the test conducted with mild steel electrodes indicated a marginal 16.3% increase in shear strength compared with the test conducted with EKG.

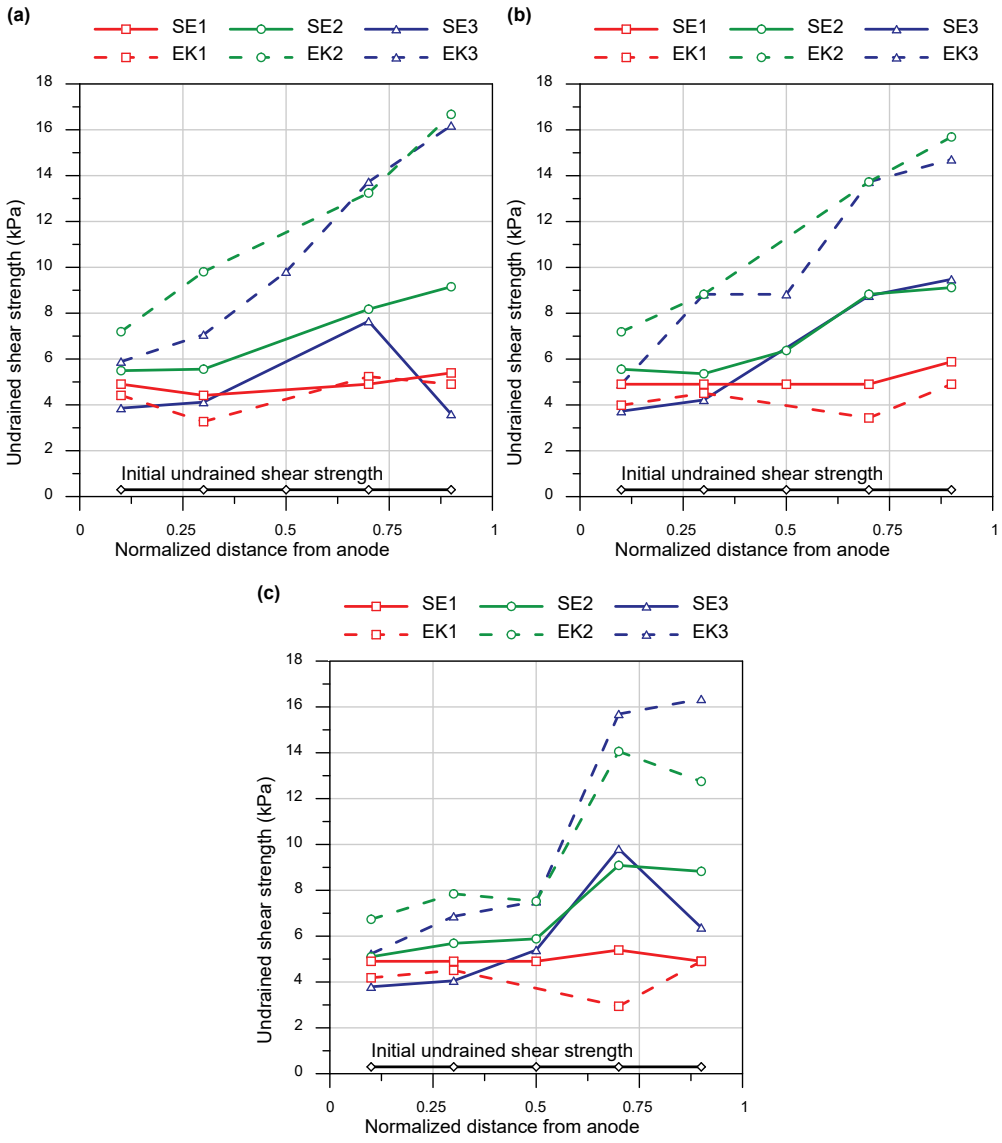

Figure 7: Variation of undrained shear strength in (a) top layer; (b) mid-depth layer; (c) bottom layer

At 150 and 100 V/m voltage gradients, the average post-treatment strengths of the tests that utilized EKGs were 79.3% and 55% higher than those conducted with mild steel electrodes, respectively. In

contrast, the post-treatment average water contents for tests performed with EKGs under the same voltage gradients were only 4.2% and 8.8% lower than those carried out with metal electrodes. Although the change in water content between the tests conducted with the two types of electrodes is marginal, the use of EKGs has led to a significant enhancement in undrained shear strength. This constitutes one of the main advantages of utilizing EKGs for treating ultra-fine tailings. However, further research is required to investigate the factors contributing to this effect and to quantify the enhancement not reflected by the change in water content.

Conclusion

Severe corrosion of metal electrodes is one of the major barriers that impede the widespread use of the electroosmotic dewatering technique in stabilizing ultra-fine tailings. The current study investigated the performance of novel electrokinetic geosynthetic (EKG) electrodes, which are manufactured from electrically conductive polymer in dewatering ultra-fine tailings, compared to conventional metallic electrodes. Based on the outcomes of this study, the following key conclusions can be drawn:

- EKGs performed well at higher voltage gradients (150 and 100 V/m) compared to conventional metal electrodes, whereas under a lower voltage gradient (50 V/m) metal electrodes resulted in a relatively better discharge volume.
- The better performance at lower gradient and the poor performance under higher voltage gradients could be mainly attributed to the lower corrosion rate in the metal electrodes at lower voltage gradients. However, the corrosion effects may start to govern in metal electrodes even at low voltage gradients under field conditions since the dewatering usually extends for prolonged periods.
- Dewatering with EKG electrodes under 100 and 150 V/m consumed approximately 31.6% and 18.9% more power, respectively, compared to mild steel electrodes under the same voltage gradients. This is mainly because the amount of current drawn during the dewatering process (resulting from lesser corrosion effects) is generally higher when EKGs are utilized.
- Dewatering with EKG electrodes under 100 and 150 V/m consumed approximately 31.6% and 18.9% more power, respectively, compared to mild steel electrodes under the same voltage gradients. This is mainly because the amount of current drawn during the dewatering process (resulting from lesser corrosion effects) is generally higher when EKGs are utilized.
- Post-treatment water content and undrained shear strength assessments showed that although the change in water content between the tests conducted with the two types of electrodes under the same voltage gradients is marginal, the use of EKGs has led to a significant enhancement in undrained shear strength. This constitutes one of the main advantages of utilizing EKGs for treating ultra-fine tailings.

In summary, the results showed that for dewatering fine, slurried tailings, the novel EKG electrodes proved to be just as effective as their traditional metal counterparts, and usually better, as corrosion effects did not hinder the electroosmosis process. While the present work only focused on the corrosion issue of conventional metal electrodes and investigating the viability of replacing them with EKGs at laboratory scale, other aspects such as long-term performance under field conditions, scale effects, capital and operational costs and logistics, etc., should be broadly investigated to promote the application of electroosmosis dewatering technique in large scale field applications.

Enhanced Conceptualization of Reactive Filtered Tailings Oxidation Using a Reactive Transport Model

Mike O'Kane, Okane Consultants, Canada

Abstract

An increasing concern within the mining industry is the need for balance between geotechnical and geochemical stability for long-term tailings storage. Often, filtered tailings (otherwise known as dry stack tailings) can enhance geotechnical stability, reducing risk associated with tailings dam failures. Typically, in the conceptualization of sulfidic (reactive) filtered tailings, there is an increased risk of metal leaching and acid rock drainage (ML/ARD) because the material is unsaturated, allowing for additional sulfide mineral oxidation. This conceptualization can lead to inherent conservatism in long-term predictions in seepage water quality where numerical models assume the entire tailings profile becomes oxic. Here, we explore incorporating a "reasonable expectation" conceptual model for tailings oxidation that includes mechanistic processes (e.g., including diffusion limitations and oxygen consumption by sulfide oxidation), which can be used to run sensitivity analyses and enhance understanding of site-specific ML/ARD risk for reactive filtered tailings storage facilities (TSFs). To support this conceptual model, reactive transport models of Potentially Acid Generating (PAG) sulfidic tailings were simulated to demonstrate mechanistic processes controlling oxygen ingress and pyrite weathering over time under different climate, TSF design, and pyrite reactivity rate scenarios. Under more reactive pyrite conditions (i.e., pyrite with faster rate kinetics), oxygen ingress may be limited to the top several meters over the first few decades, similar to conventionally deposited tailings simulations. While filtered tailings have the potential to generate greater quantities of metal loads long-term, model results show poor quality seepage produced may take many more decades, or over a century, to be observed in basal seepage. This demonstrates the importance of managing surface runoff during operations through closure in both filtered and conventional TSFs and highlights opportunities to design cover systems that manage runoff, and decrease infiltration and/or oxygen ingress, to meet regional closure objectives.

Introduction

Production of tailings is projected to rise in the coming decades to satisfy increasing societal demands for metals, as well as declining ore grades (Mudd, 2010; Northey et al., 2014). In light of recent global tailings dam failures, mining companies are investigating alternative tailings storage facility (TSF) designs from conventional tailings (where tailings are typically piped as a slurry to a storage facility at a relatively low solids content and retained behind containment dams). One such alternative is the use of filtered tailings, which involves dewatering tailings prior to mechanical deposition by truck or conveyor (MEND, 2017). Typical conceptualization of sulfidic (reactive) filtered tailings assumes an increased risk of metal leaching and acid rock drainage (ML/ARD) because the material is unsaturated, allowing for greater sulfide oxidation due to oxygen availability. The conceptualization of additional oxygen availability may lead to long-term predictions in seepage water quality where numerical models assume the entire tailings profile becomes oxic to maintain conservatism. This study proposes a "reasonable expectation" conceptual model for tailings oxidation, investigating the depth of oxygen ingress over time as a function of pyrite reactivity and water content. To evaluate this conceptual model, a series of reactive transport models are presented to compare release of ML/ARD products under a range of conventional and reactive filtered tailings scenarios, including variations in climate and material reactivity. Simulated water quality and oxygen concentrations are presented as a function of depth and time. Although conceptual in nature, model simulations highlight the mechanistic processes applicable to various TSFs under different site-specific conditions and are used to demonstrate the diffusion-limited depth of oxygen ingress and timing of release of ML/ARD constituents.

Conceptual model

Oxygen ingress into finer-textured materials such as tailings is dominated by diffusion across exposed surfaces (Aubertin et al., 2000). Diffusive flux can be described by Fick's first law:

$$F = -D_e \frac{\partial C}{\partial z}$$

where F is the gas flux (mol m^{-2} s^{-1}), D_e is the effective diffusion coefficient (m s^{-2}), C is gas concentration (mol m^{-3}) and z is depth (m). D_e is a function of porosity, saturation, and the free phase diffusion coefficient; lower porosity and higher water saturation corresponds to lower D_e for the gas phase (Millington, 1959).

Oxygen ingress can therefore be limited to shallower depths within a tailings profile if there is a higher degree of water saturation, or through a low porosity cover system that limits oxygen ingress at the surface (INAP, 2017; Bussière and Guittonny, 2021; Barritt et al., 2022; Barber et al., 2015). Increased saturation

or decreased porosity acts to limit sulfide mineral oxidation by oxygen, as shown in the example of pyrite oxidation by oxygen:

$$FeS_2 + \frac{7}{2}O_2 + H_2O \rightarrow Fe^{2+} + 2SO_4^{2-} + 2H^+$$

When oxygen is available in the pore spaces, depending on sulfide mineral reactivity, shallower sulfide mineral oxidation may rapidly consume oxygen entering the tailings through diffusion, limiting availability of oxygen to react with sulfide grains at depth. Conceptually, this process is self-limiting, as diffusion rates decrease with increasing depth of the oxidation front (i.e., the concentration gradient decreases), which travels slowly downwards as sulfide minerals are consumed near the surface (Figure 1) (Mayer et al., 2015; Zhang et al., 2023). Adversely impacted tailings porewater is first focused above the oxidation front, where the acidity generated is a function of exposure time, tailings reactivity, water content, and surface area.

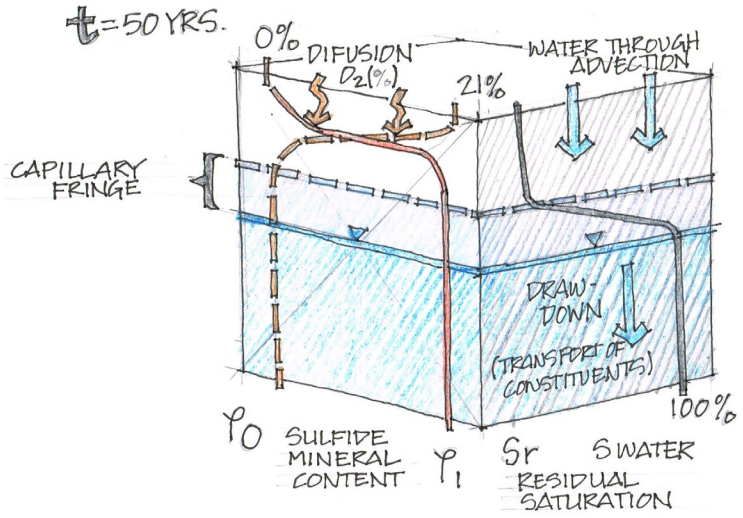

Figure 1: Sulfide mineral oxidation limited by oxygen diffusion in a tailings column, where oxidation products are transported downwards by water through advection

As filtered tailings are put in place in a drier state than conventional tailings, a "wetting up" process occurs prior to seepage emanating from the base of the landform. Over time, net infiltration across the tailings surface, or net percolation through the cover system, may result in a largely vertical porewater pressure response leading to basal seepage from the landform. Acidity generated from upper lift surface exposure during construction will then be transported downward through the landform, where the water quality of basal seepage is influenced by solids and porewater chemistry along the flow path. The time for this seepage to reach the landform's base will be a function of the flow path length (i.e., facility height) and porewater velocity. Drain-down/seepage from consolidation may also contribute to seepage rates, depending on site-specific conditions. It may take several decades for ML/ARD impacted porewater to

reach the landform's base; hence, in most cases, surface runoff is the primary pathway for manifestation of ML/ARD risk in filtered TSFs during operations and in post-closure. This timing aspect of the conceptual model highlights the importance of runoff management from TSFs to water stewardship at mine sites.

These processes of oxygen ingress, consumption, and transport of constituents from the surface downwards can be visualized through a conceptual model, as shown in Figure 1. Though these mechanisms control generation and release of metals in sulfidic tailings in all TSFs, the site-specific controls influencing these mechanisms are unique to an individual mine site. Specifically, the water saturation, water table, and capillary fringe height, as well as oxygen diffusion rates into the tailings, are controlled by the water balance and geochemistry of the material, which are dictated by regional considerations (i.e., climate, hydrogeology, deposit type, and mineralogy) and TSF design.

Methodology

To evaluate the conceptual model described above, a series of one-dimensional (1D) reactive transport models in MIN3P (Mayer et al., 2002) were used to simulate pyrite oxidation through a 20 m thick TSF block model (20 m × 1 m × 1 m). Physical material properties were assumed to remain consistent in all scenarios (Table 2), assuming steady state flow for simplification. Influences of climate, TSF design, and sulfide kinetic variability (Table 2) were simulated to enhance conceptual understanding of mechanistic processes controlling the release of metals from TSFs under different scenarios, described below. For each tailings storage design, two climate scenarios and two pyrite reactivity scenarios were modeled, resulting in 12 simulations in the sensitivity analysis.

Table 1: Physical parameters defining the tailings materials in the sensitivity analysis

Parameter	Value
Free phase diffusion coefficient in water (D_a) [$m^2\ s^{-1}$]	$2.4x10^{-9}$
Free phase diffusion coefficient in soil gas (D_g) [$m^2\ s^{-1}$]	$2.1x10^{-5}$
Porosity [$cm^3\ cm^{-3}$]	0.35
Hydraulic conductivity [$m\ s^{-1}$]	$1x10^{-6}$
Residual saturation [-]	0.05
van Genuchten - α [m−1]	3.5
van Genuchten - n [-]	3.2

Table 2: Parameters tested in 1D TSF models

Parameter	Variable tested		
Tailings storage design	Uncovered filtered (h = 0 m)	Uncovered conventional (h = 18 m)	Covered tailings (h = 19.5 m)
Net surface infiltration	Temperate (T) (250 mm year^{-1})	Drier (D) (70 mm year^{-1})	
Sulfidic tailings	Faster pyrite (k_{eff} = 1x10^{-9} mol L^{-1} bulk s^{-1})	Slower pyrite (k_{eff} = 1x10^{-10} mol L^{-1} bulk s^{-1})	

h is hydraulic head boundary or water table height and k_{eff} is the effective average rate constant for pyrite (mol L^{-1} bulk s^{-1}) (see Table 3)

Tailings storage design methods (specifically, conventional tailings versus filtered tailings) were captured as differences in water table height in the 1D models. A simulated water table 2 m below the surface was assumed for conventional tailings design and a basal head boundary of 0 m (simulating gravity drainage at the base) was assigned for the filtered tailings (Figure 2). These models represent uncovered TSFs. A third design was incorporated to simulate a covered TSF that simulates tailings below a hypothetical cover system that limits oxygen depth to the top 50 cm by assigning a water table boundary at 19.5 m. While simulated here by raising the water table height (such as a water cover in a conventional TSF), this covered TSF could also be considered to represent a low oxygen barrier cover (INAP, 2017; Bussière and Guittonny, 2021).

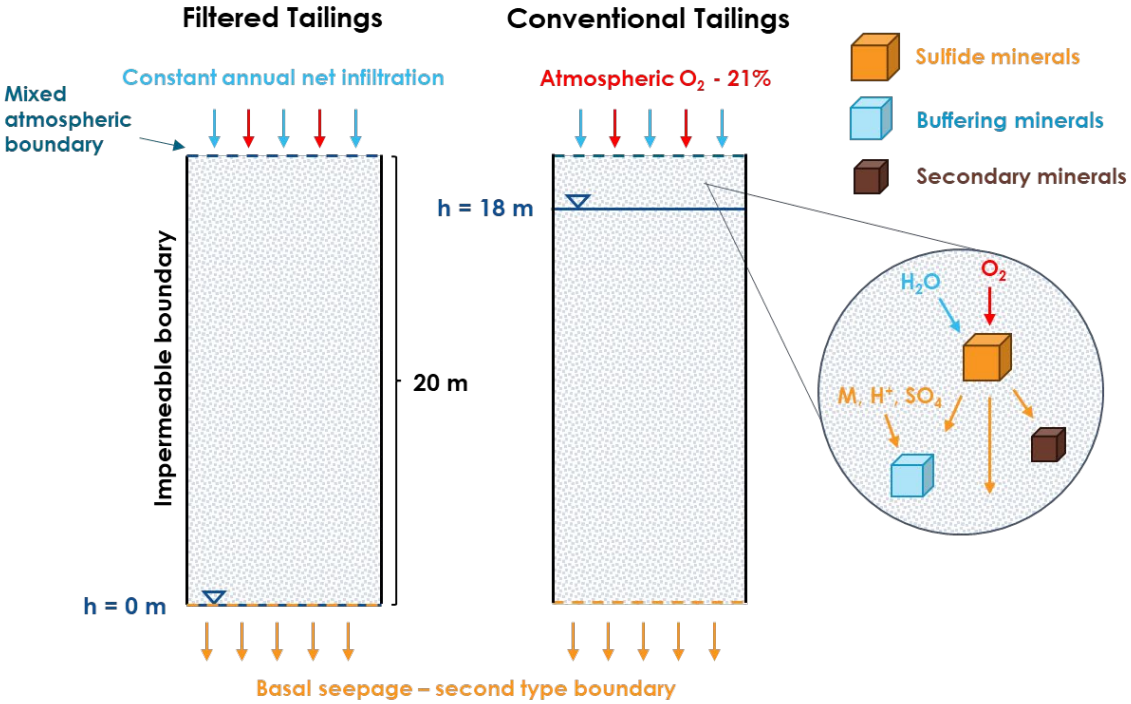

Figure 2: Conceptual model for the uncovered 1D reactive transport models

Differences between climate conditions were considered as changes in net surface infiltration, simulated as a constant infiltration rate applied on the surface of the 1D models under steady-state flow (Figure 2). Scenarios considered include a temperate climate with a net surface infiltration of 250 mm year^{-1} and a drier climate with 70 mm year^{-1} net infiltration.

Reactivity of sulfidic tailings was captured through differences in the assigned effective rate constant for pyrite. Primary minerals simulated include pyrite (7.0 wt. %), calcite (2.5 wt.%), and K-feldspar (5.4 wt. %), where pyrite oxidation is captured by the oxygen-pathway described by Williamson and Rimstidt (1994) and releases metals, SO_4^{2-}, and H^+ ions that are consumed by dissolution of calcite and silicate minerals (Figure 2; Table 3). Effective rate constants from other models were adjusted slightly to generate mineral dissolution rates within range, based on previous experience. The neutralization potential ratio (NPR) of the conceptual tailings material is 0.2, classifying the material as potentially acid-generating (PAG) (Price, 2009). While gypsum, ferrihydrite, gibbsite, and jarosite were not initially present, they were allowed to precipitate out as secondary minerals in the model. Gases were simulated at atmospheric conditions (an $O_{2(g)}$ concentration of 21 vol.% and $CO_{2(g)}$ concentration of 420 ppm), entering through the surface mixed boundary condition (and in the case of CO_2, released after carbonate dissolution).

Table 3: Minerals and reaction rates considered for the conceptual tailings models

Mineral	Reaction rate expression	logK$_i$	$k_i^{m,eff}$
Pyrite	$-\left(\frac{\varphi_i}{\varphi_i^0}\right)^{\frac{2}{3}} k_{i,1}^{m,eff} \frac{\{O_2\}^{0.5}}{\{H^+\}^{0.11}}\left[1-\frac{\{Fe^{2+}\}\{SO_4^{2-}\}^2\{H^+\}^2\{H_2O\}^{-1}\{O_2\}^{-3.5}}{K_i}\right]$	-215.3	Faster: 20 Slower: 2
Calcite	$-\left(\frac{\varphi_i}{\varphi_i^0}\right)^{\frac{2}{3}} k_i^{m,eff}(10^{-6.19}+\{H_2CO_3\}^{-3.30}+\{H^+\}^{-0.05})\left[1-\frac{\{Ca^{2+}\}\{CO_3\}^2}{K_i}\right]$	8.48	5x10^{-5}
K-Feldspar	$-\left(\frac{\varphi_i}{\varphi_i^0}\right)^{\frac{2}{3}} k_i^{m,eff}\{H^+\}^{0.5}\left[1-\frac{\{K^+\}\{Al^{3+}\}\{H_4SiO_4\}^3\{H^+\}^{-4}\{H_2O\}^{-4}}{K_i}\right]$	-10.06	5
Gypsum	$-k_i^{m,eff}[1-\frac{\{H^+\}^{-3}\{Fe^{3+}\}\{H_2O\}^3}{K_i}]$	4.58	1x10^{-7}
Ferrihydrite	$-k_i^{m,eff}[1-\frac{\{Ca^{2+}\}\{SO_4^{2-}\}\{H_2O\}^2}{K_i}]$	-4.89	1x10^{-7}
Gibbsite	$-k_i^{m,eff}[1-\frac{\{H^+\}^{-3}\{Al^{3+}\}\{H_2O\}^3}{K_i}]$	-8.11	6x10^{-12}
Jarosite	$-k_i^{m,eff}[1-\frac{\{H^+\}^{-5}\{Fe^{3+}\}^3\{SO_4^{2-}\}^2\{H_2O\}^7}{K_i}]$	5.39	8x10^{-11}

$k_i^{m,eff}$ is the effective average rate constant (mol L^{-1} bulk s^{-1}), φ_i is the initial volume fraction; K_i is the equilibrium constant at 25°C.

Results

In the higher net infiltration climate scenario, water saturation is 33% above the water table compared to 25% in the drier climate scenario modeled. Aligned with the conceptual model, oxygen ingress is controlled by both water saturation and kinetic pyrite oxidation rates, where higher water saturation as well as faster pyrite oxidation rates limit oxygen ingress. These processes are reflected in the simulated oxygen profiles with time (Figure 3). As expected, the water table height of 18 m in the conventional tailings models limits oxygen ingress below that depth. In the filtered tailings models, oxygen is limited to shallower depths in the 33% water saturation scenarios relative to 25% (Figure 3).

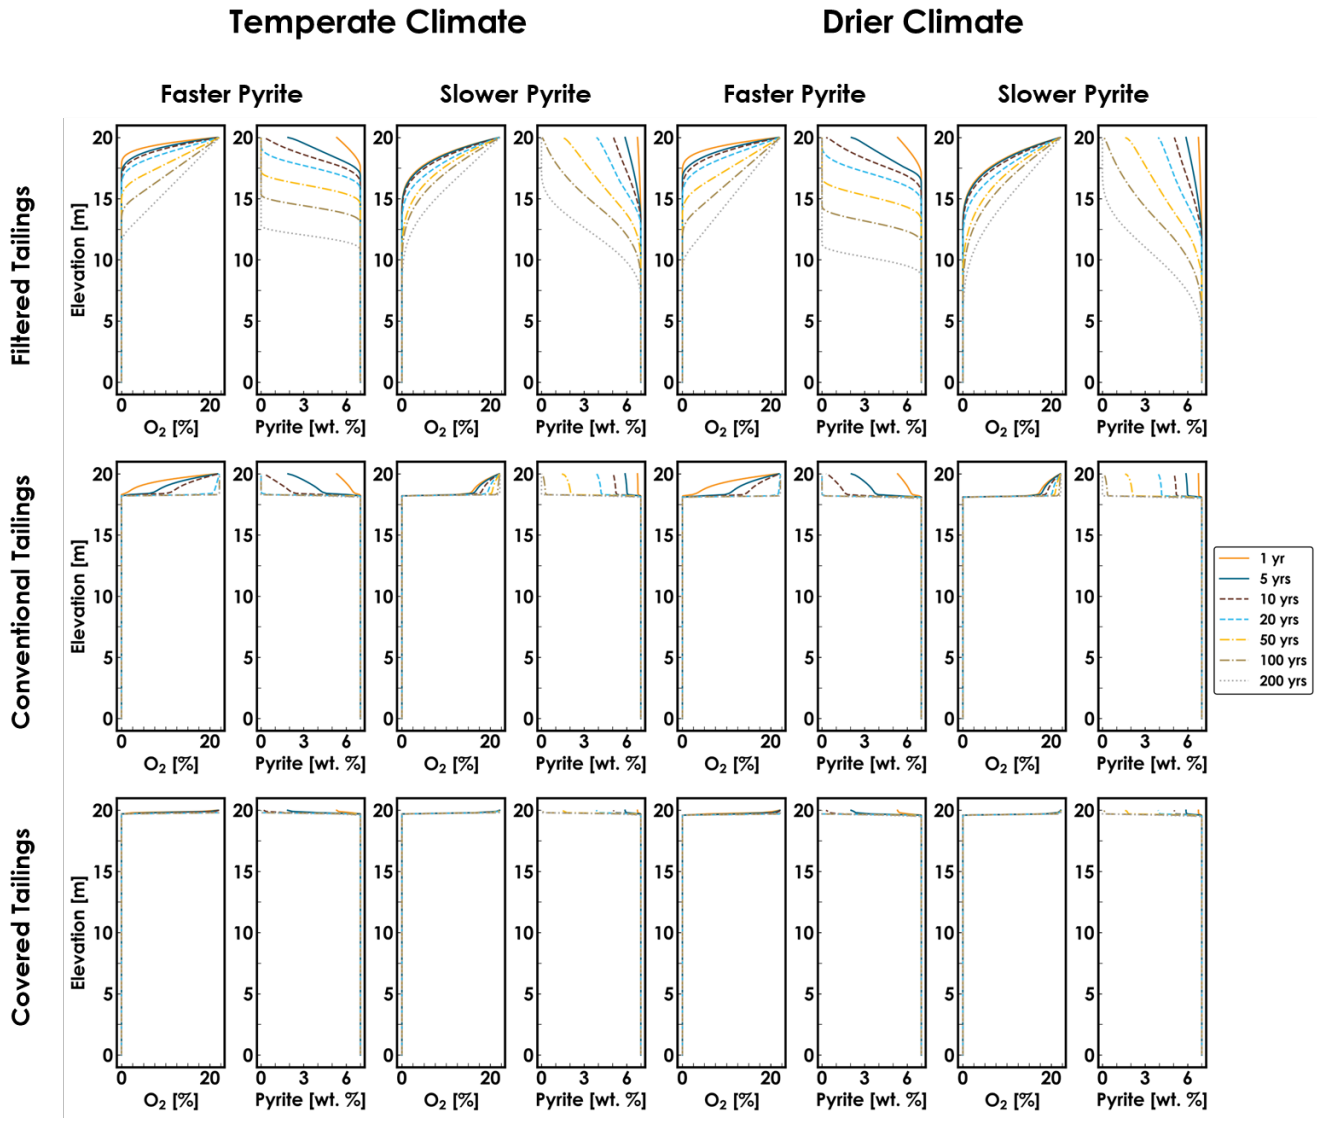

Figure 3: Depth profiles of oxygen ingress and pyrite consumption in TSF simulations from 1 to 200 years

Aligned with the conceptual model, oxygen ingress is influenced by pyrite oxidation kinetics. Models with faster pyrite oxidation limit oxygen ingress at depth more effectively than the slower pyrite oxidation models. In all filtered models, there is a gradual movement of oxygen to greater depths as pyrite is consumed (Figure 3). As a result, poor quality drainage is initially limited to the upper few meters (see Appendix) until transport processes (simulated here as downwards water flow) bring oxidation products towards the base. In all filtered tailings models, oxygen depth is eventually limited to a diffusion depth controlled by the simulated physical material properties and Fick's law.

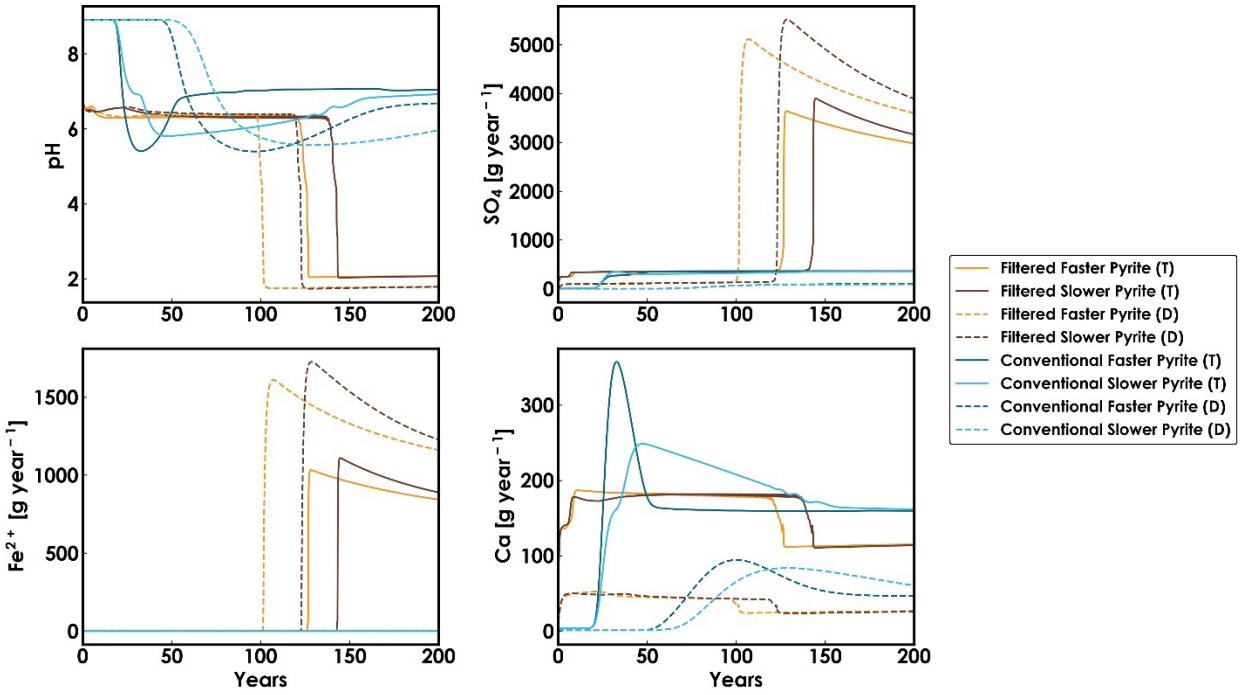

Figure 4: Comparison of basal pH and annual loads for TSF simulations

Comparing loads released from basal seepage (Figure 4), the higher net infiltration scenarios of 250 mm year-1 transport constituents released from mineral dissolution downwards at a faster rate than those scenarios with 70 mm year -1, which is observed through the delay in release curves by several decades. Loading rates show that pyrite oxidation products (like SO4 and Fe) released are comparable in the filtered and conventional TSF designs until ML/ARD impacted waters reach the base (Figure 4). Eventually, the higher water table in the conventional TSF design models results in decreased seepage loads compared to models with the same conditions under a filtered TSF design, since increasing the total water saturated volume of tailings decreases the total volume of oxidizing sulfidic tailings and the total amount of pyrite oxidized. In addition to the uncovered TSFs, a covered or oxygen limited scenario was simulated as a water table height of 19.5 m. As expected, in the covered tailings oxygen profiles and pyrite consumption profiles

(Figure 3) follow similar patterns to the conventionally placed tailings, but with a shallower depth of oxygen. This results in decreased basal loads and lower concentrations of constituents at depth (see Appendix).

Discussion

Mechanistic processes described in the conceptual model are reflected in the results of the simulated 1D tailings columns. The benefit of these simulations, while conceptual in nature, is that they provide an enhanced visualization of the spatial extent and timing of ML/ARD impacted waters through a TSF under different climate, design, and geochemical conditions. In most of the scenarios modeled in this paper, it may take several decades to see the release of constituents associated with ML/ARD in basal seepage. As highlighted in the conceptual model, during the earlier years of the TSF, poor quality water is constrained to the upper unsaturated portion of the tailings. Model simulations show that in the conventional TSF design, the water table limits oxygen ingress to a shallower depth than the filtered tailings (thus limiting the total "reactive" portion of tailings material); however, oxygen ingress is also limited by consumption through pyrite oxidation and diffusive flux, as dictated by Fick's law. Depending on the material properties, residual saturation, and sulfide reactivity, oxygen will be limited to different depths within a TSF. In some cases, such as the temperate climate with faster pyrite weathering rate, oxygen ingress is limited to similar depths in the first 20 years in both the conventional and filtered TSF designs (Figure 3). Even after a century, oxygen in filtered tailings may be limited to the top 5 m of the TSF.

In all the scenarios simulated, the tailings materials are classified as PAG, with an NPR of 0.2. Onset of acidic conditions occurs as calcite is depleted within the first five years at the surface, observed as pH decreases at depth (see Appendix). Due to the relatively low hydraulic conductivity and water saturation, acidic basal seepage conditions may not be observed until at least 100 years to beyond 200 years in the 20 m columns simulated (Figure 4).

The conceptual model, supported by simulation results, demonstrates that seepage water quality is unlikely to require management for decades to centuries in filtered tailings, whereas runoff water management is much more important prior to covering the tailings due to interaction with oxidized tailings at the surface. Furthermore, if runoff management decreases infiltration rates into the filtered tailings, this will increase the time frames for wetting up and onset of seepage. However, as shown by the higher loads associated with ML/ARD in the filtered tailings, this conceptual model also demonstrates the importance of implementing a cover system that limits poor quality runoff as well as infiltration (limiting transport of ML/ARD), or placement of a cover system with a layer of lower permeability to effectively limit oxygen ingress (limiting generation of ML/ARD) before ML/ARD seepage from a filtered TSF occurs. Cover

system options and suitability will also be site-specific (INAP, 2017; Bussière and Guittonny, 2021); TSF design techniques to manage ML/ARD will be dependent on factors like those explored in this paper.

Assumptions and limitations

For the purpose of generating sensitivity analyses of TSF designs under different climate, design, and geochemical conditions, several simplifications were made to the 1D columns simulated in this work. The materials selected for the tailings were based on physical tailings properties and mineralogical compositions that have been calibrated for other mine sites, but modified slightly to remain conceptual in nature. Additionally, 1D columns did not consider effects of sloped surfaces that may result in lateral flow in 2D simulations, and also excluded the buildup of tailings placement in the TSF construction over time (i.e., simulations began assuming fresh tailings placed in a 20 m profile). In reality, oxygen ingress occurs across exposed surfaces during deposition and in final tailings surfaces, where only the latter was simulated in this model. Future modeling work to integrate construction schedule and increasing height of TSFs is likely important to understanding the timing of onset of acidity and poor drainage quality being released, and is encouraged for site-specific TSF investigations.

Net infiltration boundaries and temperature conditions were held constant over time; heat generated due to pyrite oxidation was not considered. Temperature affects pyrite oxidation rates through the Arrhenius equation (Nicholson et al., 1988), where lower temperatures are associated with slower kinetics. As pyrite oxidation is an exothermic reaction, heat released from the oxidation process (particularly in the faster sulfide kinetics materials) should result in increasing temperatures around the oxidation sites, since tailings typically have low thermal conductivity (Harries and Ritchie, 1981; 1985; Lefebvre et al., 1997; Yanful et al., 1990). Higher internal temperatures have been known to result in death of microorganisms that facilitate pyrite oxidation reactions and limiting additional pyrite oxidation (Yanful et al., 1990). This is likely important to some climates, such as the drier scenario explored in this model, and should be considered in site-specific investigations.

Finally, the focus of this paper is on the behavior of tailings and their respective water saturation conditions; however, solute release associated with construction material of the TSF dam embankment were not considered. Dams are often constructed with mine rock or overburden material extracted in earlier years of mine life and may be a more significant source of solute loads than the tailings themselves coming from TSFs, due to high permeability of rock materials and mineral weathering through the same mechanistic processes explored in the conceptual model for tailings. Assessment of different TSF designs through sensitivity analysis should therefore consider the tonnage and loadings from materials used to construct dams in addition to the tailings materials themselves. Future work is recommended to test different models

that address the assumptions and limitations stated above, if site-specific data exists to validate model outputs.

Conclusion

It is well understood in the mining industry that release of constituents from mine waste storage facilities such as TSFs are site-specific. The purpose of the conceptual models simulated here is to provide enhanced conceptualization of these mechanistic processes to support decision-making during early project planning and modeling under different scenarios, and to demonstrate the importance of implementing calculations or models that consider the timing of release of constituents given specific design parameters and material properties that consider the diffusion limitations of filtered tailings. Results from models simulated in this work showed that filtered tailings did result in greater loads of sulfide oxidation products relative to the conventional slurry tailings over long time frames due to the greater oxygen ingress if left uncovered. The exact timing of their release will be dependent on TSF design parameters not considered in these 1D columns (namely, runoff and flow paths that control transport mechanisms constrained to the upper few meters of the TSF). If, however, it is anticipated that a conventional TSF design would include an oxic zone within the first few meters of the TSF, the quantity of metal loads produced under both conventional and filtered scenarios may be comparable within the first few decades to centuries, as the same volume of materials would be considered oxic due to diffusion limitations within the tailings profile. In both scenarios, a cover system is necessary to manage ML/ARD impacted waters from leaving as runoff and/or limit the oxygen depth into the sulfidic tailings.

The TSFs simulated in this paper are conceptual in nature, aimed to support the conceptual model; there is no “best” solution presented in this study. We suggest that sensitivity analyses in the design process can help lead practitioners to consider opportunities to construct and manage their TSF designs with closure in mind by incorporating mechanistic processes (e.g., including diffusion limitations and oxygen consumption by sulfide oxidation) to develop a “reasonable expectation” conceptual model for the thickness of reactive tailings through time, which can be used to enhance understanding of ML/ARD risk for reactive filtered TSFs on a site-specific basis. From here, practitioners can design cover systems to manage these filtered tailings with timing in mind to manage ML/ARD risk during operations and post-closure and meet regional closure objectives.

Orphaned and Abandoned Mines in Manitoba: From Identifying Hazards to Achieving Closure

Mohammad Ahmeduzzaman, KGS Group, Canada
Dami Adedapo, KGS Group, Canada
Cory Graham, Government of Manitoba, Canada

Abstract

The government of Manitoba in Canada launched a program in 2006 to develop a database, identify and assess hazardous conditions, and estimate the cost of remediation of the orphaned and abandoned mine (OAM) sites located in Manitoba. OAM are the mine sites that have been returned to the Crown's ownership because the previous mining companies have either ceased to exist or lack the financial resources to undertake the necessary restoration efforts. As part of the program, background documents (government publications, maps, aerial photos, previous inspection reports) were reviewed, the sites were visited, and risk and liability assessments were undertaken. The OAM sites were categorized based on their level of hazards and closure costs were estimated. Stakeholder consultations were conducted as part of the closure plan design, and site-specific requirements were developed, to establish the closure objectives and success criteria for each OAM site.

Subsequently, from 2020 to 2024, risk and liability estimates were updated, final closure plans were developed, and the construction phase was initiated for several OAM sites. So far, the closure of more than thirty OAM mine sites has been completed, with others to follow. The closure works for OAM sites included capping mine openings using reinforced concrete caps, encapsulation of potentially acid-generating tailings and waste rock using HDPE geomembrane, stabilization of steep unstable slopes, demolition and disposal of debris, backfilling of test pits and trenches and restoration of disturbed areas back to pre-mining condition to eliminate evidence of anthropogenic activity as much as is practically possible. An overview of the OAM program is presented in this paper. The paper includes discussions of the closure plan development process and of construction activities that were undertaken for the sites. It also discusses key factors influencing the closure plan development including stakeholder feedback, closure costs, constructability, long-term monitoring needs, climate change, and site access.

Introduction

Orphaned and abandoned mines (OAM) are the mine sites that have been returned to the Crown's ownership because the previous mining companies have either ceased to exist or lack the financial resources to undertake the necessary restoration efforts. Canada is facing the legacy of more than 10,000 inactive, orphaned mines that were developed and closed throughout the long history of mining in Canada (Hogan and Tremblay, 2006). OAM sites generally encompass shafts, adits, raises, stopes, access points to underground workings, exploration trenches, open pit excavations, subsidence areas, unsafe derelict buildings and infrastructure, waste rock dumps, and tailings disposal sites. OAM sites often lack records or have very poor documentation of their development. Various types of mine openings, which may interconnect and reach significant depths, can be obstructed by random debris, ice plugs, vegetation overgrowth, or collapsed rock. Nearby mine workings might be flooded or filled with dangerous gases. Entering or approaching these hazardous openings can result in falling, drowning, or being buried by collapsed mine workings, leading to serious injury or death. Shallow underground openings can create crown pillars, which are thin layers of ground above the underground stopes. The collapse of these pillars can also be fatal. Beyond the physical and stability-related hazards of mine workings, additional dangers include toxic mine gases, derelict buildings and structures, mine drainage and seepage, mechanical and electrical equipment, and explosives. These hazards, both individually and collectively, pose significant risks to humans and wildlife. Unsecured mine openings are among the most serious physical hazards at abandoned mine sites. These openings were typically not designed to remain stable after closure and can fail for various reasons if not properly remediated (AANDC, 2011).

Moreover, OAM sites are often associated with environmental problems such as acid mine drainage (AMD), which can lead to severe water pollution and surface contamination. AMD occurs when sulfide minerals in exposed rock surfaces react with air and water, producing sulfuric acid and dissolved iron. This acidic runoff can leach heavy metals from surrounding rocks, contaminating nearby water bodies and soil. According to Johnson and Hallberg (2005), AMD is one of the most significant environmental challenges associated with abandoned mines, necessitating comprehensive remediation strategies to mitigate its effects.

The Manitoba Government became responsible for rehabilitation and funding remediation costs of orphaned and abandoned mine sites that were developed and ceased to exist prior to the implementation of closure plans and financial assurances under the Mine Closure Regulation in 1992. In 1999, the province introduced mine closure regulations that mandate financial security for environmental liabilities incurred during mining operations to cover future remediation costs. These regulations require that mine closure plans and financial security be submitted and approved before a new mine operation permit is issued.

In 2000, Manitoba launched the Orphaned and Abandoned Mine (OAM) Site Rehabilitation Program to address the public safety and environmental health issues related to orphaned and abandoned mine sites. Under the OAM rehabilitation program, location, ownership, previous inspections, availability of historical documents, and site condition for a total of 148 OAM sites (as shown in the overview in Figure 1) scattered throughout the province were identified.

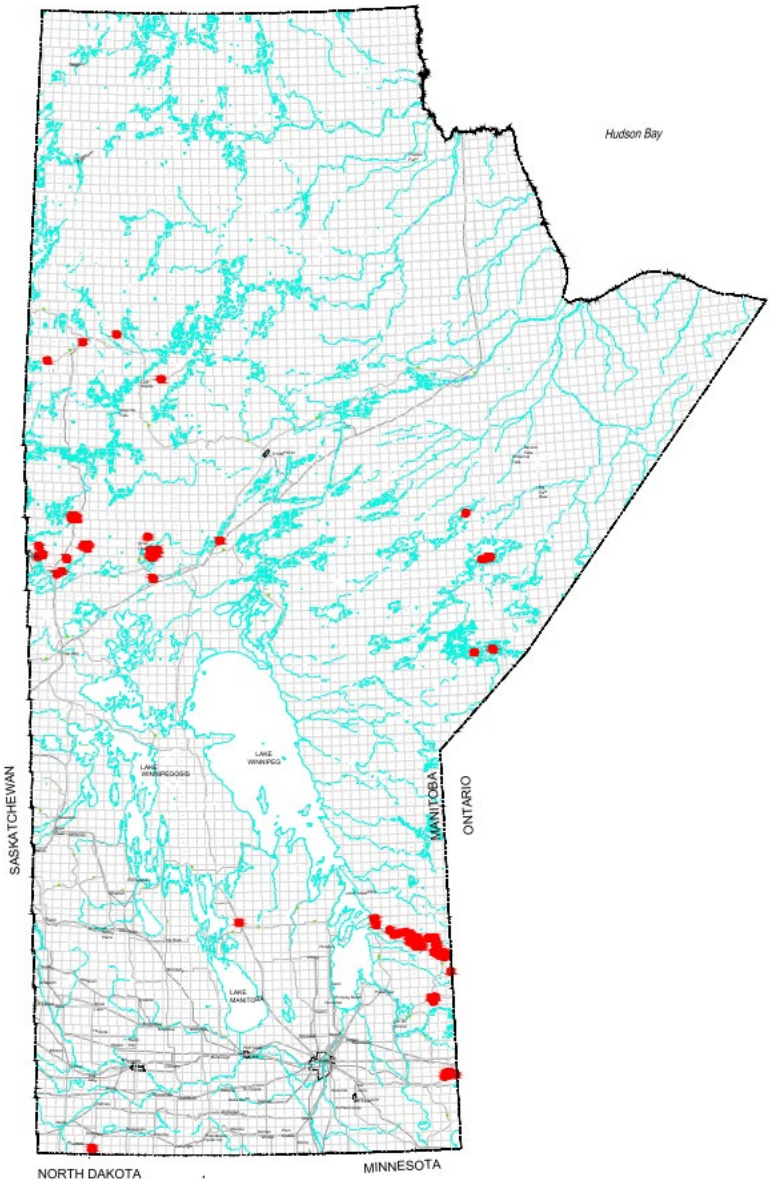

Figure 1: Overview of OAM sites in Manitoba

Most of the OAM sites operated between 1911 and the late 1970s (Richardson and Ostry, 1996). In 2006, Manitoba introduced a program to create a database, assess hazardous conditions, and estimate remediation costs for these sites. This involved reviewing government publications, maps, aerial photos, and previous inspection reports, visiting the sites, and conducting risk and liability assessments. During the

2006 program, a total of 131 sites were identified and evaluated. Sites were categorized by hazard level, and closure costs were estimated. Between 2007 and 2019, over thirty OAM sites were remediated, though some received limited attention due to various factors.

In November 2019, the OAM program was transferred to Manitoba Environment and Climate Change to align with its mandate for a cleaner Manitoba. Upon reviewing the Public Accounts, the OAM found insufficient evidence for the estimated liability. Consequently, from 2020 to 2024, risk and liability estimates were updated, closure plans were developed for over 25 additional sites, and the construction phase began for several OAM sites.

This paper provides an in-depth overview of the OAM program, highlighting the methodologies employed in identifying and assessing hazardous conditions, the estimation of remediation costs, and the execution of closure plans.

Hazard identification and closure plan development

Risk and liability assessments and closure cost estimates

A background review of available information such as review of government publications, topographic and geological maps, aerial photographs, and previous inspection reports was conducted prior to carrying out the risk and liability assessments. Upon completion of the background review, a site inspection was carried out to identify the OAM sites and confirm the present conditions. A detailed risk and liability assessment was performed for each OAM site. This assessment aimed to categorize the sites based on their potential hazards and the estimated costs of remediation. The criteria for this assessment included public safety risks (e.g., presence of open shafts, buildings and foundations, scrap metals and debris, terrain morphology, and stability and accessibility), and environmental risks (e.g., proximity to water bodies, water accumulations and discharges, presence of tailings and waste rock, ecological impacts, and human health impacts). Each site was then assigned a hazard level, ranging from low to high, to prioritize the sites for remediation. This categorization allowed the government to allocate resources efficiently and focus on the most critical sites first.

Based on the visual observations during the site inspection, closure cost with +40% to -20% accuracy was developed for the remediation of each OAM site. This cost estimate included the engineering, and project management costs, construction supervision and contract administration costs, and contractor's costs to rehabilitate the site including site mobilization and demobilization. The total cost of rehabilitating the identified 131 sites was estimated between $14.7 million and $24.9 million in 2006 $value.

Between 2007 and 2019, over 30 OAM sites were remediated, though some received limited attention due to various factors. Hence, in 2021, the province carried out another round of risk and liability assessment and closure cost estimates and subsequently commissioned the consultant (KGS Group) to

prepare closure plans, detailed design, tendering, and construction oversight of several OAM sites located at the eastern side of the province within the Canadian Shield. The hazard characterization and closure plan development process are discussed in the subsequent section.

Hazards identification

Mine openings

Out of the many hazards identified at the OAM sites, the presence of mine openings was the most significant type of hazard. During the site visits to the OAM sites, the mine shafts, vent raises, open adits, and stopes were found to be in different conditions as follows.

- Some mine openings were open without any covers, public safety fencing, warning signage, etc.
- Some mine openings were surrounded by public safety fencing with warning signs, both in worn-out shape.
- Some mine openings had relatively newer public safety fencing and warning signs but were vandalized by the public.
- Some mine openings were covered by concrete caps. At several sites, the caps failed due to inadequate structural capacity and due to foundation collapse. The caps did not have any vent pipes, and some did not have warning signs, and some caps were found to be partially to fully buried by fill materials making it extremely difficult to identify hazards.

Figure 2: Mine openings

Waste rock and tailings

In general, an abundance of waste rocks removed from the mine during its development to access the ore zones of economic value was found throughout the OAM sites. Waste rock may still contain a low concentration of ore, and over a long period, the metal content in the presence of water may generate acid

and leach out from the waste rock stockpile and affect the surrounding environment. In addition to the potential for acid generation, the waste rock had steep slopes, exhibited erosion, had unacceptable aesthetic conditions, undesirable topography by obstructing natural drainage, hazards for hikers by creating unsafe footing conditions, etc.

Mine tailings were also found at several OAM sites with the aerial extent varying from less than 500 m^2 to more than 100,000 m^2. Exposed tailings presented a risk of the generation of harmful leachate from overland flow which contacts the tailings. Tailings contained elevated concentrations of heavy metals such as arsenic, copper, or lead, which may be released into the environment. Tailings also exhibited a high potential for acid generation. Exposed tailings were easily erodible, leading to poor vegetation uptake and turbid overland flow.

Figure 3: Mine waste and tailings

Abandoned mine infrastructure and equipment

Remnants of the headframe, building foundations, mining equipment, scrap metal, and rubble from demolition were found throughout the OAM sites. The scrap metals posed hazards such as sharp edges coming into contact with skin or puncturing limbs of humans and wildlife, the collapse of the infrastructure and metal equipment over humans and wildlife, entrapment of humans and wildlife into the old machinery, and snowmobiles or off-road vehicles colliding with large machines or equipment were the risks associated with the abandoned mine infrastructure and equipment.

Figure 4: Abandoned mine infrastructure and equipment

Closure plan development

Closure vision

The government of Manitoba's closure vision for the OAM sites is to restore the site to a "satisfactory condition" with a practical, perpetual (i.e., little to no maintenance required but does not preclude regular inspection), and economically viable design that is acceptable to the stakeholders.

Stakeholder engagement

The importance of stakeholder engagement in the development and implementation of mine closure plans cannot be overstated. Successful remediation projects often involve extensive consultations with local communities, indigenous groups, environmental organizations, and other stakeholders. This participatory approach ensures that the concerns and expectations of all interested parties are considered, leading to more socially acceptable and sustainable outcomes. The work of Evans and Kemp (2009) emphasizes the role of stakeholder engagement in enhancing the legitimacy and effectiveness of environmental remediation efforts. Stakeholders such as various departments within the government of Manitoba such as Provincial Parks, Highways, Crown Lands, Historic Resources Branch, Forestry Branch, and the external stakeholders such as local aboriginal communities were engaged through meetings onsite and offsite during the mine closure plan development process and Manitoba's closure vision was coupled with the vision of various stakeholders to develop objectives of the closure work.

Closure objective and success criteria

The general closure objectives of the OAM sites were as follows.

- Eliminating unacceptable health hazards and ensuring public safety;
- Limiting the production and circulation of substances that could cause damage to the environment and, in the long-term, eliminating the need for maintenance and monitoring;
- Restoring the site to a condition in which it is visually acceptable to the community; and
- Reclaiming for future use of the areas where infrastructures are located.

In addition, additional site-specific objectives were also identified based on the feedback from the various key stakeholders.

The success criteria are specific, measurable, achievable, relevant, and timely criteria that are defined with input and agreement with appropriate stakeholders are key to completing closure works (ICMM, 2008). Examples of the success criteria developed to achieve closure of OAM sites are presented in Table 1 as follows.

Table 1: Example closure objective and success criteria for OAM sites

Hazards	Closure objective	Success criteria
Mine openings	Eliminating unacceptable health hazards and ensuring public safety;	Mine openings are to be sealed using an engineered cap with appropriate signage and venting
Acid-generating tailings	Limiting the production and circulation of substances that could cause damage to the environment and, in the long-term, eliminating the need for maintenance and monitoring;	Acid-generating tailings are to be encapsulated to isolate the tailings from air and water to eliminate acid generation
Poorly draining stockpiles of waste rock	Restoring the site to a condition in which it is visually acceptable to the community; and	The stockpiles are to be graded to eliminate water ponding and to ensure positive drainage
Scattered metal and infrastructure debris	Reclaiming for future use of the areas where infrastructures are located.	The scattered metal and infrastructure debris are to be collected and disposed of and the site is to be returned to a state that is suitable for future land use as acceptable by stakeholders

Closure plan options

A range of practical remediation alternatives were identified and assessed as part of the closure plan development for the OAM sites. Factors such as long-term performance, constructability, adherence to mine closure regulations, design life, level of risk, cost-benefit, and stakeholder feedback, were considered in selecting the preferred alternative.

For the closure of the mine openings, alternatives such as signage, fencing, steel grate, steel plate, concrete cap/bulkhead, polyurethane foam plug, backfilling, and closure through blasting were considered and based on the analysis of the abovementioned factors, concrete cap anchored into bedrock was the most preferred option.

Alternatives such as do nothing, leave as is with monitoring, regrading of stockpiles, revegetation, and encapsulation were considered for waste rock stockpiles and based on the analysis of the abovementioned factors, regrading of stockpiles and crushing and spreading of fallen trees to cover the regraded surface was the most preferred option. Encapsulation was the preferred option for all potentially acid-generating tailings due to its potential to significantly impact the environment. Caps such as clay caps, geomembrane liners, and granular fill caps were considered and a combination of geomembrane and granular was selected for encapsulation.

Demolition, cutting, burning, and burial were options for the remediation of scattered metal and infrastructure debris. Depending on the location of the site, constructability, and accessibility, demolition, cutting, and burial or disposal offsite were selected as remedial options. Based on a heritage resources impact assessment (HRIA) screening at the OAM sites, some infrastructure and machinery were considered to carry heritage value and were left in place without disturbing them.

Achieving closure of OAM sites

Contracting strategy

Remediation work for multiple sites that have geographical proximity and similar scope of work was lumped to form construction packages to increase the efficiency of the work. A single contractor was able to utilize the same sets of crew and equipment to move from one site to another and perform remedial activities.

Capping of mine openings

Reinforced concrete caps were built to cap the mine openings. The caps included a reinforced concrete slab and walls where the walls were doweled into bedrock. The foundation area of the cap was carefully examined for competence before selecting the exact location of the foundation. Vent pipes were installed at the cap for air passage and to allow the release of any pressure built up inside the openings. The caps were generally elevated from the ground with posts and signage with reflected markings (Figure 5) making them and the hazards readily recognizable to the public.

Figure 5: Capped mine shaft

Encapsulation of tailings

1.5 mm double-sided textured high-density polyethylene (HDPE) geomembrane was used to encapsulate the potentially acid-generating tailings. The details for the tailing's encapsulation varied from site to site and depending on the aerial extent, thickness, topography, and site-specific characteristics of the tailings. The geomembrane came in rolls and was unrolled on site and seamed together to build the encapsulation. The encapsulated area was covered using quarried non-acid-generating rock. The geomembrane layer was

protected from sharp objects and crushed waste rocks by sandwiching them between non-woven geotextiles. Figure 6 shows an example of tailings encapsulation using an HDPE geomembrane liner at one of the OAM (Central Mine Manitoba) sites.

Figure 6: Encapsulation of tailings using HDPE geomembrane

Regrading of waste rock stockpiles

Steep and undulating stockpiles of the waste rock were regraded to achieve a more stable slope, positive drainage, and aesthetically better condition. Waste rock was also used as a source of fill materials to backfill the test pits and trenches located at the OAM sites.

Demolition and disposal of debris

The metal and infrastructure debris that are not considered to carry any heritage value were collected, broken down, and disposed of into the openings before closure or offsite into landfills and recycling facilities.

Construction constraints

Access constraints

Some of the OAM sites were very remote and away from the provincial access roads, trails, and all-season roads. The access would often require crossing swampy areas, lakes, and rough hummocky terrains. Historically access to those sites required a combination of either or both helicopters, boats, canoes, ATVs, and snowmobiles, etc. Logistics and accessibility were critical considerations for efficiently transporting

materials and personnel to and from the OAM sites. This included the development of access roads and other infrastructure needed to support the construction activities. The challenging access sites were accessed during the winter months by building winter roads through difficult terrains and building ice roads across the lakes.

Presence of archaeologic resources

In general, most of the OAM sites contained heritage objects that are from the mining activities from the 1910s to 1930s dating back to the pre-contact indigenous period (Figure 7). The objects were also very close to where the remediation activities took place, and it was essential to ensure the objects were not disturbed due to construction activities. Hence, visual and physical buffers were established around the objects of significance before starting construction activities and the construction equipment had to be carefully maneuvered around those buffer zones.

Figure 7: Heritage objects found in OAM sites (left: pre-contact, right: 1910s)

Protection of the biological environment

Some OAM sites were in densely vegetated areas and were not readily accessible. Tree clearing was required to access those sites. The nesting period varies from species to species; however, it generally falls between April 1st to August 1st in Manitoba. Bird nest sweeps were completed by qualified ecologists to confirm the presence of bird nests in the proposed disturbance areas.

Conclusion

The Orphaned and Abandoned Mine (OAM) Site Rehabilitation Program in Manitoba has made significant progress since its inception in 2000. Through systematic hazard identification, risk and liability

assessments, and the development and execution of detailed closure plans, the program has successfully remediated over 30 OAM sites, with many more in progress. The multi-faceted approach, which includes stakeholder consultations, site-specific requirements, and practical remediation strategies, has proven effective in mitigating the environmental and public safety risks associated with these sites.

The methodologies employed, such as capping mine openings, encapsulating acid-generating tailings, regrading waste rock stockpiles, and managing abandoned infrastructure, have restored these sites to conditions that are safer for the public and less harmful to the environment. The program's emphasis on long-term sustainability and minimal maintenance requirements ensures that these remediated sites will remain secure and environmentally stable for the foreseeable future.

Challenges such as remote site access, the presence of archaeological resources, and the need to protect biological environments were addressed through innovative solutions and careful planning. The successful implementation of the OAM rehabilitation program serves as a model for similar initiatives in other regions facing the legacy of abandoned mines.

Overall, the program's achievements reflect the commitment of the Manitoba government and its partners to environmental stewardship and public safety. The continued focus on comprehensive remediation and sustainable closure practices will ensure that the benefits of this program extend well into the future, contributing to a cleaner and safer Manitoba.

Vicente Mello, AECOM, Brazil

Abstract

This paper presents the technical, legal, and normative aspects of hydraulic safety for the decharacterization of mining dams in Brazil. These aspects guide professionals involved in the design and execution of decharacterization works. Recommendations associated with good engineering design practices are also addressed, particularly in the absence of regulatory support. Additionally, the criteria, premises, and methodologies commonly adopted in hydrology and hydraulics for the decharacterization of dams are presented.

Introduction

The mining dam life cycle includes planning, design, construction, implementation, filling, operation, deactivation, decharacterization, and future uses. The significant dam failures in Brazil in recent years (the Fundão tailings dam in Minas Gerais in 2015 and the Córrego do Feijão dam in Brumadinho in 2019) have led to stricter safety measures for each phase, particularly the creation of laws for decharacterizing dams constructed by the upstream raising method. The new laws established deadlines for the completion of decharacterization projects.

The decharacterized dam is a structure that neither allows water accumulation nor receives or stores tailings/sediments, and it no longer exhibits the characteristics of a dam. This concept means that the decharacterization of a tailings dam can be carried out through different methods, ranging from the total removal of previously deposited material and valley restoration to the maintenance of an anthropized structure. Each methodology for dam decharacterization will directly impact the criteria and premises defined for the project.

Moreover, the decharacterization of a dam serves the purpose of safely reintegrating the anthropized region into nature. Thus, no significant interventions are expected in the region of the structure beyond adjustments identified during the monitoring stage after the completion of decharacterization works.

This paper delves into the primary technical, legal, and normative aspects related to hydraulic safety for the decharacterization of mining dams in Brazil. These aspects are vital for professionals involved in the design and execution of decharacterization works. The paper also addresses recommendations associated with good engineering design practices, particularly in the absence of regulatory support. Additionally, it presents the criteria, premises, and methodologies commonly adopted in hydrology and hydraulics for the decharacterization of dams, underscoring the significance of the topic.

Concept

The concept of a decharacterized dam has evolved since the creation of the National Dam Safety Policy, culminating in its current form with ANM (National Mining Agency) Resolution No. 95/2022. This resolution defines a decharacterized dam as one that no longer permanently receives tailings or sediments from its primary activity and ceases to have the characteristics or function of a dam, following a technical decharacterization project.

The technical decharacterization project must necessarily include, but is not limited to, the following completed stages:

- Termination of operations with the removal of associated infrastructure, such as spigots and pipelines, except those necessary for the safety of the structure.
- Adoption of effective measures to reduce or eliminate surface and groundwater inflow into the reservoir, as well as controlled reduction of the phreatic line within the reservoir.
- Implementation of measures to ensure the long-term physical and chemical stability of the remaining structures.
- Monitoring for a minimum period of two years after the completion of decharacterization works to assess the effectiveness of stabilization measures.

Legislations, norms, resolutions, and terms of references

Following recent tailings dam failures, legislative bodies at the national and state levels in Brazil developed several new laws and resolutions containing restrictions on construction methods and regulations concerning mining dam safety. The main ones are cited below.

- ANM Resolution No. 4 of February 15, 2019 – This resolution established precautionary regulatory measures to ensure the stability of mining dams raised by the upstream method or with unknown

methods. It also prohibited the use, construction, and raising of mining dams by the upstream method in Brazil, and it set a schedule for their decharacterization. This resolution was replaced by ANM Resolution No. 13 of 2019.

- Joint SEMAD/FEAM Resolution No. 2.784 of March 21, 2019 – Mandates the decharacterization of all upstream-raised tailings and waste containment dams from mining activities in Minas Gerais and provides other measures.
- ANM Resolution No. 13 of August 8, 2019 – Updates regulatory measures to ensure the stability of mining dams raised by the upstream method or with unknown methods.
- Federal Law 14.066 of 2020 – Amends previous laws related to the National Dam Safety Policy, creation of the National Environment Fund, establishment of the National Water Resources Policy, and mining code. Regarding decharacterization, the law includes more detailed provisions on the decharacterization process in the National Dam Safety Policy.
- ANM Resolution No. 95 of February 7, 2022 – Consolidates the normative acts on mining dam safety. This resolution also addresses minimum technical criteria for mining dam decharacterization, the minimum monitoring period after the completion of decharacterization works, and procedures for communicating decharacterization to the competent authorities.
- ANM Resolution No. 130 of February 24, 2023 – Amends part of ANM Resolution No. 95 of February 7, 2022, including phases of active and passive monitoring of dam decharacterization.

For the state of Minas Gerais in Brazil, FEAM (*Fundação Estadual de Meio Ambiente* – the State Environmental Foundation) created terms of reference listed below, in which some hydraulic technical aspects related to the decharacterization of upstream-raised dams were mentioned:

- FEAM's 2020 term of reference for decharacterizing upstream-raised dams – Establishes minimum technical criteria for preparing projects for decharacterizing upstream-raised dams in Minas Gerais state.

At the national level, the only technical standard addressing hydraulic aspects related to mining dam decharacterization projects is NBR 13028/2017, mentioned below, and its revision is underway to align with current legislation.

- NBR 13028/2017 – Standard related to the preparation and presentation of mining dam projects, including some criteria for decommissioning and decharacterization.

Criteria related to hydrology and hydraulics, specifically for decharacterized structures, are not addressed in the national legislation and resolutions, except for ANM Resolution No. 95/2022. Given the superficial nature of current Brazilian legislation and standards regarding criteria for decharacterization projects and considering recent mining dam disasters, it is increasingly necessary to evaluate good

engineering practices established by technical professionals and literature from renowned national and international authors.

Currently, some publications stand out, such as *Guidelines for the Preparation of Hydrological Studies and Hydraulic Designs in Mining Works* (Pinheiro, 2011) and various publications from the Canadian Dam Association (CDA), the International Commission on Large Dams (ICOLD), and the Brazilian Dam Committee (CBDB). These technical publications, combined with knowledge of existing legislation, provide criteria, methodologies, and premises to be adopted in dam decharacterization projects, to guide in ensuring the safety of decharacterized structures.

Methodologies for decharacterization of mining dams in Brazil

There are no detailed technical standards or guidelines that provide methodologies for the decharacterization of tailings and sediment dams in Brazil. As a result, projects are guided by the understanding and discretion of each engineer or company, if they meet the requirements outlined in ANM Resolution No. 95/2022. Among the alternatives adopted for decharacterizing mining dams, the following stand out.

Complete removal of the dam and reintegration of the area into the environment

The project involves the complete removal of the dam and ancillary infrastructure, disposal of the materials in the reservoir, followed by the restoration of the remaining valley using natural elements. This process typically includes the construction of a channel at the bottom of the valley with various types of lining, such as grasses, riprap, and other materials, depending on the local flow velocities (Figure 1).

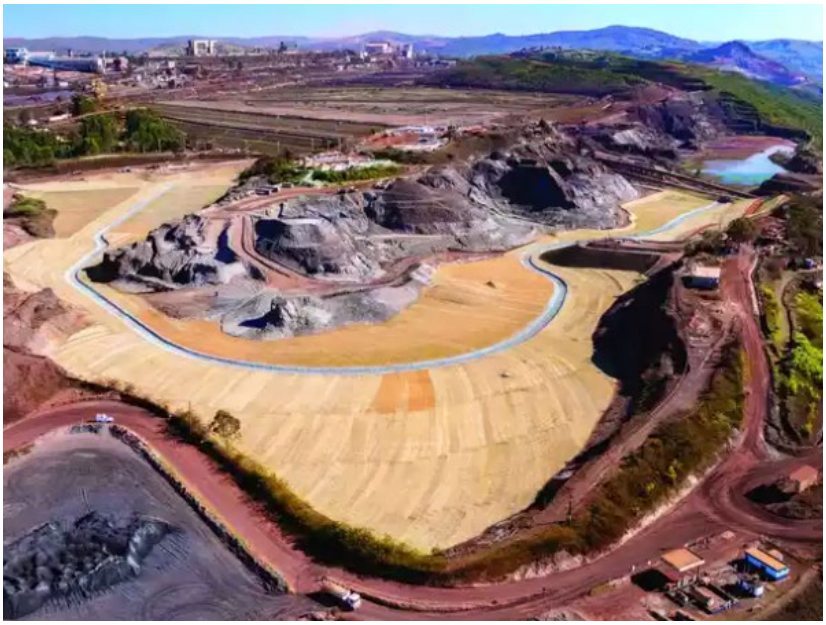

Figure 1: Dam completely removed (source: Estado De Minas, 2021)

Partial removal of the dam

The project includes maintaining part of the dam and the total or partial removal of the tailings/sediments from the reservoir. The reservoir surface is filled with low-permeability materials, and its slope is regularized and directed towards a drainage structure designed to carry all local contributions without forming a downstream lake (Figure 2). Open channels, such as "fishbone" channels, are typically planned for the remaining reservoir surface. These channels are designed without flow attenuation, minimizing water accumulation on the former reservoir surface. This structure should use appropriate linings for the flow velocities, avoiding sections that could create hydraulic flow restrictions, such as culverts or galleries. Some projects incorporate the existing spillway, which requires a hydraulic and structural evaluation.

After the reservoir backfilling, the exposed surfaces should be revegetated to prevent erosion and restore the landscape context. This solution has been identified for upstream-raised dams (with the upstream raises entirely removed down to the starter dike) and single-stage dams raised by centerline or downstream methods.

Figure 2: Dam partially removed (source: Valor Econômico, 2023)

Preservation of the dam

The project includes maintaining the structure (including the starter dike and any existing raises) and the tailings/sediments in the reservoir, filling the surface with low-permeability material, and vegetative restoration. The developer must assess the need to reinforce the dam's downstream side to increase the safety factor, in compliance with current legislation. For surface drainage, drainage channels are also

considered. These channels may or may not discharge into the existing spillways, provided their hydraulic and structural capacity to receive the flow without attenuation from the reservoir is proven.

Complete removal of the dams and the reintegration of the area into the environment is understood as the best alternative for their decharacterization, as there will be no risks related to the hydraulic and geotechnical safety of the structures, thus not requiring future maintenance. However, the complete removal of the structure may raise discussions regarding the definition of suitable locations for the disposal of materials removed from the decharacterization works, which may also involve environmental issues. Such discussions become more frequent in evaluations for the decharacterization of dams with large volumes stored. To avoid impacts from new areas, tailings can be disposed of in exhausted pits. The selection of the decharacterization alternative must always be carried out through a technical comparison, including the implementation risks, and an environmental impact assessment for each option.

Figure 3: Dam partially removed (source: Mansur, 2023)

Once the dam is entirely or partially removed, increasing the safety factor of the remaining structure, the possibilities of failures are minimized but not eliminated. Thus, the monitoring phase is crucial after the completion of decharacterization works. Developers are increasingly creating decharacterization projects that include solutions that do not entirely eliminate the dam embankment due to the absence of legal restrictions on its total or partial maintenance. They are also considering issues related to the disposal of removed materials, especially environmental impacts.

It is important to note that when the dam to be decharacterized has a sediment containment function, it must be demonstrated that the sediment generation rate upstream of the structure has reached a value similar to the natural rate. This assessment can be carried out based on field data surveys to monitor sediments downstream of the structure.

Regardless of the methodology adopted, solutions that partially or entirely maintain the dam must ensure surface water management according to rigorous hydraulic design criteria associated with low risks. This consideration is crucial for decharacterized structures, where maintenance should no longer be required.

The importance of assessing the impacts of dam decharacterization on the hydraulic safety of other structures within the same watershed is highlighted, in view of the elimination of flow attenuation in decharacterized structures. Other long-term environmental impacts and future use opportunities should also be considered.

Premises and criteria

Methodologies for dam decharacterization involve a series of interventions in the dam and reservoir to ensure long-term safety and stability. Therefore, defining premises and the criteria for hydrological and hydraulic parameters is essential.

Hydrological studies for decharacterization projects usually do not differ in terms of the chosen methodology for the complete removal of the dam or for partial/total maintenance.

The calculation of design flows, in general, is carried out by transforming rainfall into runoff, and the calculation method depends on the size of the catchment area.

For the characterization of the watershed, calculation methods for surface runoff coefficients (including the assessment of future land use and occupation) and the time of concentration are the same. However, the return periods adopted for calculating precipitation intensity differ for the alternative of complete dam removal and for the option of maintaining the structure. The terms of reference prepared by FEAM for the decharacterization of upstream-raised dams recommend a minimum return period (TR) of five hundred years for the re-establishment of the watercourse channel. The generally accepted practice is that this criterion should only be adopted in cases where the dam will be removed entirely. Resolution

95/2022 of ANM and Brazilian standard NBR 13.028 apply to partial removal or preservation of the dam, and indicate a TR of 10,000 years or Probable Maximum Precipitation as the criterion for the sizing of the spillway/drainage channel during the decharacterization/closure phase, as the dam structure will remain in the environment.

Usually, dam decharacterization projects include implementing drainage channels around the reservoir, known as “belt channels” or “contour channels,” whose function is to reduce water inflow from the watershed into the reservoir. These should be implemented even before the start of the decharacterization works. For their hydraulic design, the same criteria used for the spillway structure in operation are usually adopted. It is important to note that belt channels are often affected by siltation, resulting in a reduction of their capacity, and therefore, should not be considered for verifying the dam’s hydraulic safety.

To minimize water accumulation in the reservoir during decharacterization works, the operation of pumping systems enables the progress of the works and can contribute to reducing the water table and promoting the geotechnical safety of the structure. The criteria adopted for the design of these systems must be associated with the failure risk and usually a return period of one hundred years is adopted. It is important to note that the operation of pumping systems should not be considered in flood routing studies to assess dam hydraulic safety.

Regarding hydraulic aspects, the drainage/rehabilitation structures designed for river channels must evaluate not only engineering criteria for extreme flows (velocities and freeboard) but also verify the minimum water depth the designed structure will convey during dry periods. This verification is crucial to allow fauna (both terrestrial and aquatic) to survive throughout the year.

For a decommissioning project to achieve the environmental recovery goal of a dam area, the engineering team must collaborate closely with the environmental team, considering the habitat needs of the local fauna in the design. Therefore, the hydraulic design should avoid solutions such as large rock blocks on the channel bed with many voids, as this material allows complete infiltration of surface water through the blocks, preventing the formation of a perennial water layer over them. Along the banks, materials for covering should be evaluated to minimize erosion while allowing access to terrestrial fauna.

Monitoring

The monitoring and maintenance plan for a decharacterized dam must ensure that the structure maintains geotechnical and hydraulic safety conditions, while promoting environmental restoration to reduce risks to public health and safety.

ANM Resolution No. 130/2023 requires monitoring of the decharacterized structures for a minimum period of two years after the completion of decharacterization works, aiming to ensure the effectiveness of

stabilization measures. The resolution outlines two phases for the monitoring period: the first phase is active monitoring (mandatory for two years), which will then transition to a second phase defined as passive monitoring.

During active monitoring, actions should be planned to track the evolution and effectiveness of measures adopted in decommissioning the structure, focusing on geotechnical, hydraulic, and environmental aspects. Therefore, activities such as visual inspections and monitoring will be necessary to identify anomalies and determine the need for passive monitoring, which will be a continuation of active monitoring activities.

Typical post-closure activities include reducing the water table, operating drainage structures, preventing water accumulation during floods, stabilizing sediment generation and erosion points, promoting environmental restoration, and conducting water quality assessments. Monitoring and maintenance records help inform decisions regarding implementing additional corrective measures and/or mitigating impacts. It is also important to highlight the monitoring phase's significance in informing future decisions regarding new dam decommissioning projects.

Mining tailings dams, regardless of their construction method, are critical structures with catastrophic potential in case of failure. Therefore, the only abandonment alternative that no longer requires monitoring and oversight is the complete removal of 100% of the structure and its reservoir, along with the implementation of an environmental solution that restores the site to its natural condition prior to the existence of the dam.

Conclusion

The decharacterization of tailings and sediment dams in Brazil is a complex process that requires a multidisciplinary approach to promote long-term safety and stability. Adopting good engineering practices and adhering to legal and normative frameworks are essential for the success of decharacterization projects.

The methodologies, premises, and criteria presented in this article provide an overview of the hydrological and hydraulic aspects involved in dam decharacterization, guiding professionals in the design and execution of these projects.

The preferred decharacterization alternative will be chosen after considering the structure's specificities and technical, economic, social, and environmental aspects.

This paper notes an evolution in regulatory frameworks for the decommissioning of mining dams in recent years. However, the authors recognize the need for additional guidance to define actions and guide professionals, so as to ensure public safety and the recovery of degraded environments. Thus, there is a recognized need for the continuous evolution of these regulatory foundations to ensure the effective

decharacterization of dams, which will occur once the structure is reintegrated into nature, so that it no longer has a need for maintenance or monitoring.

Checklist for Decharacterization of Mining Dams: Engineering and Environmental Aspects

Rafael Caetano Cardoso Boaventura, AECOM, Brazil
Murilo Damato, AECOM, Brazil
Gislene F.S.R. Fournier, AECOM, Brazil
Manoela C.A. Neves, AECOM, Brazil

Abstract

Based on AECOM's experience auditing the decharacterization of over 20 mining dams in Brazil, the company developed a Checklist to assess the engineering and environmental aspects of dam decharacterization projects, the monitoring plans for the adopted solutions, and the respective impacts generated. AECOM also considered the Global Industry Standard on Tailings Management (GISTM) and the United Nations Sustainable Development Goals (SDGs) adopted as part of the 2030 Agenda.

The Checklist addresses engineering premises and the need to consider SDGs related to responsible natural resource management, including economic development and environmental protection. For its application, on-site evaluations and documentary analysis of geotechnical structures must be considered.

Regarding post-decommissioning monitoring, the Checklist addresses issues to be evaluated regarding geotechnical stability and environmental aspects, divided into physical, biological, and anthropic issues. Among the components of the physical environment are ecotoxicological indicators, water quality, soil quality, air quality, and sediment transport. Biological components include the protection of local fauna, ecotoxicological bioindicators, vegetation composition, and succession. Lastly, for anthropic components, actions and monitoring of fauna associated with human occupation and the presence of entomological vectors are evaluated. Thus, the aim is to obtain a set of environmental quality indicators for mining dam decharacterization projects.

Introduction

In Brazil, the state of Minas Gerais suffered two of the most significant socio-environmental disasters in mining history, with the ruptures of Fundão tailings dam (Municipality of Mariana, 2015) and B-I tailings dam in Córrego do Feijão mine (Municipality of Brumadinho, 2019). Between 2019 and 2021, structural problems in mining dams built using the upstream method led to the evacuation of communities, resulting

in serious socio-environmental impacts. As a result of these events, laws were created with stricter criteria regarding dam safety, defining the mandatory decharacterization of dams built using the upstream method. New federal and state legislation established standards and deadlines for the decharacterization of all dams constructed by the upstream method.

The decharacterization of a structure is a complex procedure involving numerous technical discussions due to the novelty of the legal and infra-legal determinations, the technical challenges, the risks inherent in the works, and the socio-environmental impacts that must be diagnosed and mitigated.

In Minas Gerais – a densely populated Brazilian state – large mining dams were raised upstream. These dams had nearby communities. Sometimes, the populations in the flood areas of these dams are exposed to significant risks arising from possible ruptures or leaks. These communities, located immediately downstream of the dams, depend on the proximity of water resources for their economic activities, such as agriculture and fishing, as well as homes and essential infrastructure. The safety of these populations requires effective emergency plans, awareness, and training programs for rapid evacuation, as well as constant monitoring of dam conditions.

Protecting these communities during the process of decharacterization of the dams is crucial, requiring an integrated approach involving authorities, companies responsible for the dams, and the local population itself. Thus, in addition to the need to mitigate safety risks to communities, such as preventive evacuations and construction of downstream containment structures (DCS), it is essential to pay attention to the impacts generated by decharacterization works.

The impacts caused by decharacterization are varied, ranging from the movement of trucks and equipment that generate air pollution, emission of noise and vibrations that harm the local populations and fauna to, in certain cases, the opening of new access roads and the suppression of native vegetation. The duration of the decharacterization of a tailings dam varies according to the complexity and size of each one, and the impacts generated may also vary according to the local landscape. For this reason, implementing environmental recovery plans and rehabilitating affected areas is essential to ensure long-term sustainability and minimize residual damage.

Additionally, in Minas Gerais, several tailing dams are in an emergency or alert situation due to the detection of structural anomalies, requiring increased speed and accurate techniques for decharacterization.

AECOM has developed an evaluation method based on a Checklist to effectively and comprehensively verify the engineering and environmental aspects of dam decharacterization projects, the monitoring plans of the solutions adopted, and the impacts generated.

This instrument is an essential tool for auditing all stages of the process, from initial planning to the completion of activities. This Checklist helps to identify and highlight the risks associated with the work, ensuring that all safety procedures are strictly followed. It also facilitates communication between

professionals, ensuring that no critical steps are overlooked. Using this Checklist, it is possible to monitor compliance with environmental and legal obligations, ensure the protection of adjacent populations and affected ecosystems, and ensure that the project is completed within the established deadlines and budgets.

Methodology

AECOM developed the Checklist to evaluate the engineering and environmental aspects of dam decharacterization projects, the monitoring plans for the solutions adopted, and the impacts generated.

The Checklist was developed in the following phases:

Phase 1: Identification of legal and normative requirements

The regulations and standards pertinent to the situation were identified, classified by theme, and included in a specific list for each mandatory topic in the dam decharacterization process. This included environmental regulations, engineering standards, safety guidelines, and more.

Phase 2: Analysis of risks and impacts

A list was made of the items to be observed prior to the decharacterization work that are related to the risks associated with the dam's decharacterization, and of the potential environmental impacts. Factors such as soil erosion, sediment release, and changes in rivers, have implications for fauna and flora, and surrounding communities.

Phase 3: Inclusion of items

The analysis had to include items related to environmental recovery projects, as well as monitoring plans for fauna and flora, and the impacts generated. Additionally, items related to structural stability, water quality, and biodiversity, among others, were included.

Phase 4: Inclusion of items related to GISTM and the UN SDG goals

Each phase of the decharacterization work had to be analyzed, and items had to be prepared to achieve the ultimate goal of avoiding any harm to people and the environment (zero damage), with zero tolerance for human fatalities. In addition, these criteria were interconnected with the SDGs, which address the main development challenges faced by people in Brazil and around the world.

Phase 5: Development of the Checklist

The Checklist items were grouped into five axes:

1. Decharacterization Engineering Projects;
2. Degraded Area Recovery Projects;

3. Socio-environmental Recovery Projects (adherence to the SDGs);

4. Monitoring Plans; and

5. the GISTM.

The items are evaluated as “met,” “not met,” and “not applicable.”

Phase 6: Cross-check

After the Checklist’s initial development, it was subjected to a cross-check process. Contributions were sought from other experts within the company to verify the approach in different contexts, structures, and for adherence to best practices.

Phase 7: Pilot test and final review

An initial version of the Checklist was applied to the decharacterization of a real dam to evaluate its effectiveness and identify possible improvements. After the pilot test, feedback was collected from those involved, and the document was revised for the final version.

Regarding post-decommissioning monitoring, the Checklist addresses issues to be evaluated regarding geotechnical stability and environmental aspects, divided into physical, biological, and anthropogenic means. Among the components of the physical environment are water quality, soil quality, air quality and sediment transport. Biological components include the protection of local fauna, ecotoxicological bioindicators, vegetation composition, and succession. Chemical components include toxicological indicators in water, soil, and air quality. Finally, for the anthropic components, actions and monitoring of the fauna associated with human occupation and the presence of entomological vectors are evaluated. Thus, it is intended to obtain a set of environmental quality indicators for decharacterization of mining dams projects.

Data and discussion

This Checklist was designed to be adaptable to different scenarios and should be applied so as to be most applicable to the items to be analyzed. As shown in Figure 1, and mentioned above, the Checklist was divided into 5 Axes: Decharacterization Engineering Project, Degraded Area Recovery Projects, Socio-environmental Recovery Projects (adherence to the SDGs), Monitoring Plans, and the GISTM.

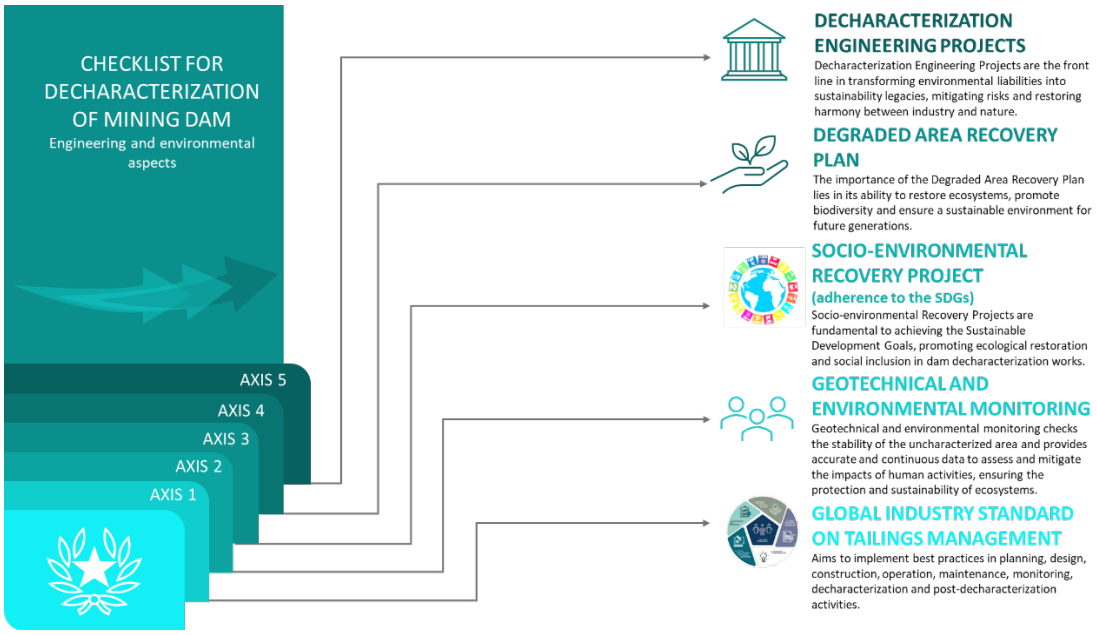

Figure 1: Main axes of the Checklist for decharacterization of mining dams

Decharacterization engineering projects

This axis was divided into three sets of requirements, adjusted to the legal and normative requirements of the State of Minas Gerais and Brazil. For application in other Brazilian states or countries, some requirements must be reviewed considering local characteristics. To fulfill the first requirement, the adequacy of the geological-geotechnical investigations, the instrumentation plans, the hydrological design criteria, and the safety factors, among others, are analyzed. This is based on the requirements of the Terms of Reference for the decharacterization of dams raised by the upstream method (prepared by the State Foundation for the Environment of Minas Gerais – FEAM).

The second analysis required is the Brazilian Standard NBR 13.028/2017, referring to the preparation and presentation of mining dam projects. In the last requirement of this set, criteria were defined to be met by the As Built Project.

Degraded area recovery plan

This axis refers to the aspects of environmental recovery of the area to be decharacterized. Its objective is to ensure the effectiveness of the proposal for the restoration of ecosystems to promote the conservation of biodiversity. First, the plan's goals should be defined, including the desired deadlines. Subsequently, the origin of the degradation, the regional and local characterization, the delimitation of the intervention area, the methodology, the maintenance plans, how the results will be evaluated, the schedule, and the ways to give visibility to these requirements must be analyzed.

Social-Environmental Recovery Project (adherence to the SDGs)

The Socio-Environmental Recovery Project combined with the UN Sustainable Development Goals (SDGs) are addressed for this axis. The SDGs provide a comprehensive framework that integrates environmental protection, social justice, and economic growth, guiding actions to address global challenges holistically. By aligning socio-environmental recovery projects with the SDGs, it is possible to create integrated solutions that meet environmental and social needs and promote the resilience of communities affected by dams.

Geotechnical and environmental monitoring plans

After the completion of the decharacterization works, geotechnical monitoring should be continued for the time necessary to verify the project hypotheses, such as the medium and long-term hydrogeological model and the final stability of the area.

Environmental aspects must be foreseen in the Recovery Plan for the Degraded Area. The pre-existing impacts and those caused by the decharacterization continue for longer than the execution of the work itself. Thus, environmental monitoring is necessary and should cover both the physical and biological environments. If any socioeconomic impacts of the decharacterizations have been diagnosed, the monitoring of these can also be contemplated. The primary objective is to provide a solid and informed basis for developing strategies and procedures that protect human lives, minimize property damage, and promote rapid environmental recovery.

Global Industry Standard on Tailings Management (GISTM)

The entire decharacterization process is evaluated in this last axis, considering the topics, principles, and GISTM requirements. This evaluation extends from identifying and documenting the changes observed and carried out on-site, to evaluating the implementation of best practices in the activities of planning, design, construction, operation, maintenance, monitoring, decharacterization, and post-decharacterization.

Results

In the end, the Checklist for the decharacterization of mining dams included the interactions between legislation, technical standards, good practices for recovery of a degraded area, GISTM, and the UN Sustainable Development Goals (SDGs). Through a document analysis, the company's technical expertise, environmental and social data, and interviews with stakeholders, we seek to understand how the decharacterization of dams can simultaneously achieve its safety objectives and contribute to sustainable development, mitigating its negative impacts. Table 1 shows the items evaluated by theme.

Table 1: Quantitative of items by axis for the Checklist for decharacterization of mining dams

Theme	Subtheme	Quantitative
Decharacterization Engineering Projects	Term of Reference for the decharacterization of Dams raised by the Upstream Method (FEAM)	12
	NBR 13.028/2017 – Elaboration of mining dam project	38
	As Built Project	15
Degraded Area Recovery Plan	General	56
Socio-environmental Recovery Project (Adherence to the SDGs)	General	23
Monitoring	Geotechnical	3
	Environmental	19
Global Industry Standard on Tailings Management (GISTM)	General	77
Total		243

In a decharacterization project audited by AECOM, the completed and commented upon Checklist was forwarded to the mining company after its application. In the completed Checklist, all items were classified as "met," "not met," or "not applicable" and commented on. With this document, the mining company can implement the necessary adjustments.

Conclusion

The decharacterization of dams generates technical and governance challenges, and long-term safety and environmental adaptability risks must be considered. To make clear the aspects that must be considered to ensure the effectiveness of decharacterization projects, AECOM Brazil's multidisciplinary team developed the Checklist to consider technical guidelines, covering the entire cycle of the work and the cumulative impacts of post-decharacterization. The process involved several stages of elaboration, validation, and revision, enhanced by the contribution of specialists from different areas (engineers, geologists, veterinarians, biologists, sociologists, and geographers, among others).

The adoption of the Checklist was crucial for identifying weaknesses and enabling actions to improve and mitigate the potential damage caused by the decharacterization of dams. In addition, fulfilling the items listed in each area highlighted in the Checklist allows mining companies to lead technological innovations that promote sustainability, invest in green mining technologies, and modernize works, while reducing environmental impacts.

AECOM Brazil has been directly involved in the audit of dams in the process of decharacterization. Intensive analyses and inspections in collaboration with the Brazilian authorities resulted in the creation of

this Checklist. The need to adhere to global standards to prevent future disasters, linked to the advent of the standards established by the UN through the SDGs, stimulated the strengthening of auditing actions beyond Brazilian legislation.

In addition to the technical and logistical challenges, the Checklist assists in the analysis of the socio-environmental impacts of decharacterization works. It should be noted that engineering projects must consider the medium and long-term objectives of the recovery plan for the degraded area. With the adoption of the Checklist, these correlations can be verified early in a practical way. In addition, the procedure makes essential contributions to monitoring plans after the decharacterization, including the monitoring of physical and environmental stability according to the objectives defined in the recovery plan. Thus, the Checklist generates significant opportunities to promote inclusive and sustainable economic growth. The Checklist provides a detailed overview of how mining can align its operations with the best sustainability and socio-environmental standards, creating practical recommendations for companies, policymakers, and civil society organizations.

Acknowledgments

We would like to thank all the experts at AECOM who worked hard to produce a comprehensive Checklist incorporating years of experience.

The Importance of Hydrogeological Models for Closure of Tailings Dams

Ana Carolina Neves, AECOM, Brazil
Waldemar Felitti, AECOM, Brazil

Abstract

The ultimate stage of a tailings storage facility's (TSF) life cycle encompasses the following steps: closure plan, closure operations, post-closure, and relinquishment. According to Brazilian legislation, all these stages, from the development of a closure plan, extending through the post-closure phase, are referred to as "tailings dam decharacterization."

Following the 2015 and 2019 tailings dam ruptures (Fundão and Córrego do Feijão), the decharacterization of upstream tailings dams has become a mandatory requirement under Brazilian legislation. This measure is crucial for enhancing safety conditions in the downstream areas of the dam and ensuring that these structures do not pose any hazards to the nearby communities and environment. The decharacterization process must adhere strictly to technical engineering and environmental aspects and standards, to allow the extensive areas occupied by the tailings to be properly restored for safe future use.

The decharacterization design, specifications, and works require detailed studies encompassing several disciplines, including hydrogeological studies.

Hydrogeological models (HM) are approximate representations of nature's conditions, elaborated for integrating and synthesizing all the available data and information, offering a systematic and comprehensive understanding of hydrogeological site conditions. A HM is technically necessary at all stages of the decharacterization process. A consistent conceptual hydrogeological model (CHM) is extremely important at the early stages of the conceptual decharacterization project to support the best decisions for the project alternative, strategy, and closure methodology. Once the level of data required to support the models increases, and the projects evolve through the conceptual and planning stages from basic to detailed projects, it becomes necessary to build a numerical hydrogeological model (NHM). This can provide fundamental information for detailed tailings dam decharacterization designs, specifications, and works. At decharacterization works, a NHM is indispensable to organize water-related monitoring data, to support dewatering/drawdown strategies, and to manage water table levels for a safe excavation or grounding. One important application of the NHM is to predict future groundwater conditions and hydrodynamics at

different construction or excavation phases. It estimates critical scenarios and potential geotechnical, engineering, and environmental risks.

At the post-closure stage, continuous monitoring is required, providing input data to the NHM and constant evaluation of the CHM. This enables the assessment of the hydrogeological and geotechnical aspects of the remaining structure, ensuring that its physical and chemical stability can be attested.

This paper examines the applications of the conceptual and numerical hydrogeological models as fundamental tools for the tailings dam decharacterization process. It argues that their application will ensure valuable support for decision-making concerning environmental and engineering aspects.

Introduction

Catastrophes involving the rupture of upstream tailings dams over the last decade in Brazil have caused unacceptable human losses and immeasurable environmental damage. Consequently, the governmental regulatory agency, the Brazilian National Mining Agency *(Agência Nacional de Mineração – ANM)* through Resolution ANM n° 4/2019, revised by ANM n° 13/2019, has prohibited the construction of upstream dams in Brazil. ANM set a deadline, determining that upstream dam owners are responsible for carrying out their decharacterization process.

Based on technical and scientific literature such as the *Waste Management – Good Practices Guide* (ICMM, 2021) and the *Tailings Management Handbook* (Morrison, 2022), this paper suggests that the protocols for tailings dam decharacterization align closely with the final stages of a TSF life cycle, as outlined below:

- Closure planning: this phase encompasses feasibility and alternative studies for closure, along with conceptual, basic, and detailed designs and plans.
- Closure operations: this stage includes TSF decommissioning, monitoring, and closure activities.
- Post-closure: routine inspections and monitoring of geotechnical, hydrological, hydrogeological, and environmental aspects are conducted.
- Relinquishment: the final stage involves the formal transfer of responsibilities associated with the TSF or, as established by the Brazilian National Mining Agency (ANM), the exclusion of the structure from the official list of tailings dams, so that the area can be available for future use.

The government determination for the upstream tailings dam decharacterization has required integrated studies across the various fields of expertise: geotechnics, geology, engineering, hydrology, hydrogeology, geophysics, and environmental sciences, among others.

A wide range of information should be considered in the tailings dam decharacterization, such as: risk assessment; physical, chemical, and mineralogical characteristics of the tailings; As Built and As Is facility

designs; regulatory and environmental requirements; engineering and mining industry standards and guidance; existing infrastructure maps; existing water management plan; topography data; climate; hydrology, hydrogeology and geotechnical monitoring; land restoration, revegetation; and studies of the availability of materials for use in the construction.

Hydrogeology makes an important interface with the mentioned disciplines, making it essential that hydrogeological models (HMs) are applied at all stages of the tailings dam decharacterization process.

The conceptual hydrogeological model (CHM) and the numerical hydrogeological model (NHM) require for their elaboration: tailings projects and As Is design; topographical data; existing infrastructure and tailings deposits (map and cross-sections); sectorization and characterization of the different types of tailings deposits; a water management plan; tailings chemical and physical characteristics; a hydrographic network; geomorphology; hydrology; climate (rainfall and evaporation data, including long-term climate change projections); hydrogeology of surficial and bedrock units; estimated hydraulic conductivity based on geological characteristics; soil characteristics; geotechnical monitoring; lithological and geological-structural information (including maps and cross-sections); water quality data; hydrogeochemical baseline; available monitoring data (well-monitoring data, groundwater level, and hydraulic head, flow and discharge rates, water level in reservoirs, etc.); spring maps and related data; and watershed delineation and flow patterns. Additional investigations may be necessary to add new information to the CHM and accuracy to the NHM, such as geophysical surveys, detailed geological-structural mapping, photointerpretation, log surveys, and hydrodynamic tests.

The model improvement and accuracy depend on data acquirements. It is expected that data will increase as the project evolves, so models demand regular updates as phases and work progress.

In general, a CHM is recommended from the closure project feasibility stage onwards. The CHN precedes the NHM and helps in the choice of the numerical code to be used to implement the numerical model. The most used codes are Finite Difference (MODFLOW) and Finite Elements (such as FEFLOW). The code choice is made mostly considering the complexity of the site and geology.

The tailings physical, chemical, and mineralogical characterization must be evaluated before deciding on tailings reclamation strategy, and the tailings acquired parameters should be included in the numerical model. It is crucial to consider the CNM and the NHM while making detailed designs for decharacterization and also while executing decharacterization operations and monitoring stages, and finally while evaluating the remaining structure's chemical and physical stability before its relinquishment.

Tailing dams decharacterization: Overview and concepts

Tailings are materials without economic interest, discarded from the processing of mined iron ore. They consist of uneconomic crushed rocks, metals, and effluent from the concentration processes used to extract

the desired elements from iron ore. Tailings are stored in a tailings storage facility (TSF); the most used in Brazil is the tailings dam. The upstream method consists of supporting the higher raised embankments on the tailings or sediments previously deposited in the dam reservoir.

Brazilian legislation defines a decharacterized dam as a structure without water accumulation and without tailings and sediments being received permanently. It no longer possesses the characteristics or performs the function of a dam. In accordance with the technical design, decharacterization comprises, but is not limited, several completed phases (ANM, 2022 and 2023).

The Brazilian National Mining Agency has established detailed regulatory legislation to ensure that the liable mining company performs the best practices and state-of-the-art technologies during the dam decharacterization process. According to ANM (Resolutions N° 95/2022, N° 130/2023) and the Environmental State Agency, the process must encompass several phases and procedures, summarized as:

1. decommissioning – ending operational work and removing related infrastructure;
2. hydrological and hydrogeological control – including procedures to reduce or eliminate the surface and groundwater supply to the reservoir and to control the water table;
3. ensuring the long-term physical and chemical stability of the remaining structures;
4. monitoring to ensure the effectiveness of hydrological and hydrogeological stabilization and control measures.

The monitoring stage must be divided into two distinct phases:

1. active monitoring: this comprises the minimum mandatory period of two years established in item "D," and may be extended as defined by the project designer;
2. flexible monitoring: an additional non-mandatory period of monitoring, unless formally required by the Brazilian National Mine Agency, or as defined by the project designer.

Implementing best practices and conducting continuous monitoring aims to meet the criteria prescribed in the technical and legal standards, ensuring long-term physical and chemical stability.

Environmental agencies of the Minas Gerais State (FEAM and SEMAD) also contributed to regulating environmental aspects by publishing the *Reference Document for the Decharacterization of Upstream Tailings Dams,* which establishes the minimum requirements for decharacterization projects and designs (Minas Gerais, 2019).

The Brazilian regulatory agencies consider a structure effectively decharacterized only upon fulfilling the minimum required stages stipulated by the mining and environmental authorities. Furthermore, the resolutions specify that completely removed mining dams and reservoirs are exempt from routine monitoring. As was mentioned, the regulatory guidelines from the Brazilian authorities concerning tailings dam decharacterization are aligned with international guidelines that define basically three stages: the

closure plan, closure, and post-closure. The closure stages begin when the tailings disposal ceases permanently, and the closure plan is implemented. This includes these activities:

- removal of infrastructures, such as tailings pipelines;
- changes in water management or treatment;
- construction of cover systems;
- a progressive reclamation plan;
- setup of reservoir, landfills, or other structural elements such as revegetation landform.

This broad range of measures aims to ensure the long-term physical and chemical stability of remaining structures, and to maintain the monitoring and surveillance plan during the post-closure period until effective site restoration.

Tailings dams can be classified according to their decharacterization works methodology (Neri et al., 2021), such as: complete or partial removal of tailings materials; the need for water level drawdown in the reservoir; and implementation of devices to reduce water input from surface and/or groundwater flow. Some designs propose the construction of downstream reinforcement buttresses to increase the safety factor.

Although there are many uncertainties related to dam conception phases regarding its final destination, there are useful tools to minimize the uncertainty, such as conceptual and numeric hydrogeological models, which can be applied to make predictions for different scenarios.

This paper presents examples of the application of hydrogeological models across different stages of a dam decharacterization project in the Iron Ore Quadrangle, Minas Gerais state. This work aims to contribute to the related subjects of hydrogeology and the decharacterization process, based on the authors' practical experiences of auditing TSF decharacterization works in the Minas Gerais Iron Ore Quadrangle. For the sake of confidentiality, the paper does not include site identification and company names.

Applying hydrogeology to tailings dam decharacterization process

Hydrogeological models are valuable tools that provide sufficient knowledge for planning tailings dams closure, on-going operation for closure and monitoring stages until its restoration (post-closure). As it was mentioned before, all these stages comprehend the process for tailings dam decharacterization, according to the Brazilian legislation and mining regulations.

Closure plan

Feasibility and plan: this consists of selecting the most appropriate combination of technology and the tailings facility location for a given site to reduce risks and minimize closure liability. From its conception, the tailings dam project for closure should be an important issue to be considered. Whatever the strategy is, the decharacterization project should be considered as part of the TSF life cycle. Planning the closure or

dam decharacterization from the point of conception is crucial, as the project's feasibility depends on costs, and the decharacterization process can be very costly, if not properly planned.

The selection of the best alternative for the dam decharacterization project must be based on information from local hydrogeology and must consider the tailings' chemical, physical, and mineralogical characteristics, aiming to achieve lower impacts and to ensure environmental safety.

It is an important concern that the decharacterization projects may require tailings dewatering and/or the drawdown of the water level of the foundation and embankments. Figure 1 illustrates a situation where the phreatic level must be lowered to achieve total tailings removal.

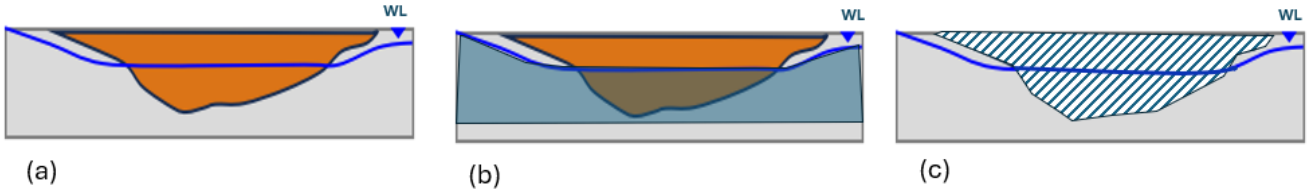

Figure 1: Amount of water needed to be extracted at excavated topography. (a) Initial condition, with intact tailings, (b) 2D representation of the amount of water needed to be removed, and (c) tailings deposits needed to be removed

Operational difficulties must be foreseen at the planning stage, and hydraulic conductivity of the waste cannot be disregarded, as it directly influences the time to draw down and the operational efforts.

The best design alternative for decharacterization must also integrate environmental and social aspects to the engineering pros and cons, and must be chosen over alternatives with greater social, biological, chemical, and physical impacts.

For a conceptual tailings decharacterization project, a CHM provides an understanding of whether the decharacterization solution must consider tailings dewatering and groundwater drawdown. An illustration is presented in the cross-sections in Figures 2 and 3, which represent an upstream dam that needed to be decharacterized, and three different engineering decharacterization approaches.

Figure 2b shows a decharacterization method in which no water drawdown is needed. This design solution is suitable for sites with unavailable disposal areas and no feasibility to drawdown the phreatic table due to hydrogeological, geotechnical, and/or environmental constraints. Figure 3 shows two different methods for a tailings dam decharacterization, both including tailings and embankments removal. The difference between them (Figures 3a and b) is the amount of tailings material removed and the existence or not of the remaining structure. There are pros and cons for each strategy, and the criteria to evaluate the best method must consider the time for dewatering, geotechnical parameters for the dam safety evaluation, and the availability of stock areas for the removed tailings.

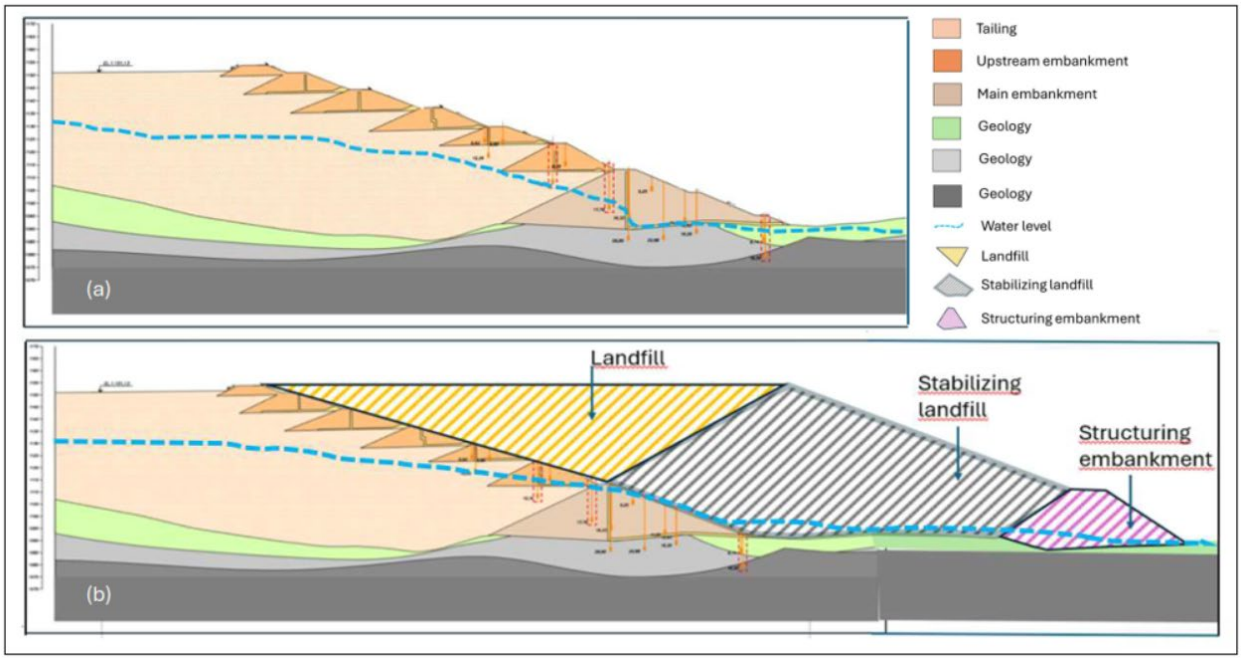

Figure 2: Schematic cross-sections for upstream tailings
(a) upstream dam section
(b) engineering strategy for stabilizing upstream tailings raise, using decharacterization fill and embankment buttresses

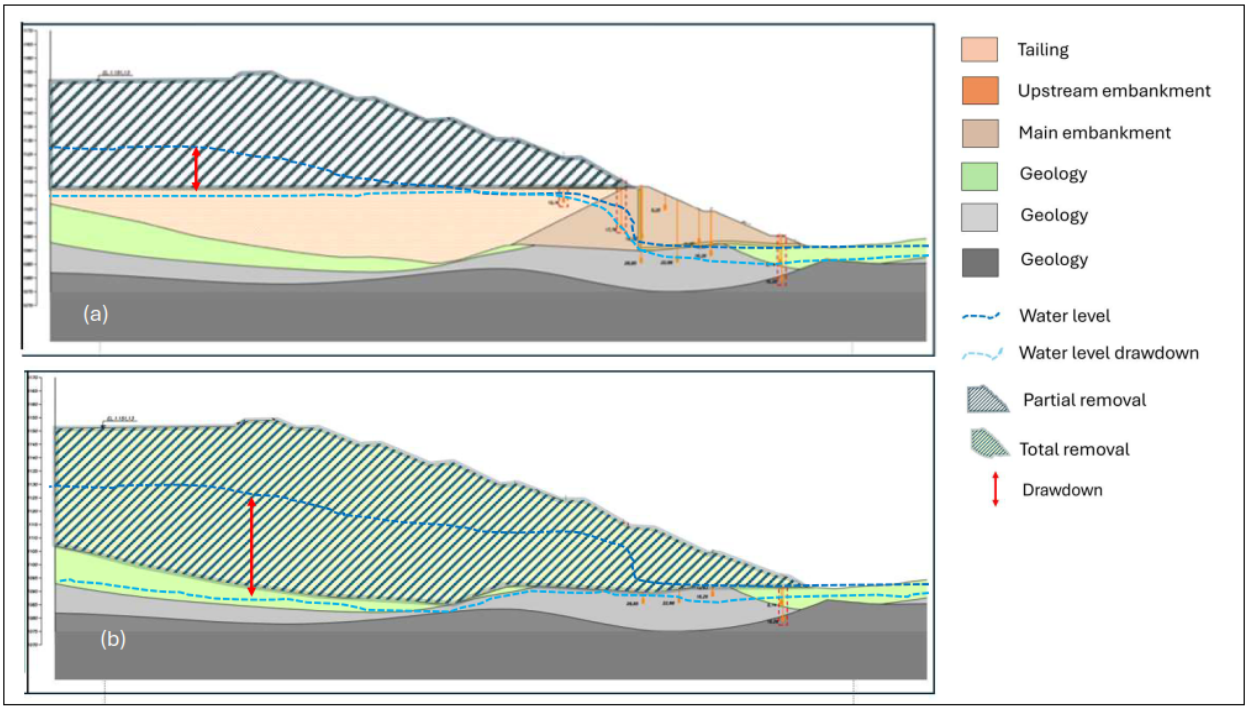

Figure 3: Schematic cross-sections for decharacterized upstream tailings dam
(a) partial tailings removal;
(b) total tailings removal

Environmental issues also need to be addressed: it is paramount to assess all the environmental and social impacts related to each project design and alternative.

Predictions can be made using a numerical model. These can simulate tailings and embankments drawdown using different techniques. Using these, the designers can evaluate the results to choose the best dewatering strategies for each case.

Both strategies, the decharacterization fill and embankment buttresses project (Figure 2b) and the partial tailing removal project (Figure 3a), require an internal drainage system. The numerical hydrogeological model (NHM) serves as an auxiliary tool to assess and compute the internal dam and buttress drainage systems capacity for the safe discharge of the water flows.

The designer must evaluate hypothetical groundwater levels during the construction stage for geotechnical stability assessments, and also for the remaining landfill embankments and natural terrain slopes. A suitable project design solution for each situation and condition must be carefully analyzed.

Concerning environmental aspects, during the planning stage, environmental professionals must consider the impacts of the water resources for each decharacterization strategy. The NHM provides predictive results for changes in hydrodynamics availability and quality; estimates the tailings transport constituents solubilized in groundwater; and provides time estimates for hydrodynamic stability. Depending on the decharacterization method, the time for stabilization could vary significantly. The choice of the types of covering and vegetation for restoration of the area should also take into account the implications for the ground and surface water resources, as they differ on recharge and infiltration precipitation percentages.

Closure operations

At the operational stage, a detailed NHM is useful for testing and implementing an effective strategy to reduce or eliminate the surface and groundwater supply for the tailings dam reservoir.

The numerical model provides information to evaluate the efficiency of the adopted procedures during operation and to manage the water table level during the excavation works. According to Brazilian legislation, the TSF owner must periodically report to environmental agencies about the procedures applied to reduce or eliminate the groundwater and surface water supply for the tailings dam reservoir during the operational stage.

Pumping wells for drawdown, excavation of sumps and drainage trenches are examples of procedures to implement water level control in the reservoir. The numerical models could indicate the best location for drainage systems, predicting the efficiency of each method.

An important aspect to be observed during the drawdown of the tailings water level is the rate of phreatic surface lowering. Numerical model simulations can provide the optimum discharge to avoid rapid water level variation, which can trigger static liquefaction of the tailings.

When a NHM is calibrated for a permanent situation, it can provide water level and discharge predictions for a specific moment (e.g., the discharge volume or water level for the end of an excavation phase). If it is calibrated for a transient situation, the predictions include the time parameter, providing essential answers for supporting engineering and decharacterization works; for example, time estimates for water level drawdown at desirable excavation levels. Figure 4 is an illustration of the water level at each excavation time, produced by numerical hydrogeological model software.

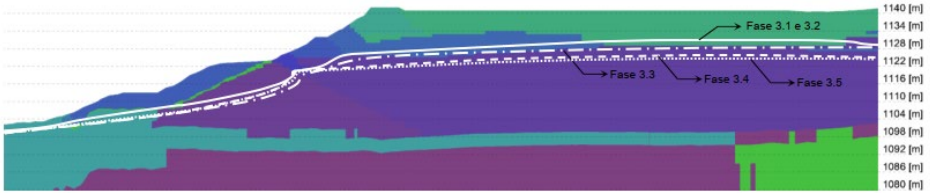

Figure 4: Illustration of water level drawdown computed for excavation stages

During decharacterization works, the NHM should be constantly updated. New data input can provide better calibration and simulations that may indicate a need to adjust the plan when unexpected conditions are encountered. As the model is updated, the implemented decharacterization design can be adjusted when water level and hydraulic head simulations over time do not achieve geotechnical safety parameters.

The NHM estimates the long-term groundwater level recovery conditions after decharacterization works, providing information for better planning of the decharacterization monitoring stages (passive and flexible).

Monitoring

The monitoring of the chemical and physical aspects of the water resources is essential throughout the entire tailings dam decharacterization process, from the initial closure design. The quali-quantitative parameters of the groundwater and surface water should be monitored. Measures of rainfall, evaporation, water level (phreatic, hydraulic heads, reservoir), and discharges (water catchment, water courses, pumping and dewatering wells, pumping in ponds), are essential data to be collected during the TSF life cycle. The existing monitoring plan should be maintained, as far as possible, for later evaluation. Historical data sets allow for the interpretation of the changes in water level, flow, and quality.

The diagnosis of physical and chemical aspects related to surface and groundwater resources, as well as the prognosis for impacts during the operational and post-decommissioning stages, are essential for the elaboration or adjustment of the monitoring decharacterization plan.

Impacts on water resources resulting from the implementation of the tailings dam decommissioning project may include changes in hydrodynamics, availability and quality. Forecasting these impacts using a

NHM will guide the optimal distribution of monitoring wells and surface points, parameters, and sampling frequency.

Water resources impact evaluations can better be assessed with the NHM, providing necessary information for mitigation and remediation procedures.

Physical stability is reached when hydrodynamic monitored parameters are in equilibrium with the surrounding environment. Similarly, chemical stability can be assessed based on monitored data, if the thermodynamics and chemical aspects are in balance with the surrounding environment. The NHM can predict when this stability should be achieved. An updated numerical model, through ongoing decharacterization works and a post-work monitoring period, is important to confirm design expectations and to forecast more realistic scenarios over time.

Conclusion

Hydrogeological models are valuable tools that can be applied and used in the tailings decharacterization process. The regulatory guidelines from the Brazilian authorities concerning tailings dam decharacterization are aligned with international guidelines that define the final stages of the life cycle of the TSF as closure plan, closure, and post-closure. The hydrogeological conceptual and numerical models must be integrated into other disciplines from the early stages of closure design: planning the tailings dam closure, ongoing operation for closure, monitoring stages, and the complete area restoration (post-closure).

A NHM helps to estimate the effects of the engineering and environmental procedures taken to ensure the long-term physical and chemical structures stability. Water level, discharges, and quality data through the flexible monitoring phase should be input data to be included in the model, with frequent updates, so that stability predictions can be improved.

As explained, transient models can predict the time required for site hydrodynamic stabilization; support geotechnical and environmental stability assessments, which are required for attesting its final stabilization; simulate critical situations; and support mitigating measures that could be implemented to avoid environmental and geotechnical losses or damage.

Tailings Dam Decharacterization Projects: Proposal for Water Monitoring Plan

Ana Carolina Neves, AECOM, Brazil
Helen Simone Chiaranda, AECOM, Brazil
Bruno Resende Lopes, AECOM, Brazil
Rafael Gomes Oliveira, AECOM, Brazil

Abstract

The term "decharacterization" of a dam structure is a technical expression commonly used in Brazil to describe the final stages of a dam's lifecycle. The entire process encompasses studies for choosing the best decommissioning alternative and methods, planning and projects development, operations, monitoring, post-decommissioning management, and final assessments for attesting safety and environmental remaining structure stability, enabling the area to be fit for future uses.

The decharacterization of tailings dams demands engineering measures aimed to close mining structures, a mandatory requirement by Brazilian regulatory agencies for dams constructed using the upstream method. The guidelines regulating decharacterization projects encompass, in addition to engineering actions, measures to ensure the structure's physical, chemical, and biological stability. They also include monitoring the effectiveness of these measures through establishing a monitoring program for as long as necessary until these stabilities are achieved. Even though monitoring is fundamental, the normative instruments do not establish clear and comprehensive guidelines defining minimum requirements to ensure the sustainable stability of the remaining structures on site. Considering the influence of water presence on the stability of physical and chemical structures, this study proposes a water resource monitoring plan with the minimum requirements necessary to meet the objectives of a decharacterization project. The proposal addresses the sampling of surface water, groundwater, and effluents, including essential aspects for defining an efficient monitoring network, such as the parameters to be monitored, sampling frequency, criteria, and methodologies for data interpretation, and corrective actions. All points outlined in the plan were based on the authors' auditing experience of decharacterization projects in the state of Minas Gerais and the Brazilian governmental recommendations, legislation, and regulations.

Introduction

The decharacterization of upstream tailings dams has become mandatory in Brazil following the failures of such structures in Mariana (2015) and Brumadinho (2019), both in the state of Minas Gerais. This regulation aims to mitigate the inherent risks associated with this construction technique, which has proven to be susceptible to failure. Adopting this regulatory policy is a necessary response to safeguard the environmental safety of communities potentially affected by potential tailings dam ruptures.

In Brazil, the term "decharacterization" is a relatively recent concept that refers to a series of intervention actions aimed at rendering tailings dams non-functional. In general, these actions involve controlling surface and groundwater runoff into the reservoir, and prohibiting flood transit in the reservoir, which results in the transformation of the dam structure into an integrated part of the surrounding topography (Sánchez et al., 2013).

The regulatory legislation of the Brazilian state of Minas Gerais (Terms of Reference for Decharacterization of Dams Built using the Upstream Method [SEMAD and FEAM, 2019]) establishes the minimum requirements for a decharacterization project. In parallel, Federal Resolutions nº 95/2022, 130/2023, and 175/2024 of the National Mining Agency (ANM) consolidate the normative acts that govern the safety of mining dams. These regulatory guidelines establish that the technical decharacterization project must necessarily include effective measures aimed at minimizing or eliminating the input of surface and groundwater into the reservoir. Additionally, the project must incorporate measures that ensure the structure's physical, chemical, and biological stability, underscoring the requirement for continuous monitoring during and after the decharacterization process. According to regulatory legislation, this monitoring should persist for the necessary duration to validate the effectiveness of the adopted decharacterization measures.

According to Article 2 of ANM Resolution nº 130/2023, updates were made to the definition of decommissioned mining dams and their minimum decharacterization stages. Recent updates require a minimum of two years of monitoring after the completion of decharacterization works, during the active monitoring phase, and the possibility of passive or flexible monitoring after the mandatory period.

The environmental aspects of decharacterization are an important issue to be considered. Actions and programs to control, mitigate, recover, and compensate for the environmental impacts caused by dam decharacterization operations must be adopted and maintained for the same monitoring period after their completion.

All the data acquired during the active monitoring period, after the completion of the decharacterization works, will determine the fulfillment of all decharacterization objectives, especially those related to geotechnical and environmental stability. In this sense, it is important to emphasize that the

geotechnical and environmental stability of the remaining structure must be demonstrated, certified, and approved by government and mining agencies.

The presence of water governs geotechnical stability, hydraulic safety, and environmental aspects. The monitoring of groundwater, surface water, and tailings dam effluents during and after decharacterization works should encompass criteria that cover water quality, water levels, hydraulic head, and flows. Additionally, it is essential to adequately establish the baseline or background of surface water, groundwater, soil, and sediments in the areas affected by the structure, as well as the chemical and physical characterization of the tailing and remnant materials. Without this data, there is a risk of imposing unnecessary requirements to achieve water quality standards that may not align with the baseline or natural conditions observed initially.

Despite the importance of water monitoring during and after the execution of the decharacterization project, the lack of information on procedures and minimum requirements are a challenge to its effectiveness. To address this lack, this article aims to provide guidelines and a proposal for monitoring surface and groundwater resources and effluents in decommissioned dams and surrounding areas, based on the authors' auditing experience in the Quadrilátero Ferrífero region, state of Minas Gerais. Monitoring is crucial for obtaining data that can support the stability of the structure from an environmental and water resources perspective, supporting the declaration of the dam as effectively decommissioned.

Tailings dam decharacterization: overview and concepts

The upstream construction method is a dam-building methodology in which the embankment fills are supported on previously deposited tailings or sediment, including those built on tailings from existing reservoirs (ANM, 2024). According to the Terms of Reference for Decharacterization of Upstream Dams, developed by SEMAD and FEAM (2019), a decommissioned dam is one that no longer receives tailings from its core activity, ceases to function as a dam and meets adequate safety conditions according to the technical decharacterization project, which comprises the following stages:

1. cessation of operations with the removal of associated infrastructure (decommissioning);
2. adoption of effective measures to reduce or eliminate the input of surface and groundwater into the reservoir;
3. execution of measures aimed at ensuring the long-term physical, chemical, and biological stability of the structures remaining on-site; and
4. monitoring for the period necessary to verify the effectiveness of the measures adopted for decharacterization.

There is a correspondence between the stages established for the decharacterization of a tailings dam in SEMAD and FEAM (2019) and ANM (2022) and the stages of closure of tailings storage facilities (TSF) according to ICMM (2021) and Morrisson (2022). The closure phase begins when the disposal of tailings permanently ceases and the closure plan is implemented, including activities such as infrastructure removal, such as tailings pipelines, changes in water management or treatment, construction of covers, progressive recovery plan, and revegetation or reshaping of the tailing reservoir, landfills, or other structural elements.

The requirements of SEMAD and FEAM (2019) and ANM (2022) are similar to those of ICMM (2021) and Morrisson (2022) for ensuring the long-term physical and chemical stability of the tailing storage facilities and remaining materials as well as maintaining the monitoring and surveillance plans for the post-closure period until the effective restoration of the area (Post-Closure and Relinquishment).

The particularity of Brazilian legislation, compared to international technical guides, is outlined in Article 1 of ANM Resolution nº 130/2023, which establishes monitoring and follow-up stages for a minimum period of two years after the completion of decharacterization works (active monitoring) and an additional non-mandatory monitoring phase (passive monitoring), aiming to ensure the effectiveness of stabilization, hydrological, and hydrogeological control measures. According to the Terms of Reference, the dam will be considered decommissioned after the completion of decharacterization works, and the effectiveness of the measures will be evaluated through the monitoring of the maintenance and monitoring program (SEMAD and FEAM, 2019), as shown in Figure 1.

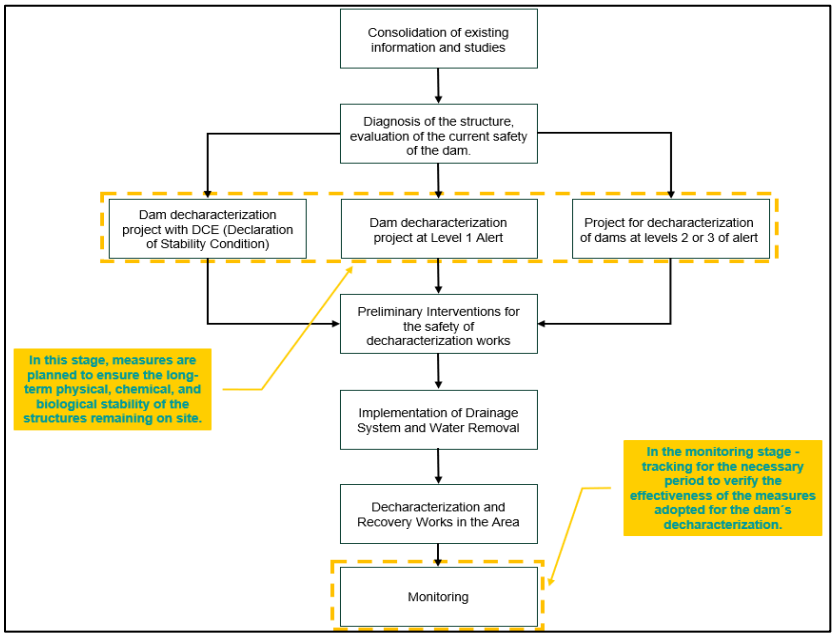

Figure 1: Synthesis of the decharacterization stages (modified from SEMAD and FEAM, 2019)

Tailings dam decharacterization project: water resources diagnostic and related impacts

Physical and chemical parameters should be monitored throughout all stages of a tailing dam decharacterization. A temporal representative data set would provide a better understanding of any changes in parameters, ensuring a good evaluation of the stability of the structure at the end of the process. The existing water monitoring network of the operating dam should be maintained and reviewed to encompass the modifications required in the decharacterization works stage and adapted for the active monitoring stage. A revision of the water resources monitoring plan is fundamental to incorporate all the probable or predicted impacts on surface and groundwater from the decharacterization works. Understanding hydrodynamic and chemical aspects concerning surface and groundwater resources, along with predicted impacts throughout operational and post-decharacterization phases, is crucial for developing or adapting the monitoring plan.

In Brazil, the Foundation for Technological Development of Engineering, State of Minas Gerais (Neri et al., 2021), conducted a study on the socio-environmental impacts associated with the decharacterization of tailings dams. The report presents a standardized list of activities involved in the decharacterization process, indicating potential socio-environmental impacts. Based on the practical examples in Neri et al. (2021) and the authors' expertise, the following potential impacts on water resources resulting from the implementation of tailings dam decharacterization projects are listed:

- Alteration of surface and/or groundwater dynamics.
- Increase or decrease in recharge areas.
- Landfilling of discharge areas and suppression of springs.
- Alteration (reduction or increase) of local or regional water availability.
- Reduction or increase in base flow rates of watercourses.
- Contamination of surface and groundwater resources.
- Alteration of surface and groundwater quality.
- Generation of acid drainage.
- Sedimentation of watercourses.

Regarding surface water resources, the impacts predicted during decharacterization works mainly affect the watercourses downstream of the worksites. Interventions imply the possibility of sediment input and other forms of degradation and pollution, intervention in areas of permanent preservation, diversion of watercourses, basin transposition, and construction of downstream containment dams. Given these possibilities, the surface water monitoring network during and after the decharacterization works should encompass the downstream watercourses where there will be direct interference with the project,

considering the impact as effective in these locations. However, there is also a need to monitor the watercourses in areas of indirect influence.

In numerous tailings dam decharacterization projects, lowering the groundwater level becomes necessary. This can be achieved by installing pumping wells or constructing structures like sumps and trenches within the tailing reservoirs. Such measures have the potential to significantly impact local hydrodynamic conditions.

It is important to conduct the diagnosis of the surface and groundwater resources, sediments, and soils within the area undergoing decharacterization efforts. Similarly, it is crucial to assess the potential impacts on these matrices. This ensures a comprehensive understanding and effective management of environmental impacts. This is a fundamental predecessor activity that will support an effective monitoring plan, guiding the optimal placement of monitoring points, parameters, and sampling frequencies. The monitoring plan should consider the specificities of each location. To support the development of a specific plan for the area subject to decharacterization interventions, this work proposes some minimum requirements necessary to assess changes in the monitored parameters. Implementation of a comprehensive monitoring program that collects both spatially and temporally representative data will effectively confirm the physical and chemical stability necessary for the decharacterization of a tailings dam.

Decharacterization baseline and background establishment

The decharacterization baseline refers to the condition and quality of the matrices (surface water, groundwater, soil, and sediments) prior to the implementation of the decharacterization works. The term background will be used to indicate the natural status of the matrices (hydrogeochemical and geochemical characterization) prior to the presence of the mining, without anthropic influence.

For baseline and background establishment these things are necessary:

- Representative locations for sampling each matrix considering the geological aspects and types of soil.
- Technical and statistical criteria for defining the number of observation points (location distribution).
- Sufficient and representative temporal data collection at each observation point.
- Technical and statistics methodology for data analysis.

Acquired monitoring data will provide support to evaluate and compare matrices characteristics in the pre-works stages, supporting measures to mitigate or remediate identified impacts. A robust historical data series of qualitative and quantitative data is necessary information for supporting the analysis of the hydrodynamic and chemical stability of the remaining structure.

Hydrogeological model

An effective surface and groundwater resources monitoring network should be supported by a conceptual hydrogeological model. Hydrogeological models are approximate representations of the natural environment. They are essential for the assessment and refinement of the water resources monitoring plan during decharacterization. Hydrogeological models integrate and synthesize all hydrogeological and relevant information, providing a systematic and comprehensive understanding of the site conditions. Although they are necessary for all stages of the decharacterization process, they are crucial for environmental purposes in the planning and post-works phases. During the planning phase, the hydrogeological model supports decisions on selecting the best methods for carrying out the decharacterization project and works, aiming to reduce impacts on water resources. At the post-works decharacterization stage, the models are fundamental to supporting the analysis of the physical and chemical stability of the remaining structure.

Numerical models can be applied to predict future groundwater and surface water qualitative and quantitative impacts. The continuous monitoring of hydrodynamic parameters (flow rate, groundwater level, hydraulic head, and water level in reservoirs) and water quality parameters provides new information to improve conceptual and numerical models. Consequently, a better representative model contributes to improving the monitoring network, facilitating a comprehensive assessment of the hydrodynamic and chemical stability site condition.

Water monitoring plan

The establishment of a water monitoring plan is intended to meet the decharacterization project's objective of verifying the maintenance of hydrodynamic and chemical stability by the structure undergoing decharacterization. Monitoring will allow for the evaluation of the effectiveness of the engineering actions employed in controlling the release of chemical load from the tailings to water resources. To this end, the plan must fulfill minimum requirements, such as:

- Monitoring network for surface water, groundwater, and effluents.
- Parameters monitored.
- Sampling frequency.
- Sampling and analysis methodologies.
- Data quality management procedures.
- Criteria and methodologies for data interpretation.
- Corrective actions.

Matrices analyzed

The selection of the matrices to be analyzed is intended for the evaluation of the effectiveness of the decharacterization measures adopted to reduce water input to the structure's reservoir and protect water resources. It is necessary to monitor:

- Effluents from surface water drainage captured by the dam's hydraulic structures and reservoir (including main and peripheral drainage channels and berm channels).
- Effluents originating from water percolating through the reservoir, captured by the structure's intermediate and deep internal drains.
- Effluents entering and exiting treatment systems.
- Surface waters potentially receiving drained effluents from intervened structures.
- Groundwaters potentially receiving drained effluents from the structure.

Monitoring network

To meet hydrodynamic and hydrological criteria, the monitoring plan should include strategically located monitoring points. These points will measure flow rates in watercourses and surface drainage systems, flow rates in bottom drains of dam or reinforcement structures, water levels in reservoirs, groundwater levels, hydraulic heads, flow rates in lowering wells, and flow rates in drainage systems such as trenches and sumps. Additionally, the plan should incorporate monitoring points for climatic conditions like precipitation and evaporation, although these will not be extensively covered in this work.

The monitoring network should be defined for surface water, groundwater and effluents, aiming to obtain data for the remaining structural stability assessments. It is important that the quality monitoring plan is accompanied by flow rate and water level monitoring, to provide data for an integrated analysis.

For effluents generated by the drainage of surface waters and waters that percolate through the tailings, the sampling grid should consider the discharge points of these drains, in locations where there is sufficient turbulence to ensure mixing and the consequent representativeness of the effluent to be sampled. Entry and discharge points of treatment systems, if they exist, should also be included in the effluent monitoring network (CETESB and ANA, 2023).

To define the sampling network for surface and groundwater, it is necessary to identify the watercourses and aquifer systems that may be impacted by the implementation of the decharacterization project. The basis for developing the monitoring plan and the sampling network for the different matrices should be the diagnosis of the physical environment (water, soil, morphology, hydrography, hydrogeology, and geology), the prognosis of impacts, and the hydrogeological model. Once the extent of the area to be monitored is defined, the sampling network should include points upstream and downstream of the structure undergoing decharacterization.

Regarding surface waters, the location of the points should also consider the presence of tributaries and the existence of liquid effluent discharges along the monitored water body, independent of whether they originate from the structure's drainage or not. The assessment of the variation in surface water quality should include points located before and after complete mixing with the discharged effluents and at the mouth of the tributaries. Sampling at different depths should also be considered (CETESB and ANA, 2023).

For groundwater, it is important that the monitoring network is supported by the hydrogeological model. The upstream and downstream points should be positioned according to the direction of groundwater flow. The monitoring wells must have their filter sections positioned to monitor the hydrogeological unit and the aquifer system under evaluation. Therefore, the number of points and their locations will depend on the characterization of the hydrogeological units and the aquifer systems (fractured, granular, or karstic) and the specificities of the site, such as the presence of faults and fractures, layer structuring, and topography, always using monitoring data to delineate the potentiometric map and the direction of the main groundwater flows. To comply with Brazilian technical standards, NBR 13896:1997, from the Brazilian Association of Technical Standards (ABNT), recommends that the monitoring well system must consist of at least four wells, one upstream and three downstream in the direction of preferential flow of the water table. The presence of springs and active wells for water extraction and groundwater lowering should also be considered.

Monitored parameters

The selection of the parameters to be monitored should consider the physical-chemical, chemical, and mineralogical characterization of the tailings contained within the structure, as well as the porewater present in the interstices of this material. In addition to the constituents identified in these matrices (tailing and pore water), the selection of parameters should also consider the analysis of:

- The same parameters in all monitored matrices in the site, such as sediments, tailings, soil, and water, to identify tracer elements.
- All major anions and cations, as well as relevant trace metals in both their total and dissolved fractions.
- Volatile and semi-volatile organic compounds.
- Substances covered by reference legislation.
- Chemical compounds used for blasting and during the mineral beneficiation process, as well as their byproducts and residual products.

Initially, a list of parameters that is broad and inclusive should be considered. However, this can be reduced after a year of monthly data has been collected, as it may be determined that some parameters are nonessential.

Sampling frequency

The sampling frequency should be defined based on the minimum amount of data and the time needed to evaluate the chemical stability of the structure undergoing decharacterization. Helsel et al. (2020) and APHA et al. (2023) present statistical calculations for defining the sample size, while Barnett (2022) presents a minimum estimate of 15 samples when using non-parametric methods for the statistical analysis of data and ten samples when using parametric methods. Regarding time, the Terms of Reference (SEMAD and FEAM, 2019) appropriately do not define a minimum period, allowing flexibility in response to specific project conditions, while ANM Resolution nº 130/2023 establishes a minimum period of two years after the completion of works to ensure the effectiveness of stabilization measures. Based on a minimum of 15 observations (since environmental variables are characterized by not having a normal distribution) and a minimum monitoring period of 2 years, it is recommended that surface water, groundwater, and effluent collection and analysis be conducted at least monthly frequency during the active monitoring period. Based on the evaluation of the results, the initially proposed frequency can be reviewed after a one-year data collection period.

Sampling and analysis methodologies

In Brazil, laboratories responsible for water and effluent sampling and chemical analysis must be accredited according to the Brazilian standard ABNT NBR ISO/IEC 17025:2005. Samplers and procedures for collecting, preserving, conditioning, transporting, and storing samples must be described in the monitoring plan and are based on the National Guide for Sample Collection and Preservation (CETESB and ANA, 2023). Analysis methods must also be specified in the plan and must follow the indications of the Standard Methods for the Examination of Water and Wastewater (SMWW) (APHA et al., 2023) and/or the U.S. Environmental Protection Agency (U.S. EPA). Specifically for the quantification limits of analytical methods, the ABNT NBR 16435:2015 standard establishes that these must be equal to or lower than the applicable legal values established by the environmental agencies, and, in the absence of national standards, international reference standards can be adopted.

Data quality management

To ensure data quality and reliability, the water resource monitoring plan should incorporate control samples. These samples are essential to maintain sampling procedure quality and trace any potential errors or contaminations. According to the National Guide for Sample Collection and Preservation (CETESB and ANA, 2023), recommended control samples include duplicates, field blanks, equipment blanks, transport blanks, reagent blanks, syringe and filter blanks, reagent water blanks, and temperature control during transport. These measures help maintain the integrity and accuracy of collected data.

The guide recommends that control samples represent between 5 and 10% of the total number of samples, except for transport temperature control, which should be used for all sample transport requiring refrigeration. For duplicate samples, the suggestion is to distribute the collections according to the diversity of sampling situations, such as the type of environment, matrix, collection strategy, and order of magnitude of the chemical substances of interest. Relative percentage differences (RPD) of up to 20% are acceptable between the results of duplicates and samples.

To guarantee the quality of analytical procedures in the laboratory, the implementation of method blanks, laboratory duplicates, spiked matrix, spiked matrix duplicate, and spiked blank should be planned (INMETRO, 2018; APHA et al., 2023). A control sample should be analyzed for every 20 samples.

All control procedures and data must be stored in a secure digital environment, and it is desirable to make use of cloud-based technologies.

Data interpretation

A methodological proposal for data analysis and interpretation should also be included in the water monitoring plan. For comparing the upstream data group with each of the downstream data groups, a minimum proposal should initially consider the evaluation of the normality of the variables distribution and the selection of parametric or non-parametric hypothesis tests, depending on the result of the normality tests. To evaluate the trend of variation in the concentrations of the analyzed compounds over time, a trend test and a linear regression model can be used (Helsel et al., 2020). It is also advisable to consider the use of advanced multivariate techniques, including advanced analytic methodologies such as machine learning.

Surface water results in relation to historical data can be evaluated using the hypothesis tests mentioned above. For groundwater, Barnett (2022) recommends defining a baseline through the calculation of the 95% Upper Confidence Level (UCL).

Corrective actions

Corrective actions and measures should be included in the monitoring plan to mitigate potential alterations in water and effluent quality related to the chemical instability of the structure. Measures to reduce the input of surface and groundwater to the landfill, systems for treating effluents from drainage and surface waters, and groundwater remediation actions should be described in the plan.

Conclusion

The decharacterization of tailings dams requires rigorous monitoring of surface water, groundwater, and effluents to ensure the physical and chemical stability of the structure and surroundings. The proposed water resources monitoring plan includes the following main topics: the representative distribution of sampling

points for chemical analysis and hydrodynamic data; monitoring of flows and water levels; the definition of the monitored parameters; the sampling frequency for assessing the chemical characteristics of water; data management procedures; and corrective actions. The monitoring plan also incorporated considerations regarding the methodologies for collecting and analyzing samples and data quality management, ensuring accurate and reliable results. The proposed items are supported by the definition of a baseline or background, the physical environment diagnosis, the assessment and prognosis of qualitative and quantitative impacts, and the hydrogeological model development.

It is noteworthy that the proposed water monitoring plan was based on the principle of meeting the decharacterization projects' objectives regarding the verification of hydrodynamic and chemical stability maintenance for the structures, adhering to the recommendations of Brazilian state and federal legislation and regulations.

The application of these minimum requirements in future tailings dam decharacterization projects is important to ensure environmental safety and public health in a structured and trackable way, reducing the risks of water contamination and guaranteeing the stability of the remaining structures.

Boodarie Tailings Storage Facility – Our Journey to Closure

Nathalia Revelo Mendez, BHP, Australia
Daniel Meunier, BHP, Australia
Darren Springer, BHP, Australia
Bria Whiter, BHP, Australia
Simon Harris, BHP, Australia

Abstract

BHP is committed to working with the International Council on Mining and Metals (ICMM) and other organizations to pursue improvements in global tailings management practices, including the Global Industry Standard on Tailings Management (GISTM).

Keeping the people and communities where BHP operates safe is of the upmost importance, and it is for this reason that BHP is continuously looking for ways to reduce or eliminate hazards and adopt the best practice standards in our operations. For this reason, tailings dam failure has been classified as a material risk for the business, requiring the strictest governance, maintenance, risk management, and operational standards to be applied, with appropriate training of operators to understand the risks and how are we affecting or protecting the community and the world with our day-to-day operations.

BHP ceased operation of the Boodarie hot briquet iron (HBI) facility (located 8.5 kilometers south-west of Finucane Island in Port Headland, Western Australia) over 10 years ago, but the 200-hectare tailings facility was not rehabilitated at that time. In 2020 a project to convert the tailings facility to a free-draining landform was started. By early 2023 all credible dam failure modes have been removed and the residual storage impoundment (RSI) no longer constitutes a dam under the GISTM, meaning that the facility does not meet the GISTM definition of a dam anymore, but is still on its journey to closure. The facility is now on a pathway to declassification as a dam by the regulator of the Department of Mines, Industry Regulation and Safety of Western Australia (DMIRS).

The closure journey for the Boodarie tailings storage facility has taught us valuable lessons and ways to accelerate the reduction of dam-related risks, ensuring a safe, efficient, and value-adding exercise, while also achieving social value outcomes through the involvement of traditional-owner contracting companies in the execution of the rehabilitation work. This paper seeks to share engineering, governance, risk

management, environmental, and community engagement lessons for consideration by other mining companies planning to, or already on, the journey to rehabilitation of their tailing facilities.

Introduction

BHP has been on a continuous improvement journey within the tailings management space, much like the entire tailings industry, since the 2010s. While BHP has always governed and monitored tailings storage facilities (TSFs) in line with applicable international and local standards, tailings management was managed at a business level, so each individual asset independently managed identification, assessment, and management of risk for their tailing's storage facilities. However, after the release of the 2013 CDA guidelines and a series of industry failures in the early 2010s, BHP began to take a more holistic, business-wide approach to tailings.

The first step in this process was to undertake dam risk reviews for all known TSFs across the business. A BHP Global Tailings Practice Lead position was created, and Tailings Review Boards were introduced. Engineer of Record (EoR) and Responsible Dam Engineer roles were formalized and embedded for each facility. A tailings working group was also established so that all personnel involved in the management of tailings across BHP were given the opportunity to regularly share learnings and new developments.

In 2020, BHP established global, mandatory minimum performance requirements for tailings and water storage facilities through the development of Our Requirements (OR) for water and tailings storage facilities. The OR also established requirements around second-line assurance review requirements for high priority TSFs, which was later cascaded to all TSFs. More recently, BHP has committed to the implementation of GISTM across our assets, prioritizing very high and extreme facilities for first rollout.

For BHP's Western Australian Iron Ore (WAIO) operations, this improvement journey has allowed for iterative review of TSFs with each improvement. It was through this continuous review against the developing standards that it was identified that while most of the tailings stored within the facility had been removed for reprocessing, the inactive Boodarie residual storage impoundment (RSI) still met the definition of a TSF.

As a result of this classification the facility was extensively reviewed and re-assessed in accordance with Our Requirements, which led to the decision to rehabilitate the facility to reduce the ongoing risks associated with it. The intent of this paper is to share the learnings of BHP's journey towards closure and the subsequent reclassification of the Boodarie RSI from a TSF to a landscaped tailings profile.

Background

The Boodarie RSI was an inactive iron ore TSF located approximately 8.5 kilometers southwest of Port Headland (see Figure 1). The facility was constructed in 1995 to store waste from the now largely decommissioned and demolished Boodarie HBI facility.

Figure 1: Location of Boodarie RSI

The upstream raised TSF and associated infrastructure covered an area of approximately 200 hectares and operated from 1999 to 2004, with deposition of the non-acid forming iron ore tailings through a central discharge point. During its operational life it was raised twice, with a final embankment height of nine meters. The facility was not operated for the full design life due a significant plant fire that halted production; as a result, the tailings did not cover the full surface of the footprint.

Planning for decommissioning of the Boodarie hot briquet iron (HBI) site began in 2004. Capping of the TSF residue was completed in 2008, using reject material from the beneficiation plant to control fugitive

dust from the TSF surface. During further decommissioning planning, an opportunity was identified to sell the iron ore tailings as a commercial product. Over 4.3 million tonnes of iron ore tailings were excavated and hauled out of the facility for sale from 2010 to 2012. This significantly reduced the facility's risk of loss of tailings containment. However, approximately 330,000 m^3 of tailings were still stored within the impoundment.

Final plant decommissioning was completed shortly thereafter. The RSI was put into care and maintenance, managed by operational teams from BHP's Port Headland operations. As part of WAIO's continuous improvement tailing journey, the facility was risk reviewed several times against the tightening management criteria. During these reviews it was identified that there was a potential overtopping risk associated with rare extreme weather events, which might result in a water build-up leading to potential credible dam failure modes. This risk was outside of BHP's business risk appetite, even though no such significant events had been observed during the TSF's life.

As a result, a rehabilitation project was initiated in 2020 with the aim of converting the Boodarie RSI to a free-draining landform and removing all credible dam failure modes.

Defining clear objectives

To ensure the success of the project it was very important to have a clear understanding of what the regulators required, what the company required, and most of all, what would be the best outcome for the community in which BHP operates.

The key drivers for undertaking the Boodarie RSI Tailings Dam Rehabilitation Project were:

- Risk mitigation – removing outside of business appetite risks.
- Meeting our requirements – upholding BHP's regulatory obligations.
- Upskilling Indigenous communities.

As closure is a long process and has different interpretations across the globe and even within the Pilbara mining industry, depending on the facility and the most recent guideline, BHP decided that the primary objectives for the RSI closure would be removing all critical failure modes and building a useful landform for future use.

BHP acknowledges that removal of all failure modes is not possible for all facilities; however, reducing the number of failure modes, considering the operating environment, community, and regulatory requirements, and risk mitigation, should all be part of the decision-making process for defining the closure stage of the facility.

The closure solution

The preliminary concept for the closure solution was to encapsulate the existing in-situ tailings material within the existing embankment material, aiming to create a natural-looking, free-draining landform. After the project initiation in 2020, a study team reviewed alternative options considering the knowledge base, gap-closing activities, and regulatory, stakeholder, and corporate commitments. As part of these activities, stakeholder engagement was undertaken with the Western Australian regulators to understand their requirements. While there was support for the initial concept, further studies indicated that there were elevated erosion risks associated with the design.

The project was progressed through BHP's project phases and design optimization continued, which resulted in a final design solution that differed from the concept design. This solution would return the site to near original topography, while reducing the risk of erosion.

The execution works commenced in 2022, with a local Indigenous civil contractor engaged to complete the works. Onsite quality assurance and quality control (QA/QC) was completed by the engineering design consultants to ensure compliance with the design. Given the low volumes of tailings within the facility, the project was able to remove all embankments, and relocate the remaining tailings residue into existing low embankment borrow areas on the facility. The tailings were then capped with an engineered cover and the land was reshaped to near original topography. The site was able to be seeded within the 2023 wet season window, using a locally harvested seed mix supplied by a local Indigenous vendor.

Upon completion of the works, the EoR and the Senior Independent Technical Reviewer (SITR) conducted a review of the project construction. This included all construction records that verified that all credible flow failure modes had been removed, that the encapsulated residue was chemically benign, and that the facility could be considered a landscaped tailings profile in accordance with BHP's tailings guidance.

Boodarie RSI TSF is now moving into the post-closure monitoring phase of its life cycle. The monitoring being conducted over the coming years is to confirm that the facility has successfully achieved the closure objectives and the defined completion criteria. The post-closure monitoring phase is expected to be completed over the next twenty years.

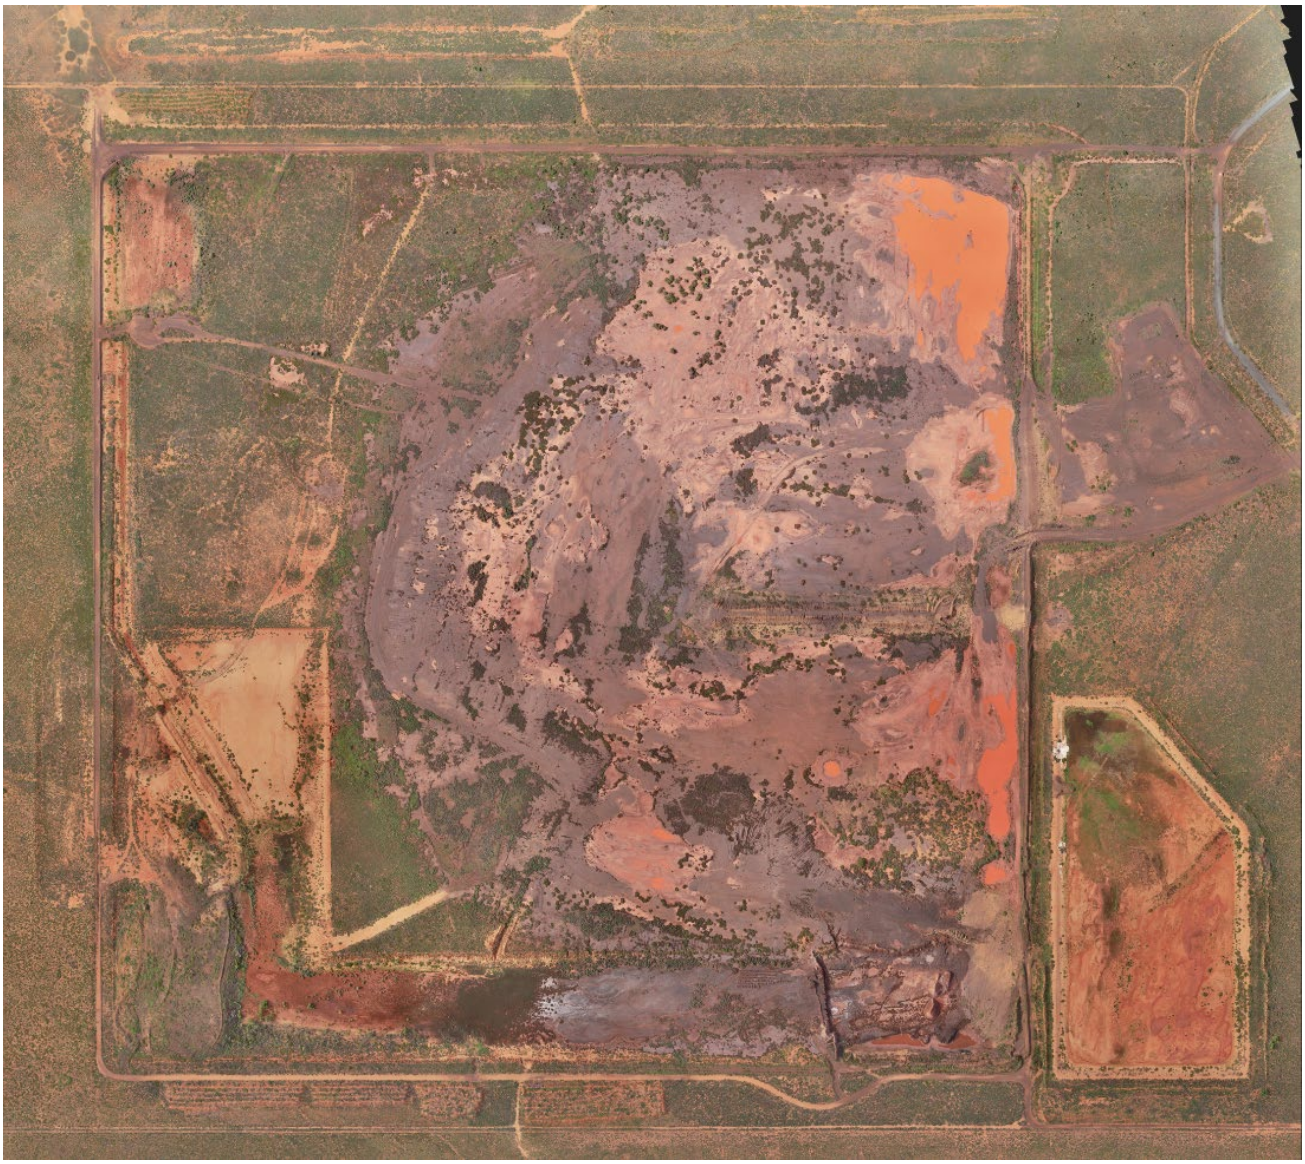

Figure 2: Boodarie RSI (aerial photo, 2019) – prior to final rehabilitation

Lessons learned

Governance matters

Through continuous improvement of BHP's tailings governance, we were able to utilize subject matter experts within the tailings industry to identify gaps or unappreciated risks associated with the Boodarie TSF. We consolidated a formal Tailings Centre of Excellence BHP-wide. This included technical subject matter experts (both internal and third party) and a Global BHP Tailings Practice Lead, as well as other TSF-related roles such as EoR, Responsible Tailings Dam engineer, dam owners, and various governance

roles. This allowed BHP to clearly define requirements for water and tailings storage facilities management to ensure that tailings management is prioritized at all levels through the business. These supports and frameworks allowed WAIO to successfully remove a TSF from our portfolio and reduce the risk to BHP's business.

Hidden opportunities

Changing the identification of a previously designated waste material to a saleable material added value to the business in a number of ways. There was a cost benefit as a result of the sale, and the removal of 4.3 million tonnes of tailings significantly reduced the facility's risk of loss of containment. Moreover, the reduction of material allowed for a modified design that reduced construction volumes and schedule times and also allowed for the successful removal of all credible geotechnical failure modes.

While the sale of tailings is not always feasible for other facilities, it is important to look for secondary use opportunities that can reduce the volumes of tailings material to be managed, in order to make closure easier.

Reclassification to a landscaped tailings profile

Through the removal of the RSI embankments and critical failure modes, BHP was able to successfully remove one TSF from the global portfolio. While there is still an erosion risk for the landscaped profile, it was important to define suitable tolerance levels to ensure that it does not constitute a critical failure mode. The project team successfully delivered the required engineering specifications (see Figure 3), which subsequently allowed for the reclassification of the facility from a TSF to a landscaped tailings profile (see Figure 4).

Community involvement

BHP saw the execution of the closure project as an opportunity to engage a traditional owner company, so as to benefit BHP and the community. The main execution activities were bulk earthworks. However, due to the complexity of being a TSF, higher levels of QA/QC than standard civil rehabilitation projects were required. During the tendering process, BHP aimed to find a suitable civil contracting company with the right expertise to partner with to deliver this technical closure project.

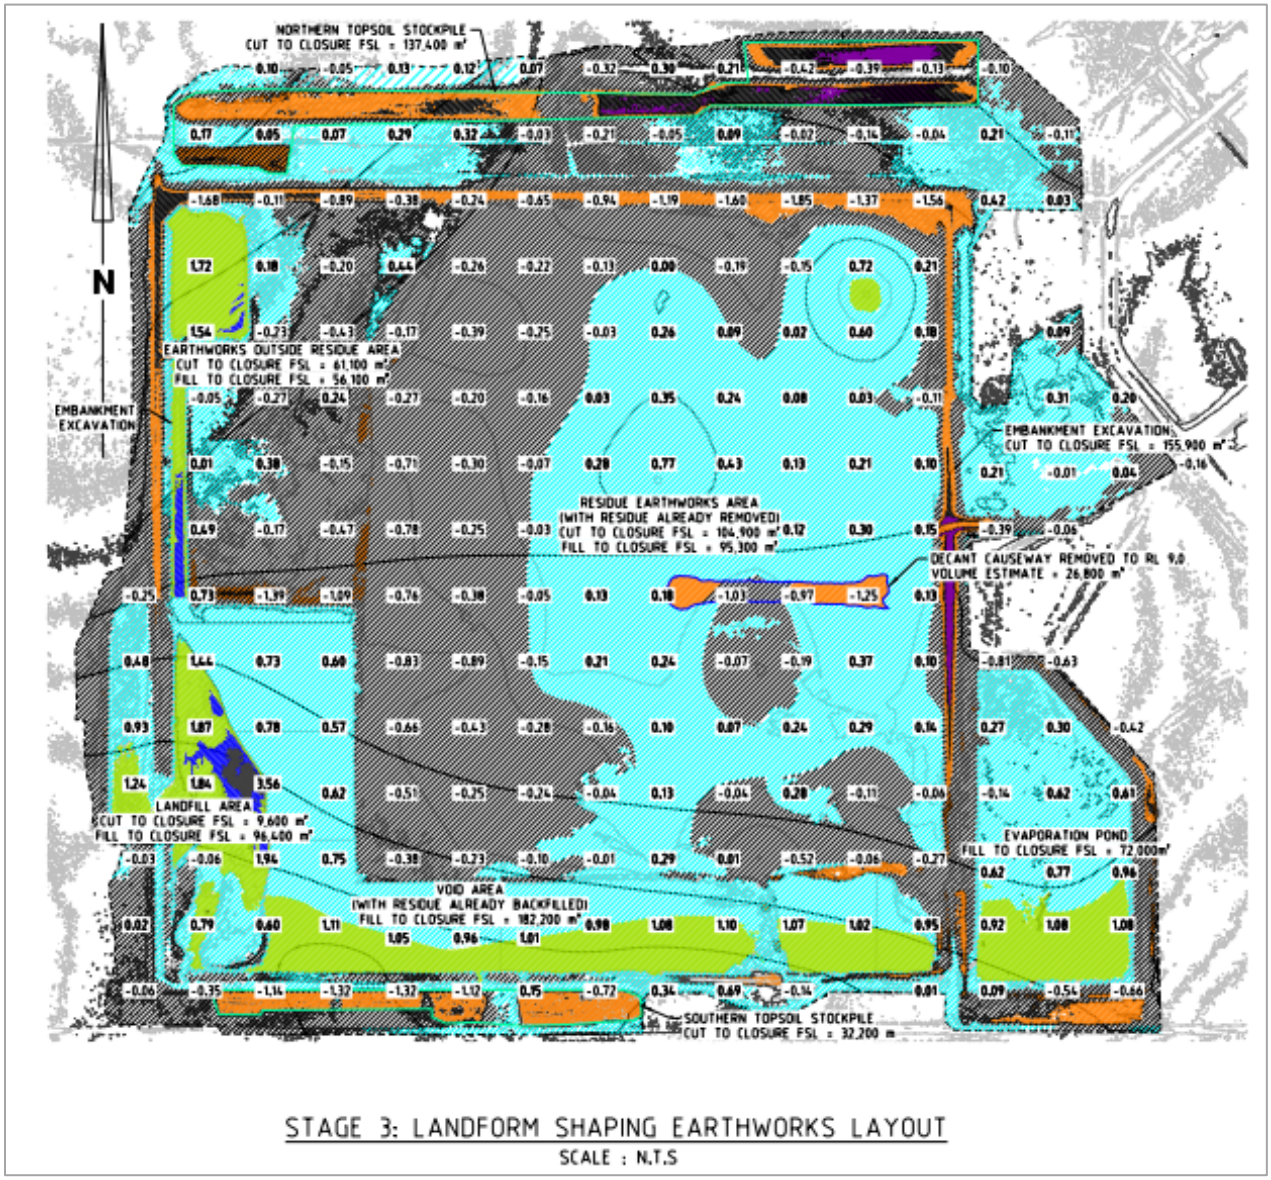

Figure 3: Closure design – landform shaping requirements

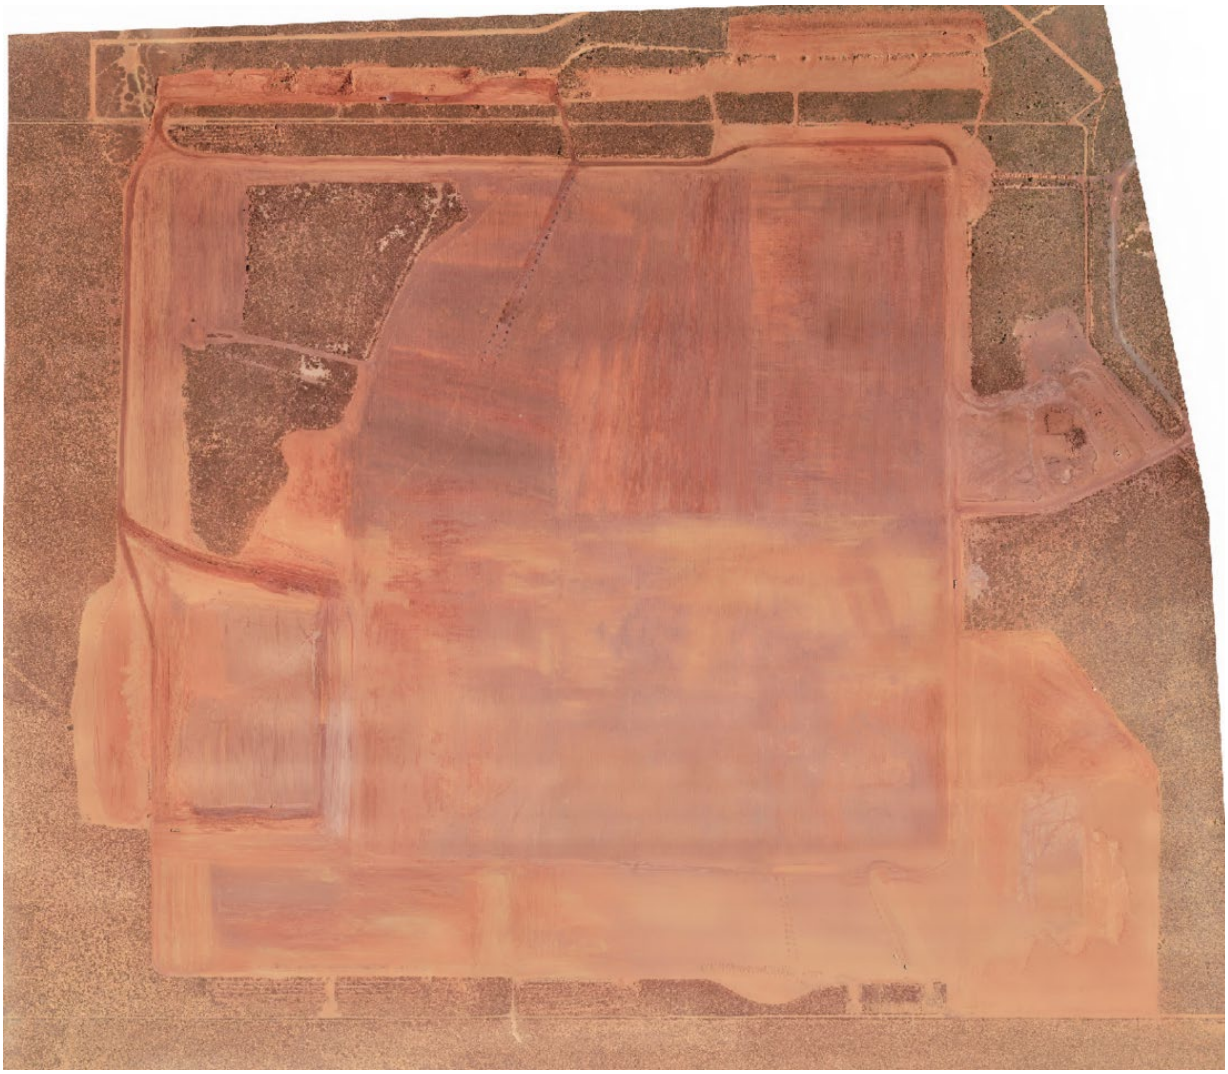

Figure 4: Aerial view of the completed closure works (2023)

The contract was awarded to a 100% Indigenous-owned company, with 48% Indigenous people participation in the project work force. For the BHP WA Asset Projects (WAAP) group, it was the largest direct engagement with a 100% Indigenous-owned company to date.

Figure 5: Indigenous company employees performing a field leadership activity

The contracting company was able to bring its experience to the project, optimizing execution plans and methods that resulted in delivery of the decommissioning and rehabilitation works ahead of both schedule and budget. This engagement and project performance showcased the collaborative work that can be achieved through the development of Indigenous partnerships. This will help to empower Indigenous contractors and communities to thrive under future economic and environmental conditions.

Conclusions and recommendations

We are stronger if we are together. By sharing the recommendations below, which worked for WAIO, BHP wishes to help to reduce the risks that TSFs pose to communities in their project areas.

- Take advantage of low-complexity projects, so that your company can engage, train, and create value for traditional owners and communities in your project areas.
- Ensure all TSFs are managed with the highest governance to ensure alignment to GISTM, so as to reduce risks.
- Evaluate tailings and assess if there is a potential use. Tailings can be reprocessed and used for many of the wonderful things that minerals do for the world.
- Determine whether there is an unidentified value stream that can reduce the closure impacts of a project.

- Aim to remove all critical failure modes, because by not having them, the facility will not pose a major risk to the community.
- Aim to declassify the facility, so that all TSF-related governance and GISTM requirements are removed, resulting in cost savings in operational expenses.
- Aim to have good relationships with closure experts, dam owners, governance teams, operators, and environmental departments. This will make everyone's lives easier and contribute to outstanding results.
- Aim to involve traditional owners. As well as removing the risk, a significant value for the community was achieved by the involvement of a traditional owner who owned a civil earth works company. The project had 48% Indigenous people representation in the workforce.
- Aim for a correct management of change process. This will help to remove all ongoing operational and group risk control requirements for the facility, which will result in great cost savings too.
- Share your experience and get in contact with anyone with your same objective. It is likely that someone in the industry has already done it and can guide you during your journey.

Acknowledgements

We wish to thank BHP and the project team for allowing us to publish these valuable lessons that can assist our industry as a whole. We also wish to thank the Indigenous contractor for allowing us to involve them in our project and for their willingness to learn and grow in the industry.

Design

TAILINGS AND
MINE WASTE 2024

Lessons Learnt by Applying a Risk-based Approach to Tailings Storage Facilities

Peter Chapman, WSP Australia Pty Ltd, Australia
Scott Gover, WSP Australia Pty Ltd, Australia
Jordan Ribbons, WSP Australia Pty Ltd, Australia

Abstract

The transition from standards-based design to risk-informed design has been discussed in industry for many years, but only implemented on a select basis, usually where more certainty is required to support capital investment for risk mitigation measures. However, the use of risk-based design has recently been accelerated as the industry undertook the initial round of reviews in the context of the Global Industry Standard on Tailings Management and incorporated Environmental, Social and Governance aspects in the journey towards responsible mining.

Many owners have been undertaking portfolio-based quantitative risk assessments to support assessments of whether the concept of "As Low as Reasonably Practicable" has been met. This process has highlighted both the benefits of risk-based approaches as well as the inherent flaws in standards-based engineering, particularly where there are high loss of life consequences.

This paper presents selected outcomes of quantitative risk assessments undertaken across 16 tailings storage facilities for multiple owners and multiple commodities. The assessments were undertaken across tailings storage facilities with constructions techniques, across a variety of countries and climatic zones, and considering both active and inactive (legacy) facilities. The key outcomes are presented in the form of risk-driving failure modes, considering both the probability of failure and the estimated consequences (usually potential loss of life), as well as the likelihood of the causes occurring (that is, excluding intervention and progression). By considering both views, the result can be used to identify the systematic deficiencies in design that indicate that standards-based approaches are not sufficient to manage high consequence TSFs, resulting in an over-reliance on identifying and rapidly addressing issues that evolve during operations.

Introduction

The transition from standards-based design to risk-informed design has been discussed in industry for many years, but only implemented on a select basis, usually where more certainty is required to support capital investment for risk mitigation measures. However, the use of risk-based design has recently been accelerated as the industry undertook the initial round of reviews in the context of the Global Industry Standard on Tailings Management (GISTM) and incorporated Environmental, Social and Governance aspects in the journey towards responsible mining.

This paper presents selected outcomes of quantitative risk assessments undertaken across 16 tailings storage facilities (TSFs) for multiple owners and multiple commodities. The assessments were undertaken across TSFs with varying constructions techniques, across a variety of countries and climatic zones, and considering both active and inactive (legacy) facilities. The key outcomes are presented in the form of risk-driving failure modes, considering both probability of failure (pF) and the estimated consequences (potential loss of life, PLL or N), as well as the pF of the causes occurring (that is, excluding intervention and progression). By considering both views, the result can be used to identify the systematic deficiencies in design that indicate that standards-based approaches are not sufficient to manage high consequence TSFs, resulting in an over-reliance on identifying and rapidly addressing issues that evolve during operations.

Risk-based design

As outlined in Chapman (2022), whilst the standards-based design approach appears to have been largely successful, it drives design behavior towards compliance rather than safety. Morgenstern, in his 2018 Victor De Mello lecture (Morgenstern, 2018), indicates that standards and guidelines are continuing to evolve. Chapman (2022) noted that the recent TSF failures, including Mt Polley, Samarco, Cadia and Feijão did not fail due to an extreme earthquake or rainfall event, but rather a series of undetected events that ultimately led to failure under "normal operating conditions." As noted in the relevant failure reports, the owners and operators of the facilities considered them to be compliant. This suggests that standards-based design, even with good governance, may have moved the industry significantly forward, but cannot support the next step in the TSF safety journey, towards zero catastrophic failures. It is in these circumstances that risk-informed design can provide a framework for additional risk management.

Morgenstern (2018) indicates that quantitative risk assessment (QRA) techniques have been shown to reduce risks over time, as demonstrated by the example of landslides in Hong Kong, provided there is sufficient information to support the assessment. Chapman and Williams (2019) show that a QRA can provide improved clarity and differentiation compared to more routinely adopted risk assessment approaches, particularly those that adopt a qualitative 5 × 5 matrix approach. The authors concluded that

the use of a QRA can demonstrate not only that the likelihood of catastrophic failure is lower (and also shows how low it is), but also provides the designer with information on the largest contributions to failure, allowing effective mitigation measures to be put in place. If a QRA approach is developed during the design stage, it can also be used as a decision-making tool during design and as a risk mitigation tool during operations.

The industry appears to be moving towards risk-informed design, and yet the process is not yet sufficiently accepted and implemented as a key tenet in TSF design. This paper provides a summary of a series of risk assessments completed across multiple owners and commodities on a variety of TSF construction types. The results highlight the marked difference between compliance and safety.

Approach to risk assessments

There are various ways to approach a QRA, with various levels of detail being applied in industry. The two most common approaches are fault trees and event trees.

Fault trees are logic diagrams based on the principle of multi-causality. They are used as a tool to analyze the potential for failure of an item or system using a top-down approach by tracing all branches of potential events that could contribute towards failure (or any undesirable top event). Fault trees use a series of "AND" gates (all contributing events need to occur) and "OR" gates (only one of the contributing events needs to occur) to graphically and mathematically estimate the probability of the top event occurring. A simple fault tree example, developed by the authors, is provided in Figure 1.

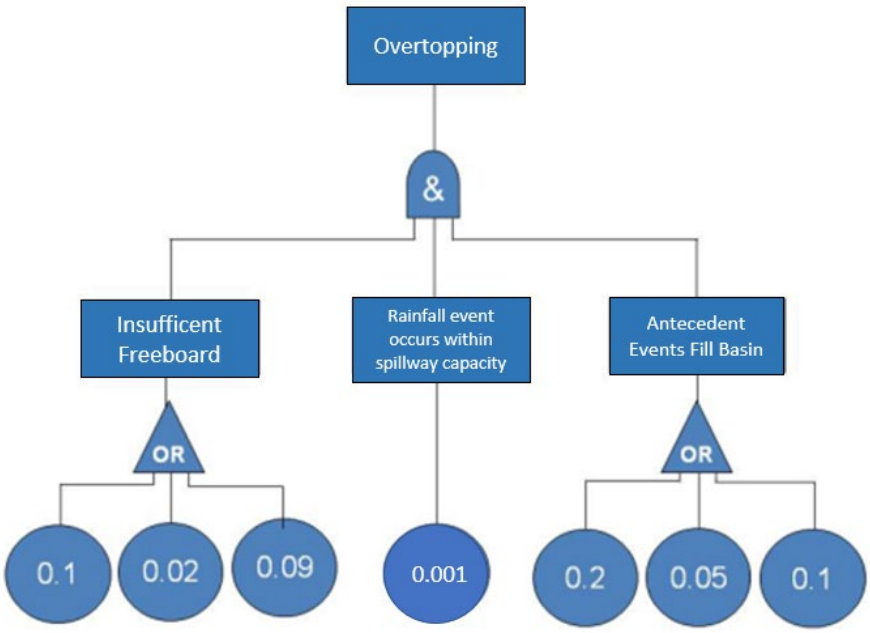

Figure 1: Fault tree example

Figure 1 demonstrates that insufficient freeboard AND a rainfall event occurring AND an antecedent event to fill the basin are required to contribute towards the top event of overtopping. At the next level down in the fault tree, the probability of a rainfall event occurring within the spillway capacity has been assigned a probability of 0.001 (1 in 1000), but insufficient freeboard and an antecedent event filling the basin could be made up of three different possible contributors that could occur independently of each other (OR gates), each with a different assigned probability.

An event tree analysis uses the same logic and mathematical techniques as a fault tree analysis. However, a fault tree considers how an undesirable top event may occur, whereas an event tree considers the impact of an event or failure occurring in a system, and subsequently works out the effect that such an event will have on the overall system risk or reliability. Event trees consist of an "initiating event" (and associated probability or frequency assigned to it), and a series of subsequent events with binary statements (yes/no, true/false etc.), each of which can be assigned a probability. A series of final outcomes can therefore be derived, each with a resulting probability of the particular outcome occurring. A hypothetical event tree example is presented as Figure 2.

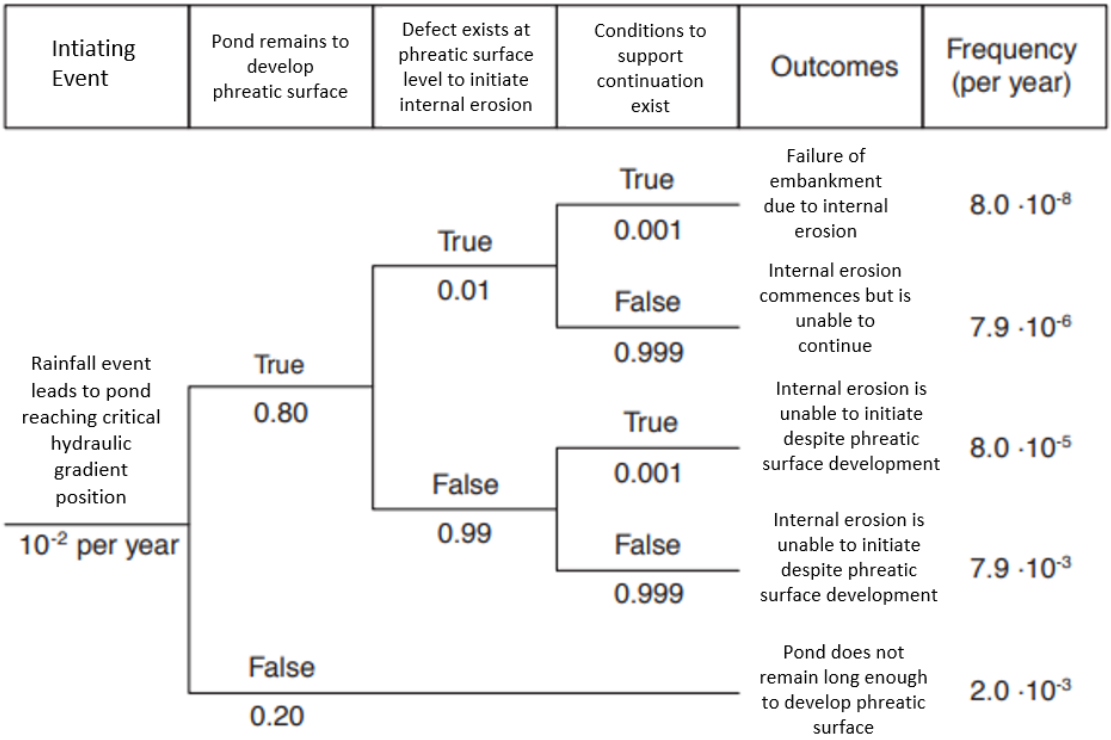

Figure 2: Event tree example

Figure 2 demonstrates that there is a 1×10^{-2} chance that an initiating event of rainfall event leading to the pond reaching the critical hydraulic gradient occurs per year. If the initiating event occurs, 80% of the time this will result the pond remaining long enough to develop a phreatic surface, of which there are

further conditions that need to be met in order for internal erosion leading to embankment failure to occur. These conditions are assigned a probability, which branch into a series of possible outcomes. The probability of each individual outcome can then be calculated (frequency/probability of initiating event × probability of each of the subsequent events).

As part of the preparation process for the QRAs undertaken, consideration was given to the approach to be adopted. A Microsoft Excel spreadsheet, primarily using an event tree logic approach adopting the "true" pathway, was adopted. A spreadsheet approach allows the Client ready access to the tool, in order to support future sensitivity analyses and updates if required, noting of course that the veracity of formulae and calculations within a spreadsheet needs to be continuously checked. The spreadsheet also contains notes and justifications, for future reference by the Client and others. For the purposes of the program, the veracity of the spreadsheet were verified using a commercially available fault tree software code (in this case, TopEvent FTA).

Summary of approach

The risk assessment process undertaken relies on appropriately identifying a non-duplicative set of potential failure modes (PFMs), followed by progressively subdividing them into their contributory components ("causes") through "AND" and "OR" logic gates, until it is possible to assign a probability to an individual "cause" with reasonable confidence. A brief summary of the approach adopted is described below:

System hazards (mechanisms that have potential to do harm, i.e., could potentially result in failure) were identified for which the consequence of failure could lead to a significant release of tailings and/or water (hazards include seepage, high precipitation, earthquakes, uncontrolled decant pond, etc.).

a) The "causes" of the potential release of material from the facilities were derived from the identified hazards, as well as drawing upon our understanding of the operation, gained through review of existing information and discussions with the Engineer of Record (EoR) or designer, along with other similar examples elsewhere ("causes" include slope failure, large-scale erosion, overtopping, piping, etc.).
b) The causes were logically combined through a series of "AND" gates and "OR" gates, depending upon whether the causes are statistically dependent (all had to occur), or independent of each other (any one or more would need to occur), respectively. The causes were progressively subdivided into their contributory components through the "AND" gates and "OR" gates, until it was considered possible to assign a probability to an individual cause with (what we consider to be) reasonable confidence, in this case through a workshop environment, supported by modelling/analyses undertaken by the EoR and a QRA framework prepared in advance by WSP.

c) Probabilities were assigned to the appropriate causes to yield a "fault tree." The probability of occurrence of the "top fault" (failure of the facilities leading to a release of a significant volume of tailings and/or water) were calculated by the fault tree according to the following formulae:
   i) for OR gates: Pt = 1 – (1-P1) × (1-P2) × ... × (1-Pn).
   ii) for AND gates: Pt = P1 × P2 × .... × Pn.
   iii) where P1, P2, etc., are contributory components to Pt.

d) The event analysis comprised a "failure location assessment" (in which the probability of occurrence for a given failure location was established), and an "exposure assessment" (in which the number of people exposed to a flow failure were identified based on dam break studies completed by the EoR/designer and supplemented by information from site personnel). The analysis was used to estimate the probability of loss of life or serious injury arising from the various failure mechanisms, for various failure locations.

The causes were based on the PFMs discussed in the workshop, with reference to a Failure Modes and Effects Assessment (FMEA) where available for a facility, as well as our wider industry experience related to risk assessments.

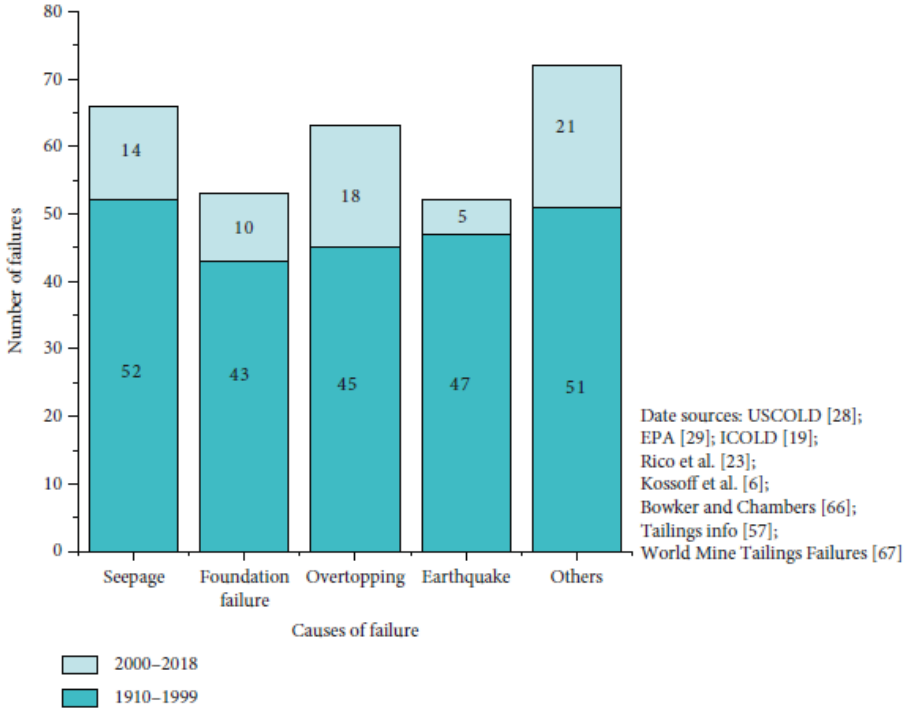

Figure 3: TSF failure distribution by cause (provided by Lyu et al., 2019)

Various documents have summarized "causes" of TSF failure. The data summarized in Bulletin 121 – Tailings Dams, Risk of Dangerous Occurrences, Lessons learnt from practical experiences (ICOLD, 2001) indicate that the bulk of catastrophic TSF failures are attributed to slope instability (including

foundation and earthquake in this category), overtopping, or piping erosion/seepage. This is supported by Lyu et. al (2019) who has characterized the leading cause for documented TSF failures from 1910 to 2018 (refer to Figure 3). The causes identified from investigations into more recent TSF failures (post-2018) have supported this dataset.

Prior to the workshop, the failure modes that could be relevant were pre-populated into the spreadsheet, with reference to the typical failure modes and building on the authors' experience with similar facilities. Each failure mode was given a description that included the "initiating event" or "damage mechanism." The damage mechanism is the impact or effect that could cause internal or external damage to, or failure of, the part of the TSF that resists failure. This is distinct from the cause of failure, which describes the source of the change. For example, slope instability could result from a rising phreatic surface (the damage mechanism), but the cause could be an increased pond size, or blocked drainage, resulting in the rising phreatic surface.

Table 1: Summary of failure modes considered in each QRA

Failure mode	Damage mechanism / initiator
Instability	Failure due to seismicity
Instability	Liquefaction/strain softening due to rapid loading from material entering the facility (e.g. avalanche or landslide)
Instability	Liquefaction/strain softening due to rapid loading from material placement
Instability	Removal of resisting forces (downstream slope) due to cracking/erosion of slopes
Instability	Removal of resisting forces (downstream slope) due to excavation at toe
Instability	Rising pore pressure resulting from large rainfall event
Instability	Rising pore pressure resulting from seasonal groundwater fluctuations
Instability	Slope failure due to non-conservative parameters/layering adopted for foundation
Instability	Slope failure due to non-conservative parameters/layering adopted for tailings
Instability	Slope failure following erosion due to poor surface water management at toe
Instability	Slope failure following erosion due to poor surface water management on slope
Instability	Slope failure due to local oversteepening
Instability	Slope failure under static conditions (normal conditions)
Internal Erosion	Differential settlement at abutment
Internal Erosion	Increased hydraulic gradient and initiation of piping erosion along conduit
Internal Erosion	Increased hydraulic gradient and initiation of piping erosion through embankment
Internal Erosion	Increased hydraulic gradient and initiation of piping erosion through foundation
Overtopping	Insufficient capacity to contain/manage the design rainfall event
Overtopping	Insufficient capacity to contain/manage a rainfall event – freeboard compromised
Overtopping	Insufficient capacity to contain/manage a rainfall event – outlet blocked
Instability	Liquefaction/strain softening due to rapid loading from waste rock

A summary of the failure modes considered for a typical QRA is presented in Table 1. The event tree for each was adjusted to suit local conditions, retaining the overall failure mode category for consistency between QRAs. The failure modes were discussed in each workshop and were updated/adjusted as required.

Key tenets of approach

The approach adopted, while generally consistent with the guidance available globally, was aimed at providing a summary of the risk-driving failure modes for TSFs, not water dams. The authors acknowledge the importance of partitions and system responses curves in detailed QRAs, but also note that the level of data available for a TSF, in general, is far less than a typical water dam. As such, the following limitations were acknowledged in the process:

- The EoR and/or designer was involved in the process and provided information critical to the failure modes assessed. The information provided anchored the assignment of probabilities in line with the item below. Where sufficient information was available to indicate that a failure mode could not occur, it was excluded given unanimous agreement from the QRA workshop attendees.
- The outcomes of the assessments included input from all the workshop attendees, which included personnel from a range of backgrounds including geotechnical engineering, hydrology, and operations. The potential for inaccuracy arising from the subjective opinion of a single individual was reduced by adopting the technique of "Expert Engineering Judgement" (ANCOLD, 2003), in which a group of knowledgeable persons discusses and assesses the likelihood of occurrence of an event, with reference to available information. The judgement of the group was supported with information from published literature (e.g., Silva et al. (2008) and Gover [2018]). Under this process, once agreement was reached, the assigned probability was the "agreed" probability of an event occurring. Where there is some uncertainty, these items were marked for potential future assessment, should they be a key contributor to the overall risk.
- Fully developed system response models are not typically readily available for TSFs, as they are designed to design criteria linked to the consequence category for the facility. For example, the facility may be designed to store an extreme rainfall or resist an extreme seismic event, but the response to smaller events may not have been explicitly considered. This results in the need for interpolation between known points as part of the risk assessment process. For this reason, partitions for events were not undertaken, but care was taken to identify the "key" event that would result in a step-change in the pF. For example, the expected return period of an earthquake that would result in liquefaction was identified, with more frequent events excluded on the basis that liquefaction would not occur, and less frequent events excluded on the basis that once liquefaction

occurs, the facility has already reached a state of failure[1].

- TSFs are evolving structures and hence the risk assessments were undertaken assuming the agreed baseline configuration. It should be recognized that ongoing operation of the TSF may result in a change to the risk assessment conditions. Where appropriate, this was discussed with the Client and included in the assessment, particularly in relation to alternative scenarios, but those results are not reported in this paper.
- Generally, detailed assessments of internal erosion using the techniques outlined in the "piping toolbox" (USBR, 2008) were not undertaken during the process. The intent of these approaches has been incorporated into the risk assessment, considering the potential for a hydraulic gradient to exist, the presence of defects within the embankment and/or foundation, the presence of conduits through embankments and the material characteristics being considered. Where internal erosion was noted as a risk-driving failure mode, more detailed assessments were recommended and the results of which were incorporated into the QRA once the detailed assessments were completed.

Data representation

Limits of tolerability are provided in both (ANCOLD, 2022) and (CDA, 2013). These are essentially guidelines for societal tolerability and are established based on the frequency of a particular hazard and the number of casualties if the hazard is realized. Tolerable risks should ideally be determined by society, with the risk of dam failure compared against all other societal risks, but no mechanism currently exists for this. It is typically only outrage at previous rare disasters that inform these limits.

Both references incorporate ALARP into their limits of tolerability, which prevents the interpretation of these limits as the boundary of "do something or do nothing." These limits can therefore be interpreted as a guide towards prioritization of risk management, i.e., where to focus investment and resources, and do not preclude implementing mitigation measures for risks below the tolerability limits (if it is reasonable to do so). (CDA, 2013) goes on to note that "society does not have infinite resources to spend on managing risks and often the resource spent in one area is the same resource that is missing in another area where investment could be more beneficial."

Noting that tolerability limits are developed for the cumulative pF of a facility (i.e., F-N), for the purpose of this paper, these are reproduced on f-N plots as "Reference Lines" to facilitate discussions related to individual failure modes. This has been shown to be acceptable by FERC (2016) which states "The analysis and evaluation of the individual potential failure modes can lead to an improved understanding of the potential failure modes that affect the combined annual probability of failure of the

[1] In this example, if large-scale liquefaction of the tailings did not result in failure of the facility, the failure mode could be excluded.

dam. It can also provide insights that can lead to the identification of both structural and non-structural risk reduction measures, including interim measures."

Summarized outcomes of assessments

In order to provide a comparison between the 16 TSFs, the full QRA dataset has been filtered to failure mode (i.e., stability, overtopping and internal erosion), facility type (i.e., upstream, downstream and centerline) and location. This is summarized in Table 2. The data are presented on f-N charts in Figure 4, Figure 5 and Figure 6 respectively. Finally, Figure 7 presents a filtered dataset of static versus seismic stability failure modes. The conclusions drawn from each view of the dataset are then discussed.

Table 2: Summary of dataset considered

Aspect	Value
Instability points	894
Overtopping points	244
Internal erosion points	113
Upstream TSFs	6
Downstream TSFs	9
Centerline TSFs	1
Asia	1
Australia	9
Europe	3
North America	3

The following observations are noted when the dataset is considered from a failure mode perspective:

- While all three failure modes include points plotting above Reference Line 1, instability was identified as plotting in the intolerable zone most often, regardless of PLL.
- When the points below Reference Line 1 are considered, there is no typical trend visible that suggests one failure mode is lower risk (i.e., plotting lower) than the rest.
- There is no typical trend indicating that a particular failure mode is better managed when there is a high PLL. In fact, the data appear to indicate that there is no trend between pF and N (PLL). In other words, the failure modes do not appear to take into account the PLL, despite higher consequence categories, and hence higher event loadings, being adopted for TSFs with higher PLL values. For instability under static conditions, this is consistent with standards-based engineering, where the same factor of safety minimum value is applied regardless of the consequence category. This is discussed further in relation to Figure 7.

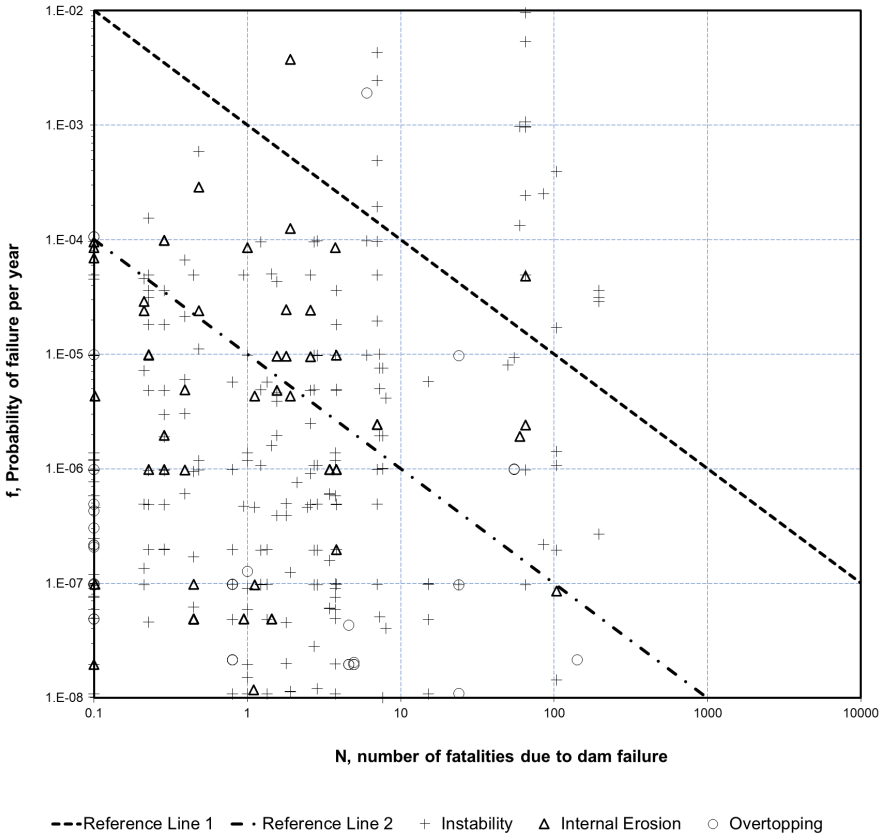

Figure 4: QRA dataset filtered to failure mode

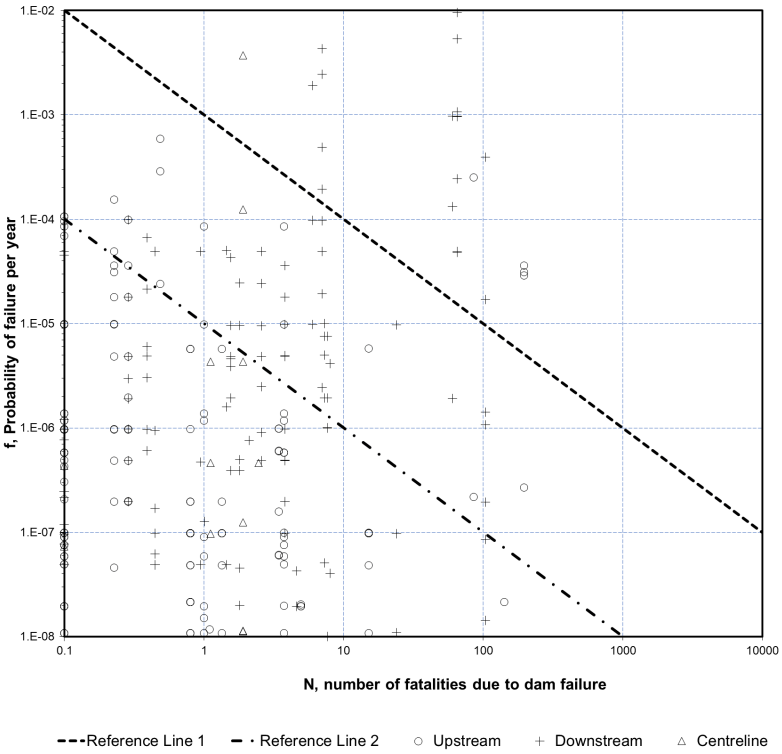

Figure 5: QRA dataset filtered to facility type

The following observations are noted when the dataset is considered based on construction type:

- Contrary to typical expectations, downstream-raised TSFs have more points in the intolerable zone (above Reference Line 1) than upstream facilities. As noted in Table 2, there were significantly less centerline facilities included in the dataset.
- There is no typical trend visible that suggests one facility type is safer (i.e., plotting lower) than the rest, with both upstream and downstream TSFs indicating variable pF values for the range of PLLs.
- With reference to Figure 4, instability was the key failure mode for both downstream and upstream facilities that plotted above Reference Line 1.

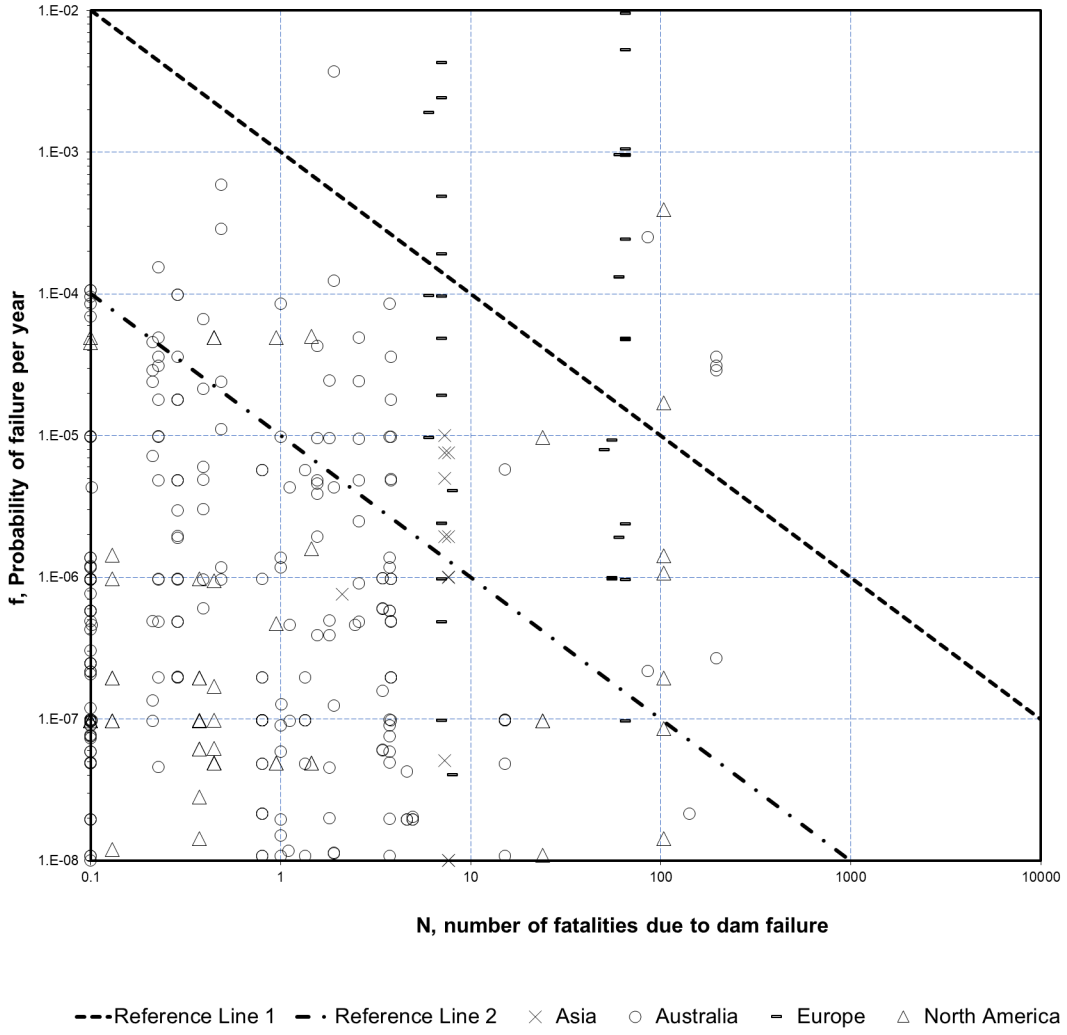

Figure 6: QRA dataset filtered by location

The following observations are noted when the dataset is considered based on location:

- There is no clear trend between location, with facilities above and below Reference Line 1, with high and low PLLs, in every location, with the exception of Asia. Due to only one assessment being

undertaken in Asia, the dataset is limited.

- The TSF design guidance for each region has the same factor of safety minimum value, although it is noted that the European sites were inactive and there was uncertainty about the data at the time of the assessment.

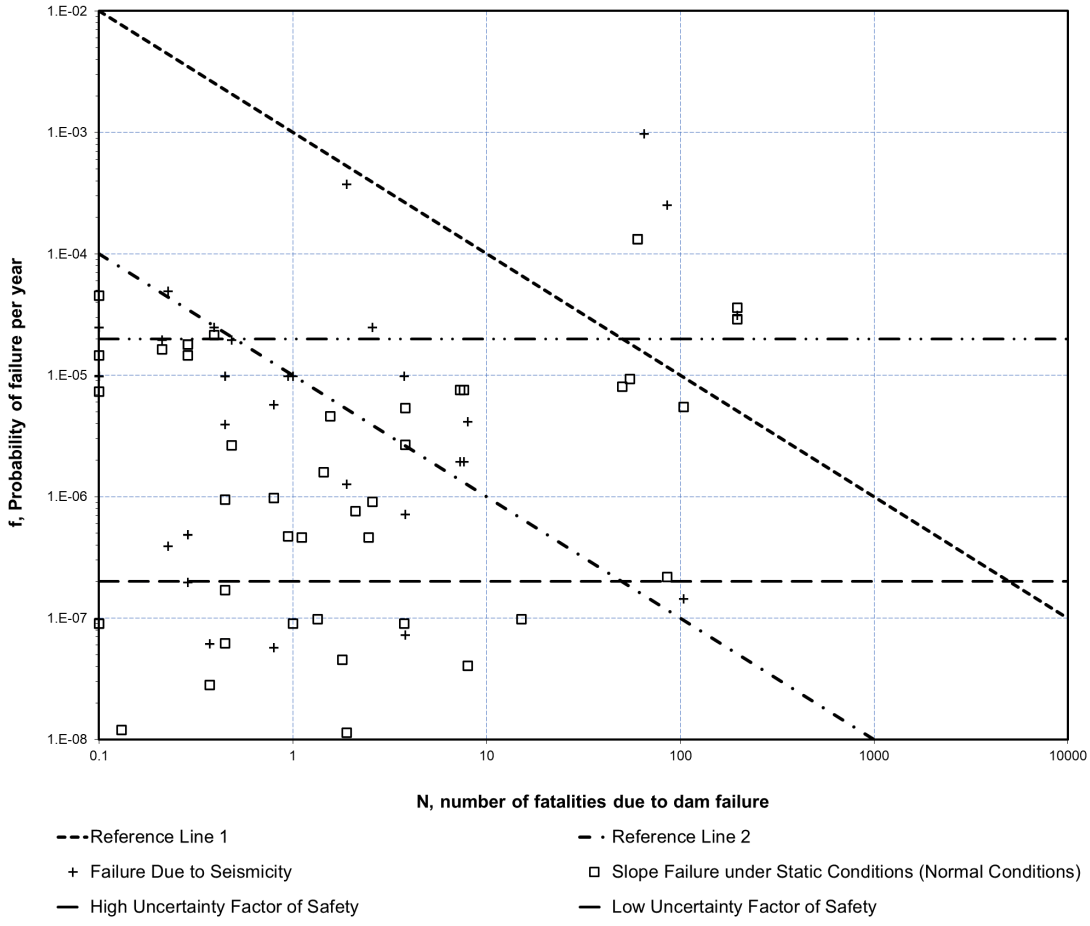

Figure 7: QRA dataset filtered by static versus seismic stability

Figure 7 shows the dataset for instability under static conditions (no upset conditions applied) and seismic conditions. The following observations are noted:

- There are points above Reference Line 1 for both static and seismic conditions.
- Under seismic conditions, there is a trend indicating an increased pF with increasing PLL, despite the requirement for a high design loading when the consequence category increases. For TSFs with high PLLs, meeting the design loading indicated by the relevant standard/guidelines did not indicate a tolerable risk position, despite being compliant.
- Under static conditions, whilst all the facilities were thought to be "compliant" (i.e., a factor of safety ≥1.5), prior to the assessment, significant uncertainty was noted in the parameter sets

adopted, resulting in a range of pF values being agreed in the workshops.

Two groups are evident from the results presented in Figure 7– those with high uncertainty in the assessment and those with low uncertainty. This is consistent with the data presented by Silva et al. (2008) and Gover (2018), where low confidence in the parameters supporting the stability assessment results in in a higher potential probability of failure. It follows that designs of new TSFs, along with taking into account best practices and new technologies, should also target high confidence datasets, in order to support a design that can be demonstrated to be ALARP. This would also include a better understanding of the natural variability of the materials (foundation and embankment) and implementing controls to suit, as part of managing the inevitable uncertainty that will exist.

Conclusion

QRAs undertaken on 16 TSFs have highlighted both the benefits of risk-based approaches as well as the inherent flaws in standards-based engineering, particularly where there are high loss of life consequences. When plotted in different datasets, the data indicate that there is no typical trend indicating that a particular failure mode is better managed, particularly when there is a high PLL. In fact, the data appear to indicate that there is no trend between pF and N (PLL). In other words, the failure modes do not appear to take into account the PLL, despite higher consequence categories, and hence higher event loadings, being adopted for TSFs with higher PLL values. The data also indicate that downstream facilities had significant points in the intolerable zone, despite being considered more robust than upstream facilities. For instability under static conditions, this is consistent with standards-based engineering, where the same factor of safety minimum value is applied regardless of the consequence category.

By considering both facility type and static versus seismic instability, the results can be used to identify the systematic deficiencies in design that indicate that standards-based approaches are not sufficient to manage high consequence TSFs. This is indicated by the facilities being considered “compliant” prior to the assessment, but significant parameter uncertainty led to intolerable values under static conditions and, where high PLL values were estimated, meeting the design loading indicated by the relevant standard/guidelines did not indicate a tolerable risk position, despite being compliant.

Based on the data presented, is it imperative that a risk-based approach be considered, in addition to standards-based design if required, to have an improved understanding of potential failure mechanisms, particularly when there is a significant population at risk and PLL. An increased focus on reducing uncertainty through investigations, testing and analysis for TSFs with high PLLs is strongly supported by the authors.

Acknowledgements

The authors would like to thank Leila Ang, Brendan Cummins, Andy Liu, and Nigel Moon for their contributions to the risk assessments, as well as the Clients who provided us the opportunity. The authors would also like to specifically acknowledge Andy Liu for his significant contribution to the data interpretation to support this paper.

Evaluating the Stability of Upstream and Brittle Facilities – Case History Validation of the "Rules"

Michael Davies, Davies Mining Consulting Ltd, Canada
John Lupo, Mayhem Creek LLC., USA

Abstract

Roughly twenty-five years ago, one of the current authors and a colleague provided the industry with "Upstream Constructed Tailings Dams – A Review of the Basics." That publication provided ten "Rules" for the design, construction, and operation of upstream tailings facilities, based upon soil mechanics principles that were then calibrated with case histories. These Rules have been cited many times since, and when followed, have universally led to sound outcomes. However, at times the Rules have seemingly been ignored – and in some of those cases, catastrophic outcomes have resulted.

The authors are two former mining company executives who were also global tailings practice leads and, prior to that, designers. From the owner perspective later in their careers, the challenge that seems to most often exist is discerning how "grey" the Rules are, and which are the most critical. From a designer standpoint, how conservative does the design have to be to avoid the triggers that lead to the checkered past of upstream facilities? This update reviews each of the previous Rules in the context of case examples that have occurred both prior to and, most importantly, since the original publication. The review leads to several focused conclusions about the Rules that are directly aimed at key failure prevention issues, and which should assist owners, designers, and regulators. Although originally envisaged as Rules just for upstream constructed facilities, the rules are applicable to other tailings construction methods for which brittle failure may be of concern.

The paper clearly identifies a list of non-optional attributes for designers, owners, operators and reviewers to fully embrace for both themselves and any upstream facility or facility with a similar brittle failure concern. The update is of particular value for legacy (operating or closed) facilities where the details regarding the previous design and/or development history can be murky at best, and therefore guidance on a paradigm based upon both sound soil mechanics fundaments *and* case history outcomes is needed to enable confidence in evaluations.

Upstream/brittle facilities – the basics

Davies and Martin (2000) provided a set of 10 "Rules" for upstream constructed tailings dams based on both their commonality across the industry and also on their considerable presence in the global tailings failure database. The Rules included a combination of issues ranging from nomenclature confusion to technical considerations to governance aspects. After more than two decades, some of the less technical items can now likely be retired, as very few practitioners are still trying to convince others that by simply calling an upstream facility something else it will abide by a different level of physical laws. Further, the vilification of the very concept of using upstream construction has become very popular, to the point that many facilities that have had an incident (from a close call all the way to catastrophic) that are *not* upstream facilities have been given that label by those with a mission of banning the practice altogether.

We will arrive at all of the above later in this paper, but the basics still apply: an upstream facility is one in which the dam crest, including the upstream edge of the crest, moves over beached tailings at any point in its sequential raising. This is unambiguous. The best test for an upstream constructed facility is whether a vertical line extended to the foundation of the facility from the upstream edge of the crest ever touches beached tailings. If the answer is yes, regardless of how much it touches, the facility is an upstream constructed facility. To argue along the lines of "only x% is upstream" is to argue not to worry about one or two weak continuous layers in a large slope; however, this is not an argument that will stand any test of logic.

The aspect that seems to escape many is that merely being an upstream facility does not constitute a black mark on the facility. On the contrary, many of the largest facilities in the mining industry are both upstream constructed and some of its safest. A theme throughout this paper is that a properly conceived and operated upstream facility will potentially have failure modes that other geometries may not; however, they can be constructed, operated, and closed/reclaimed with no higher risk profile than non-upstream facilities. Of all the documented tailings failure case studies, there is not one that has met all of the Ten Rules laid out in 2000. By contrast, those facilities that have followed the Rules have continued to function without incident.

The Ten Rules revisited

Table 1 provides a summary of the Ten Rules from Davies and Martin (2000), along with a note about the current thinking on each. As was evident to the authors, it is likely acceptable to consolidate the Rules down a bit into a tighter set of items. Assisted by the case history, the remainder of this paper is focused on precisely that attempt at developing a tighter set of Rules.

Table 1: The ten upstream tailings facility Rules (after Davies and Martin, 2000)

No.	Rule	Comment(s)
1	If there are any beached tailings beneath the upstream crest of the tailings dam, then the structure has been developed using upstream construction.	Far more obvious in 2024 than in 2000, as few are now trying to use alternative terms like "modified centerline."
2	Maximizing the beach above water (BAW) zone is good practice when developing an upstream tailings dam.	As it pertains to creating a sufficient shell of drained and dilatant material, this remains very relevant.
3	Upstream constructed tailings dams are not necessarily bad engineering practice.	This remains very topical, but is more political than technical in 2024.
4	Upstream dams require a good foundation – preferably well-drained and of adequate constitutive behavior.	This remains relevant.
5	Correct tailings bulk densities and in-situ stress conditions need to be used when estimating in-situ state.	The authors are seeing less confusion in practice on this issue. It can perhaps be combined with a more overall design requirement.
6	If the impoundment has an upstream constructed dam, and the dam slopes are steeper than about 4H:1V, the facility has a greater susceptibility to static liquefaction with minimal trigger application.	This can be even more strongly stated in 2024 through confirmatory soil mechanics practice/theory.
7	Undrained strength analysis (USA) should be used for upstream dams where the tailings are uncompacted and largely to wholly saturated.	Again, this is all fundament training in soil mechanics, and remains perhaps the most relevant design requirement. Unfortunately, it was missed with several failures.
8	Design geotechnical requirements and actual operating criteria must be compatible.	This remains relevant.
9	Laboratory-scale and literature-predicted beach slopes tend to be incorrect. We should not rely upon steep beach slopes to meet operating criteria.	This seems to have been an issue that has been well addressed over the past 25 years with few, if any, unrealistically steep beaches being designed and then not realized.
10	Designers should avoid designing upstream tailings dams where the designer will not be able to maintain a high level of involvement in the monitoring and evaluation of the facility.	This aspect was well addressed in the 2020 GISTM.*

* Global Industry Standard on Tailings Management

The comments in Table 1 are based upon the authors' combined experience for each of the Ten Rules developed in 2000. All of the Rules still apply, but there is no question that emphasis can be altered, and some reworking of the items is possible. Moreover, items like Rule 10 that address an overall governance issue have been addressed across the industry, assuming adherence to one of the Mining Association of Canada Tailings Guidance series (e.g., MAC, 1998) or the largely duplicative Global Industry Standard on Tailings Management (GISTM, 2020). It is also the expectation of the authors that anyone working with tailings facilities in 2024 is a student of the core teachings of Peck (1980) and considers sound judgment to be essential for any role in this field. With this initial evaluation of the 2000 work, the paper now turns to the twenty-five years since the paper was published. Over that period of time, in terms of upstream

constructed tailings facilities, what has been observed in terms of both the practice of tailings management and the actual performance of facilities?

The elephant in the room – should upstream tailings facilities exist?

Some key mining jurisdictions (e.g., Chile and Brazil) have banned the use of upstream tailings facilities, and many outside of the industry continually call for a cessation of the practice. To not address the basic question of "why upstream at all?" would be grossly disingenuous when developing a summary position paper on the topic. The claim by some that upstream facilities are disproportionately represented in the failure database ignores the fact that they are also historically the most common type of tailings facility. There is also considerable variation in the nature of upstream facilities in terms of structural competency, as the construction methodology can vary considerably. There is also a claim by many that the industry only uses upstream construction as it is the least expensive option. This was likely valid in many cases prior to the 2000 paper, but the authors' experiences do not reveal that as the sole or even the main driver twenty-five years later. The modern tailings facility has to consider many key points beyond just the economic viability that upstream constructed facilities can provide. These include the following:

- Considering whether the upstream facilities allow progressive reclamation and erosion/dust protection on the shell to occur during operation.
- Setting the ultimate footprint for the facility at the outset to allow certainty for infrastructure placement and community boundaries.
- Depending upon location and topography, the planners can dramatically reduce the footprint of the project by requiring far less construction material (and hence less energy expended, etc.).
- Developing closure surface drainage systems at the outset and maintaining these throughout operations.
- Putting in long-term instrumentation on slope sections – and as the toe and slope remain constant after being placed, it is possible to monitor comparative surface movements over time via technology like InSAR, drones, and other remote sensing options, whereas this is not necessarily the case with other methods.

In Chile, the March 1965 failure of the El Cobre tailings facility (which caused more than 200 deaths) prompted widespread discussion in Chile and public pressure for stricter control over tailings facilities. The Chilean authorities issued Decree No. 86 in 1970 to regulate the design, construction, and operation of these facilities, and included one special clause, which was the prohibition of the tailings facility upstream construction method. Over the sixty years since that tragic event, similar calls for restrictions on upstream construction have stemmed from events such as Samarco/Mariana (2015) and Brumadinho/Feijão (2019).

Most notably, the 25 January 2019 upstream tailings facility that collapsed at the Córrego do Feijão iron ore mine (9 kilometers east of Brumadinho, in the state of Minas Gerais, Brazil) released a mudflow that engulfed the mine's headquarters and its downstream surroundings and caused the death of 270 workers.

This paper does not attempt to be a full case study evaluative review of any one failure and does not provide commentary on the many publications (inclusive of expert reports from such failures). However, it is very clear that many more than one of the Ten Rules provided in 2000 were ignored in all of these failure events. Some argument as to the degree of contribution of any one Rule over another is inevitable, but this is often like arguing about what broken bone was more severe for a patient who was decapitated; the point being that the failure happened because Rules were broken. The Rules, as stated in 2000, are not a "use as many as you can" situation. We cannot hope that "following 7 is better than following 3." Then or now, *none* of the Rules should be considered optional. There is no "better" based upon any degree of partial compliance. Of course, basing the entirety of the structural integrity evaluation on a flawed premised (e.g., drained strength), which seems almost universal in all of the upstream case histories, almost always ensures becoming a failure case history. However, the other nine Rules can each in their own way create a pathway to a catastrophic outcome.

This all sounds pretty bleak. However, one also must remember that many of these Rules fully apply to any other geometry as well; particularly if there are any credible brittle (strain-softening) failure mechanisms present and/or susceptibility to failure by facility overtopping or suffusion. If we get past Rules 2 and 7 (and these are both directly related to Rule 6), all of these other items apply to everything from dry stacked tailings facilities through the most robust downstream rockfill shell facility. Even Rules 2 and 7 can play a role in a "drystack" filtered facility if operational controls are not both appropriate for site conditions and followed within very tight boundaries.

So, why do the authors then come out firmly on the side that upstream facilities should be part of options for tailings facilities both today and into the future? The answer is simple; it is because sometimes they *are* the best option when all things are considered. Moreover, and perhaps most importantly, there are no case histories of an upstream facility having ever failed if it was following the Ten Rules. This perhaps is the best evidence that the Rules work. It follows from this that is you obey the Rules then using upstream constructed tailings facilities can be an option for you. However, the one essential component that was not stressed as much in 2000 as today, and that is addressed in the next section, has become evident over the past twenty-five years and needs highlighting.

The hard truth – competence matters

Perhaps a positive step for global regulation of tailings facilities is to get beyond the often meaningless fixation with "one size fits all" items like limit-equilibrium factors of safety and move towards regulating

the competency of those involved in owning, designing, and reviewing tailings facilities. Being a qualified owner perhaps needs to go beyond present-day practice and evolve towards having to use pre-qualified designers and reviewers. To do this, regulatory practice should evolve past the present levels. For example, the current fixation with computed "factors of safety" is not a sound regulatory basis. The reality is that, dependent upon material behavior types, some facilities with computed values near unity will be safer and less able to – if at all – fail catastrophically than facilities with far higher computed values. While the seductive simplicity of striving for target values is obvious, the practice oversimplifies the situation to the point where disastrous outcomes are possible. This perspective is substantiated based upon forensic evaluations of facility failures where the designers of these facilities had almost universally demonstrated high factors of safety prior to their demise. Instead, we need to have a regulatory process that only allows upstream facilities (or any for that matter – but that is another topic) to be constructed by:

- Owners who clearly demonstrate commitment to a governance model like MAC or GISTM, inclusive of having internal personnel with vetted experience with similar structures and who demonstrate application of sound, risk-informed decision making.
- Owners who retain Designers/Engineers-of-Record who have demonstrated experience with similar facilities in similar climatic/tectonic settings and most certainly have vetted competency in undrained strength evaluation, the fundamentals of static liquefaction, and in the practical application of these principles in sand embankment construction. If these personnel are to be changed at any point, strong succession plans and change management processes must be in place.
- Owners who commit to having fully Independent Reviewers who meet all the tests of the Designer/Engineer-of-Record, with the additional buffer of more experience, varied experience, and a thorough understanding of failures that have occurred across the history of the industry.

The above would address what Morgenstern (2018) termed "weak engineering." The analogy the authors suggest is that of the medical profession, although many other equally valid comparisons across other human activities potentially impacting human health and safety can be applied here. Using the "ban upstream facilities" approach in medicine would mean that some types of surgery could not be used any longer as not all surgeons are capable of the procedures. For example, perhaps almost every licensed cranial surgeon practicing today can effectively remove a concerning mass from a brain with typical risk outcomes. However, for the most leading-edge surgery on the more involved brain tumors, only a smaller number of surgeons are qualified for such procedures. If having such a surgery is the best option for the patient, why deny it? We realize that those opposed to upstream facilities will cry foul as such an analogy, but before they do, what about airline pilots? Is there not a pecking order in competence with certain sizes and complexities of aircraft? Do airlines not offer certain plane options that are perfectly safe if the Rules are

followed by the appropriately trained pilots? Well, why can't the same logic be applied to upstream tailings facilities? For those owners in jurisdictions where the practice is common, and many of the facilities are very large and demonstrated to be safe and have followed the Rules – why is it not a valid option both today and moving forward?

Perhaps the confidence society needs to have to remove a blanket fear of the practice is some assurance that those involved are competent, and vetted as such, coupled with the unblemished record of those facilities that follow the Rules. If we combine the above noted competence requirements for the key roles with the essential technical elements offered near the end of this paper, then that confidence should be attainable. If we were to embed these requirements into professional licensing (e.g., P.Eng./P.E.) and employ externally verified (through independent review boards) processes for vetting the designer, then most, or even all, of the concerns can likely be addressed.

Case history learnings

Table 2: Notable upstream tailings facility case histories

Case	Rules Not Followed	Comments	Key Reference
Stava, Italy, 1985	2, 6, 7 and 10	Very steep slopes, no one is quite sure who was responsible for the design, no beach guidance and the only stability work was drained evaluation. Failed in static liquefaction.	Davies and McRoberts (2002)
Brumadinho/ Feijão, Brazil, 2019	2, 6, 7 and 10	Saturated relatively steep slopes with high pore pressures evaluated with drained strengths. Failed in static liquefaction and likely occlusion of high pore pressures.	De Melo et al. (2019)
Mariana/Samarco, Brazil, 2015	2, 6 and 7	Undrained failure with contributions from abutments that was seemingly ignored in laying out design and construction sequencing. Failed in liquefaction.	Embargoed
Sullivan, Canada, 1990	2, 6 and 7	Rapid construction without the ability for pore pressures to dissipate. Designs only considered drained strengths. Failed in static liquefaction.	Davies et al. (1988)
Confidential, North America, since 2000	2, 6 and 7	Drained evaluation only considered, very little beaching occurred subaerially and previous "near failures" were not used as bellwether. Failed in static liquefaction.	Authors' files
Porco Mine, Bolivia, 1996	2, 6, 7 and 8	Lack of alignment between design beach requirements and operating pond realities led to large zone of loose saturated tailings that failed in static liquefaction.	Martin et al. (2002)

Table 2 provides a list of notable upstream tailings facility failures where there is sufficient knowledge to be able to compare the contributing factors to the failure event with the Ten Rules established in 2000 and

summarized in Table 1. Each case is identified with those top few Rules broken based upon public domain information (in all cases except a confidential case on which the authors have detailed information). The only Rule not included is Rule 1. There is no question that each and every case involved an upstream constructed facility. These findings are then used to allow the paper to wrap up with some technical essentials that all such facilities require to avoid becoming a case history candidate.

The interesting conclusion from Table 2 when looking at the broken Rules deemed to have contributed the most is that Rules 2, 6 and 7 are present for each and every failure event. Table 2 includes the two most tragic events in the industry's documented history (Stava and Feijão combined led to more than 500 fatalities), along with textbook examples of sudden "collapse" failures of upstream facilities that have been independently reviewed and documented. From the consistently broken Rules 2, 6 and 7, clarity on what the technical essentials are for upstream construction becomes evident.

The technical essentials

Case histories, such as those in Table 2 and the many others, inclusive of "close calls," are very helpful. The latter can be very helpful by defining the edge of imminent collapse, which can assist greatly in modeling future behavior. Ignoring the set of Rules from 2000 and simply looking at "what good looks like" from the collective experience of the industry with upstream facilities, inclusive of the failure case histories, the following appear to be essential for a successful upstream constructed tailings facility:

1. A stable foundation without a brittle failure mode is present along with any other included elements following standard practice (such as filter zones, erosion protection, sizing of drainage features, surface water management etc.). This would be essential for all geometries (upstream, centerline, or downstream) and is included for completeness.
2. An active surveillance program and commitment to a sound quality assurance program that regularly manages beach width, embankment pore pressures, and deformation characteristics of critical embankment sections in as close to real-time as practical. This program should have strategic key performance indicators (KPIs) that are underpinned by conservative trigger action response plans (TARPS) for all instruments that are inclusive of at least two levels of response/evaluation prior to levels reaching a facility safety concern level.
3. An adequate zone, both in width and from the base of beached tailings to the top of the embankment, of either sufficiently unsaturated or dilatant tailings. In terms of saturation, if solely relying upon that characteristic, it appears that staying below about 70% is required. For the achievement of a sufficient zone of dilatant tailings, the initial lifts are often the most challenging. Early in a facility's life, it is necessary to have a combination of the pond being

relatively close with insufficient geometry to create the strong downward gradients and resultant densities from subaerial beaching. For this period in the construction cycle, mechanical compaction/cell construction is likely required from start-up and then for some portion of the construction dictated by measured performance (e.g. cone penetration testing for in-situ state).

4. For any materials that can potentially become saturated, use undrained analyses with appropriately obtained strength (e.g. lower bound for the stress state) and constitutive relationships and appropriate triggering stability analyses/deformation modeling based upon these relationships. Properties should be routinely confirmed, as required, through investigations and updated analyses that embrace any advances/learnings on material sampling, in-situ testing, constitutive characterization, and methods of analyses.
5. For any materials in the tailings facility or the foundation that may be susceptible to seismically induced liquefaction due to their saturation and/or density state, carry out such evaluations using the maximum credible (or the 1 in 10,000-year event, whichever is most appropriate) applicable ground motions for the site in evaluating the potential for post-liquefied strengths to impact structural integrity.

Should the above essentials, which embrace the Ten Rules, be followed and maintained within a governance structure of ownership, engineering and independent review as described in this paper and implied by publications like MAC Guides and the GISTM, upstream constructed tailings facilities can have a risk profile on par with any other type of tailings facility.

Finally, Rule 6 from 2000 can further simplify things. If the foundation and other elements for the facility are stable and/or designed and constructed with appropriate design criteria per established practice, an upstream facility constructed with an overall slope of 4 horizontal to 1 vertical or flatter only need demonstrate seismic stability. Static brittle response at slopes flatter than 4H to 1V are not possible in any loading path and a "collapse" failure is not available. Where the material balance and site footprint allow, the adoption of these flatter slopes can be an excellent way to avoid almost all credible failure related to instability.

Where the rubber hits the road – operations

All the Rules, with the exception of 8, are focused on design. Rule 8 focuses on the compatibility between the design and operational criteria. What is implied here is that the facility must be operated in a way that is compatible with the design. A sound change management system should be in place, but even then, a lack of compatibility can still arise. While avoiding this incompatibility between design and operation may seem

obvious, experience unfortunately shows that implementation can be very challenging leading to less than desirable consequences in some cases. For example, in the early years of the facility and/or right after a raise, pond management can become difficult, resulting in an inability to achieve the minimum beach length or freeboard requirements. Difficulty in pond management may have follow-on effects with deposition (e.g., poor sand production or non-uniform beaching), which can worsen the situation. Effective layer density state (e.g., non-contractant) is less likely to be achieved. These are some of the reasons the authors recommend above formal mechanical beaching/cell construction with compaction for such situations and in particular for the start-up of new upstream facilities, unless it is absolute and independently verified by qualified people that it will not be required.

Changes in staffing within the operations team can result in the loss of institutional knowledge, leading to practices that are counter to the original design intent. Succession planning in the operations team is as important as succession planning within the EOR's team. If a consistent experienced team that has demonstrated an ability to meet the technical essentials noted above for the constructed facility is changed or replaced, then most certainly method specification is not to be used and complete adoption of a performance specification with a comprehensive control and assurance program will be required. All of this can be assisted greatly by the aforementioned use of surveillance program KPIs and TARPs that can be augmented with practical operation procedures. All of these materials should be concisely and readily available through a facility's Operations, Maintenance and Surveillance Manual (OMS).

For long-life facilities (e.g., a number of decades), the original design criteria/intent will likely change due to modifications in raise configuration to account for land constraints, ore mineralogy, mill throughput, sand production/quality, etc. In these cases, the design and design basis will likely need to change, requiring a corresponding change in the operational criteria and practices. The operations team needs to be working closely with the designer to fully understand the implications of these changes. Incremental changes need to be looked at in their cumulative entirety compared to the current design in terms of the design's operational requirements to avoid complacency.

Finally, the owner needs to have made and demonstrated a clear statement of a safety culture that underpins all aspects of tailings management. This culture embraces the concept of all site personnel and community members having no impacts on their health or safety from the tailings facility. The culture also recognizes the benefits of regularly updated risk analyses so that risk-informed decisions are made based on current information.

Conclusion

The Ten Rules established in 2000 remain valid nearly twenty-five years later. At the same time, the list can be reduced thanks to other initiatives being adopted by the industry (e.g., better governance through

strong programs like MAC or GISTM) and a reduction in "playing games" with nomenclature and other issues regarding upstream facilities (what is or what is not such a facility). To that end, the authors believe that keeping the Ten Rules handy is useful, but emphasize five essential technical components, along with a sixth (flatter than 4H to 1V), that can render many of them very robust facilities in terms of instability concerns.

The failure case histories available, the current understanding of undrained response of tailings to shear loading, and the demonstrated successes of many major upstream facilities all align with keeping this geometry as a viable option for the industry. As the authors note, only appropriately qualified owners, operators, designers, and reviewers should be involved with such facilities. They encourage those who regulate and permit such facilities to, instead of bowing to calls to ban the practice, instead concentrate on getting assurance as to the teams involved in each case.

How to Design a Tailing's Dam Full Removal? Lessons Learned from a Case Study in Brazil

Benicio Junior, Klohn Crippen Berger, Brazil
Claudio Rodrigues, Vale S.A., Brazil
Neil Singh, Klohn Crippen Berger, Canada
Luciano Souza, Klohn Crippen Berger, York

Abstract

Following the catastrophic mining dam failures in Mariana (2015) and Brumadinho (2019), Brazil enforced stricter legislation on mining dams, including the prohibition of upstream raising construction methods and the mandatory decommissioning and decharacterization of existing upstream-raised dams as stipulated in ANM Resolution No. 13/2019. This case study presents the decharacterization project of a high-priority dam featuring two pits and a reservoir, initially holding approximately 2,000,000 m³ of tailings. The project involved extensive trade-off studies, geotechnical and hydrogeological assessments, and pilot testing to identify the optimal decharacterization approach.

The selected solution, involving the complete removal of upstream tailings and the creation of a uniform flat slope with a central channel over the starter dam, was chosen for its reduced consequence classification and potential for tailings reuse. The project was divided into multiple phases, with each phase addressing specific challenges and leveraging remote excavation technology. Detailed investigations and pilot tests provided critical insights, leading to phased excavation and continuous model refinement. During the design and governance review process, the final design outcome was modified from a decommissioned starter dam to complete removal of the embankment and tailings, and restoration of the original valley.

Key challenges included remote investigation and excavation, tailings variability, 3D modeling complexity, stakeholder engagement, and stringent water management requirements. The project's iterative design approach, underpinned by robust stakeholder engagement and advanced modeling techniques, facilitated successful decharacterization while ensuring safety and compliance with regulatory standards. Lessons learned emphasize the importance of early and continuous stakeholder involvement, iterative design processes, the observational method, and the critical role of hydrogeological and deformation models in managing complex decharacterization projects.

Introduction

After the disasters in Mariana in 2015 and Brumadinho in 2019, Brazilian legislation became stricter regarding mining dams. These incidents led to the prohibition of the upstream raising construction method through National Mining Agency (ANM) Resolution No. 4/2019, which was later replaced by ANM Resolution No. 13/2019. Besides banning the construction of new upstream dams, Article 8 of the mentioned resolution required the decommissioning and decharacterization of existing upstream structures. ANM Resolution No. 95/2022 consolidates the normative acts that provide for the safety of mining dams, later amended by ANM Resolution No. 130/2023, defining a decharacterized structure as a structure that does not permanently receive inputs of tailings and/or sediments from its core activity, and which no longer possesses characteristics or performs the function of a dam, in accordance with the technical project. The project goal was for the TSF to be decharacterized.

According to ANM Resolution No. 13/2019 and the Terms of Reference for the decharacterization of upstream-raised dams by the State Environmental Foundation of the state of Minas Gerais, decommissioning is defined as the cessation of operations and the removal of associated infrastructure, such as spillways and pipelines, except those necessary to ensure the structure's safety. Whereas decharacterization is defined as decommissioning plus the implementation of effective measures to reduce or eliminate the influx of surface and groundwater into the reservoir. This includes preventing flood routing in the reservoir during the design of the spillway system, ensuring the long-term physical, chemical, and biological stability of the remaining structures, and monitoring the effectiveness of these measures for as long as necessary.

Typically, decharacterization projects in Brazil involve either one of the following alternatives: full removal of upstream embankments, partial removal of upstream embankments, or sufficient buttress to allow the dam to no longer be classified as an upstream raise.

Facility description

The total area of the facility that will be presented in this case study is composed of two pits (Pit A and Pit B) and the Reservoir, as shown in Figure 1. At the start of the decharacterization project, the dam stored around 2,000,000 m³ of tailings within the three areas of disposal. The tailings were well above the rim of the two pits, forming a continuous deposit from the dam.

The starter dam, built in the 1970s, has undergone four upstream raisings and a buttress reinforcement, at various stages during operation until the 1980s. The dam stands at a maximum height of 42 meters, with a crest width of approximately 10 meters and a length of 246 meters. The reservoir area at crest elevation

covers around 235,000 square meters, covering the reservoir area and pits A and B, which were filled during the 2010s.

There are two downstream reinforcements berms with maximum heights of 10 meters and 9 meters, and widths of 3 meters and 19 meters, respectively. The dam upstream slopes are not specified, as the beach meets the crest, while the downstream slopes have gradients ranging from 2H:1V to 1.64H:1V. The dam fill is comprised of a homogenous compacted saprolitic soil sourced locally.

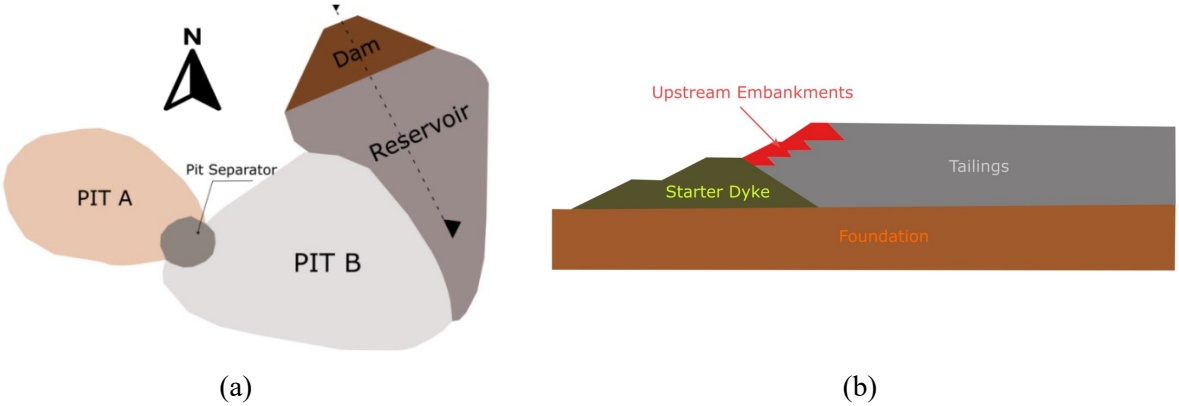

Figure 1: Schematic view – (a) plan view (b) cross-section

A granular internal drainage system runs beneath through the starter dam as basal drain. Foundation soils are residual phyllite soil, averaging 5.0 to 6.0 meters thick, overlying phyllite saprolite of similar thickness. The residual soil at the dam's base is thinner than at the abutments due to partial excavation. Beneath the saprolite, the material transitions to moderately resistant phyllites with increasing depth.

The dam is classified as high priority (DPA) with a high-risk category at the federal level and a low-risk category at the state level. According to CDA and GISTM standards, the dam is designated as Very High consequence.

Trade-off studies and conceptual engineering

Based on the initial goal to decharacterize this upstream raised dam, seven alternatives were analyzed in a trade-off study. This study included a qualitative analysis of all alternatives and a detailed evaluation of the three most viable options: upstream portion removal, rockfill buttressing, and complete removal with a downstream check dam.

For each alternative, risks associated with geotechnical, hydrological, and hydrogeological conditions were assessed. A Potential Failure Modes Analysis (PFMA) was conducted to identify potential failure modes, involving discussions with all stakeholders, including engineering and operational teams, the Engineer of Record, the Design Reviewer, and the corporate geotechnical team.

A technical gate was then held to determine the best alternative for further detailed engineering. After thorough analysis, the stakeholders decided that the removal of the upstream raised portions of the dam was the optimal solution, considering technical, environmental, and social aspects. The technical gate process was used at each major design and decision stage of the project.

After this initial technical gate, the chosen solution was to remove all upstream tailings, creating a uniform flat slope with a central channel to connect the reservoir with two pits. This alternative was selected for several reasons:

- With no upstream raises left, the dam would no longer be characterized as an upstream raise, and the remaining dam (Starter Dam only) would have a reduced consequence classification.
- The alternative buttressing solution would have required advanced technologies for proper QA/QC and extensive investigation at the dam's toe, necessitating remote equipment.
- The high iron content of the excavated tailings (> 60% hematite, Gs ~ 4.5) offered opportunities for re-processing, which would offset the cost of the decharacterization works.

A conceptual design was developed for the selected alternative, which included a gap assessment, initial data consolidation, and technical specifications for the next engineering stage. The concept involved hydraulically connecting Pit A, Pit B, and the reservoir with a channel excavated in the tailings with outflow to a concrete channel on the left abutment of the dam.

A conceptual deformation model developed in FLAC 2D indicated that the excavation process was technically feasible, with a low probability of initiating static liquefaction during excavation. However, due to the limited availability of data to characterize the tailings and limited construction records, the initial FLAC model used critical state parameters from the Fundão dam as representative of the tailings. This gap in critical state laboratory testing was to be addressed through site investigation and lab testing of the tailings in subsequent engineering phases.

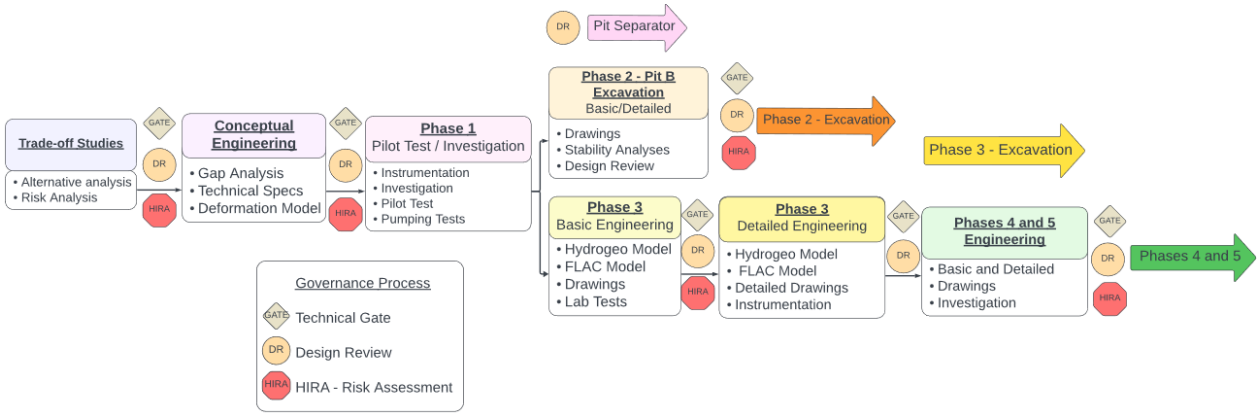

Figure 2: Project flowchart with initial phases in detail

During the conceptual engineering phase, the project was conceived of as proceeding with excavation of long continuous layers beginning from Pit A and extending across Pit B and the Reservoir. Phase 1 however, began as a pilot test in the most upstream portion of the excavation in Pit A. The pilot test was intended to assist in determining water management, and thickness of each continuously excavated layer down to the Starter Dam. Instead, the pilot test revealed a completely different approach that separated the work into five phases. Figure 2 illustrates the project phases, emphasizing the initial stages.

Phase 1 – project development and Pit A excavation

Phase 1 advanced the project from a conceptual engineering gap assessment and preparation of initial technical specifications into a pilot excavation test program, coupled with site investigations, pump tests and instrumentation installation to better characterize the tailings, dam fills, and foundation materials.

Pilot test and pit separator

The primary objective of the pilot test was to explore excavation criteria under controlled conditions, away from the dam crest, using unmanned equipment which would then lead to a plan for the full tailings removal. Initially, it was assumed that the tailings in Pit A would exhibit similar saturation levels as those in the reservoir, making the excavation trial representative for the remainder of the excavation, closer to the dam. However, during the installation of push-in piezometers and CPTu tests in Pit A, it was discovered that the water table was lower than anticipated for the pilot test's maximum excavation depth. This finding provided an opportunity to adjust the initial plan.

The CPTu tests also revealed that the region between Pit A and Pit B, initially thought to be larger and deeper, was shallower and narrower (Figure 3). The approximate depth to the old pit crest between Pit A and Pit B, was confirmed to be at a maximum depth of 6 meters, sloping upwards towards the abutments. This discovery enabled the physical separation of both pits, by excavating a "Pit Separator" down to native ground, excavating the dry tailings in Pit A to a shallow slope and reinforcing the Pit A tailings surface with rockfill. This separation not only significantly reduced the risk of tailings from Pit A contributing to a larger tailings' failure, but it also allowed Pit A to be re-designated so that manned equipment instead of remotely operated equipment could be used. Moreover, it created a substantial area for temporary tailings disposal during subsequent phases of excavation. This innovation notably enhanced the efficiency of excavation by minimizing the distance that remote-controlled equipment needed to transport tailings.

Additionally, the temporary disposal area in Pit A served as a stockpile zone where remote trucks deposited tailings from other areas. Manned equipment then transferred these tailings to their permanent disposal location, optimizing operational productivity across several projects.

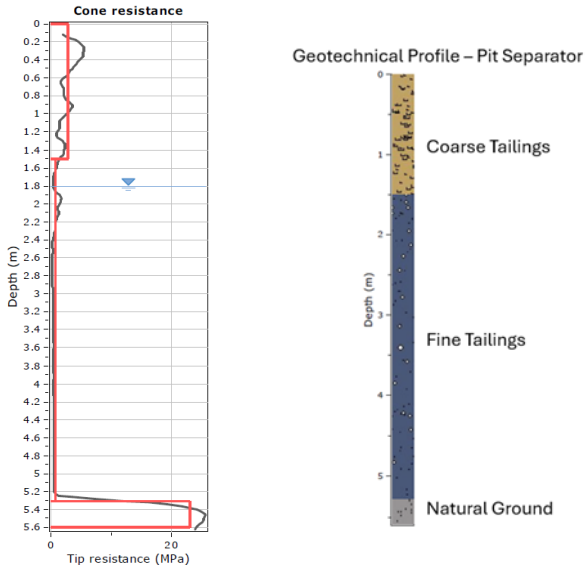

Figure 3: CPTu results in the pit separator region

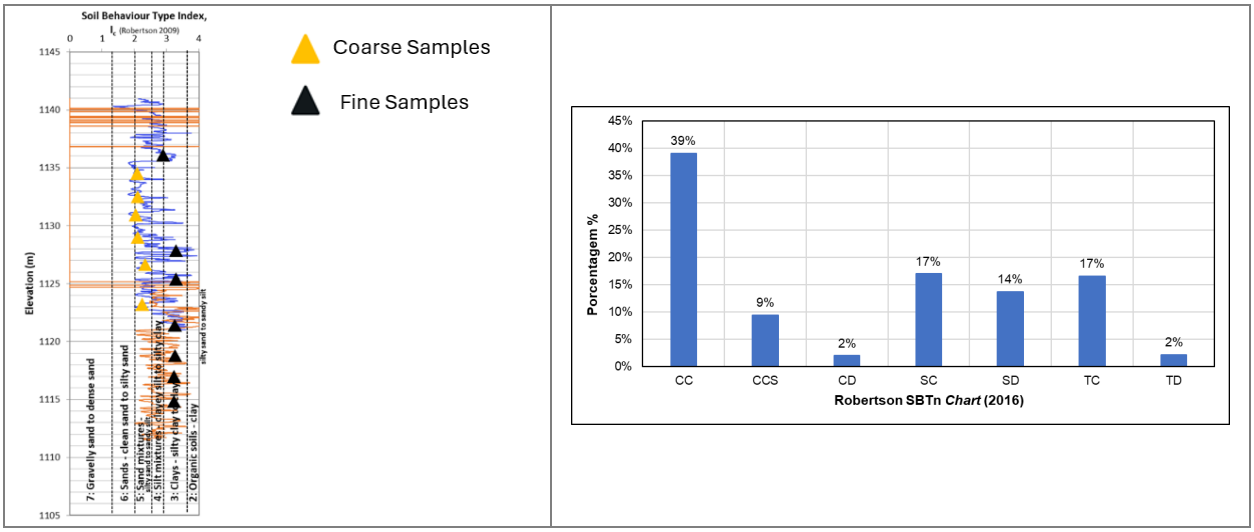

The Pilot Test phase also marked contractors' first experience with state-of-the-art remote excavation technology, a critical step in early project mobilization. This phase facilitated operator training, identified opportunities for improving remote excavation technology, and provided valuable insights to the design team regarding the limitations of remote operated excavation.

Phase 2 – investigation campaign and Pit B excavation

With the completion of the pilot test, initial investigation and pit separator, the next phase had originally been intended to be the main excavation of the upstream raises and tailings from Pit A to the Reservoir, but instead, with the separation of Pit A from the system, focus turned to excavation of Pit B. An investigation campaign and pumping tests were conducted to inform the basic and detailed engineering phases. Regulatory constraints required all activities within the tailing reservoir, including inspections and investigations, to be performed remotely or with lifelines (Andrade et al, 2022). Lifeline systems were installed at the crest and between Pit B and the Reservoir, effectively limiting investigation to the areas below the lifelines, excluding berms and upstream embankments. Furthermore, following the Brumadinho incident, drilling in tailings dams could not involve water or fluids, necessitating the use of hollow auger systems with restricted depth capabilities. Additionally, vibrations tests were run to estimate the level of vibration associated with investigation and excavation activities.

Over 60 CPTu and SCPTu tests and 15 push-in piezometer installations were conducted using Deep Drive® (Wood et al., 2023) remote equipment, which allowed for instrumentation outside lifeline areas. MASW surveys were also conducted across multiple sections of the dam and reservoir.

CPTu results, which included behavior and permeability assessments, were used to categorize tailings into fine, intermediate, and coarse in the reservoir and Pit B. Figure 4(a) demonstrated a correlation between soil behavior and grain size distribution, and a laboratory testing program was prepared to assess each of the three tailings categories.

(a) (b)

Figure 4: CPTu results – (a) Comparison with samples grain size; (b) Distribution of tailings based on soil type behavior

Laboratory testing was conducted primarily on remolded specimens due to difficulties in obtaining undisturbed samples. The laboratory testing campaign focused on determining critical state parameters for the tailings, crucial for deformation modeling. Figure 4(b) shows that over 80% of the tailings exhibited contractive behavior. However, due to restrictions on using only remotely operated machinery and the inability to collect manual samples, efforts to characterize foundation and embankment materials were limited. Some key challenges of this process were:

- Sample Collection: Despite planning to use disturbed samples from the beginning, field operations faced significant challenges in obtaining representative fractions for the three types of tailings. Depth limitations and inadequate representation of coarse and intermediate tailings needed multiple collection attempts, causing schedule delays.
- Communication: Coordination with a third-party commercial laboratory for critical state testing posed communication challenges initially. As the campaign progressed, closer collaboration improved feedback on test conditions.
- Behavior Variability: Despite classification into three types, the tailings exhibited inconsistent behavior during laboratory tests. Tests under similar remolding conditions and grain size distributions showed variability in stress paths, particularly in contractive tests, extending the duration of the laboratory campaign.

Figure 5 illustrates the Critical State Lines for the three tailing types and compares them with the Brumadinho tailings used in the conceptual phase. Despite differences in grain size distribution, the three types exhibited similar critical state lines, suggesting that these differences were not significant. Interestingly, the assumption of using Brumadinho CSL parameters proved conservative compared to actual test results.

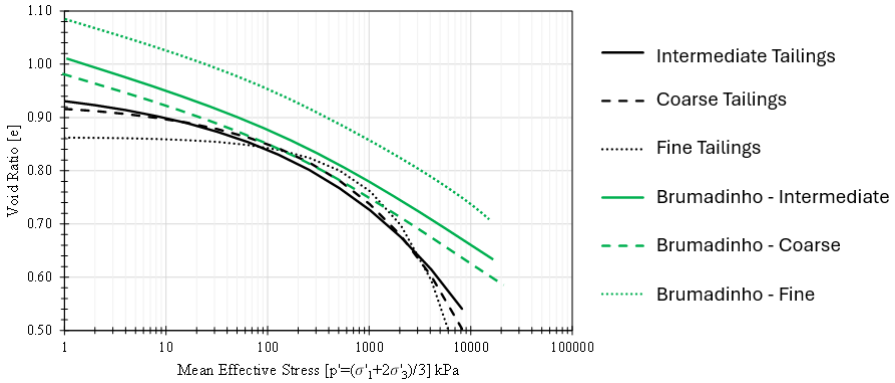

Figure 5: Critical State Line results and comparison with Brumadinho tailings results

Pit B excavation

Because of the construction of the pit separator between Pits A and B, and with the confidence gained during the Phase 1 excavation and the site investigation campaign, the next design step applied the results of Phase 1 (Pit A pilot test and pit separator excavation) and the site investigation test results on excavating Pit B.

Following the project governance structure, the decision to divide the excavation into segments (Pit A, Pit B and Reservoir) was reviewed by all stakeholders following a risk assessment (HIRA) and a technical gate. It was concluded that based on the distance between Pit B and the main dam, and the success of Pit A excavation, that excavation of Pit B could be allowed to proceed (as Phase 2 of the works) separating the excavation of the Reservoir into a new Phase 3. The governance structure allowed clear and open communication between the engineering team, the designer, and constructors to approve this meaningful change.

Similar to Phase 1, the excavation during Phase 2 provided additional validation of project design criteria, and application of the observational method allowed modifications to construction requirements which then fed into the Phase 3 design. Phase 3 was the most critical excavation phase which would begin excavation of the dam upstream raises and the main reservoir and so Pit B excavation results provided the basis for parameters such as speed and depth of excavation, dewatering requirements, and vibration limits.

Phase 3 – reservoir excavation

The goal of (both basic and detailed) engineering for Phase 3 was to better understand the geotechnical and hydrogeological characteristics of the Reservoir and the upstream dam raises. The separation of Phase 2 Pit B excavation from the Reservoir excavation reduced the pressure on moving forward with the engineering for Phase 3, giving the team more time to work on modelling to characterize the Reservoir and, in particular, the upstream dam raises.

Initially, because of restrictions to access the Reservoir and dam downstream areas, geological mapping was not possible. After Phase 1 (Pit A excavation) and the start of Phase 2 (Pit B excavation) the restriction on access was partially lifted, allowing new mapping activities and personnel access to the Reservoir and dam areas (with new warning and tracking systems). The new mapping advances the preparation of a detailed hydrogeological model. Piezometric data, flow data and field observations fed the model and led to the conclusion that the east portion of the reservoir received most of the groundwater contribution, but due to the regional structural bedrock dip, this contribution was less than what was predicted initially. With this updated information on the geological features of the area and a complete hydrological history for all piezometers, the numerical model presented excellent results with a nRMS < 6%.

The calibrated hydrogeological model was used to provide piezometric conditions to be used in the 3D deformation model, providing an excellent calibration that represented the piezometric conditions for each step of excavation. Since the hydrogeological model was calibrated in the transient condition, it was possible to have an estimate of the piezometric surface for each stage of excavation considering the annual variation of rainfall and the amount of water being intercepted at each stage.

Due to the limited information regarding the construction history of dam construction and tailings deposition, it was not possible to model the construction sequence satisfactorily. The calibration of the model focused on matching the current state parameter, K0 and G0 condition in the reservoir based on CPTu estimates, and then modeled the excavation in layers, with the hydrogeologic model providing estimates of the phreatic surface at the beginning and end of each step. The deformation model results showed that the areas with susceptibility to liquefaction during the proposed excavation sequence were limited to small portions at the top of each layer.

Phases 4 and 5 – starter dam excavation and final channel

The revised project goal was to complete excavation of the Reservoir and all upstream raises down to the Starter Dam level, leaving the Starter Dam in place in three phases.

However, once again, the robust governance structure and procedures provided a new opportunity to completely restore the valley to pre-mining conditions. The owner indicated an interest in remining some

specific portions of Pit B that would deepen the excavation on Pit B and the Reservoir. This led to a new trade-off study to assess the best option for this new remining opportunity. The option to fully remove the Starter Dam was the chosen option. This new direction closed the iterative process of design that both started and ended with trade-off studies.

From the beginning, no-risk closure was a primary focus for all stakeholders. The project transformed from a two Phase (pilot test – main excavation) to a three Phase (Pit A, Pit B, and Reservoir Excavation) to a five-stage final solution that will now include a full removal of all tailings and the dam, not just the upstream raises. This was made possible by a team that was always looking for opportunities for improvement. At the end of the project, the once tailings-filled-valley will be fully restored. Design of Phases 4 and 5 are ongoing and the works are expected to be completed by the end of 2026. The main challenges for these new project phases will be similar to the previous phases: minimal information on topography, construction history and uncertainties in piezometric information and in foundation characterization. The same iterative process and project governance structure is anticipated to bring the final works to a successful conclusion.

Discussion

Challenges

The project history highlights important challenges faced by the engineering teams during the development of the engineering for all five phases of engineering. Key challenges include:

- **Remote works for investigation and excavation –** Restrictive regulations set in place in Brazil after the recent incidents limited accessibility of manned equipment, forcing most early works to be conducted by remote equipment or innovations such as an overhead lifeline, and a remote-controlled CPTu rig.
- **Tailings variability –** Although CPTu testing indicated three distinct tailing types, fine, medium, and coarse, the tailings did not show significant behavioral differences. The exception was the permeability of the coarse tailings' layers.
- **3D modelling (deformation and hydrogeological) –** Even though three-dimensional models present great advantage while dealing with complex problems, they have challenges associated with their complexity. The development of a single geological model that should be able to represent the same hydrogeological and geotechnical conditions increased the time necessary to finish the models especially with the difficulties in determining both hydrogeological and geotechnical soil parameters, but both models proved to be vital for a full understanding of the behavior of the tailings during the excavation.

- **Stakeholder engagement –** With multiple interests in the table and with strict internal and external governance, dealing with all the stakeholders was a big challenge to the project. In general, the design team had to interact with the client's internal line of defense and exterior stakeholders including the EoR, the Design Reviewer, the HIRA Facilitator, the Federal Prosecutor audit team, and national and state legislators.
- **Water management –** State law requires that the minimum return period for a spillway system during the excavation works should be higher than 1,000 years. This impacted the planning of each phase and required creative solutions to maintain adequate spillway and water channels for each phase.

Lessons learned

The development of engineering provides lessons learned in both governance and technical areas that could be helpful for similar projects in the future.

In terms of governance, stakeholder engagement and management communication were critical to the success of the project. The process of continual review is vital to a high-risk engineering project; a high-profile project such as a tailings dam removal also involves engagement of national and state officials, audit teams and external reviewers. By establishing a process of open communication, and regular, detailed technical gates, the overall process became easier as transparency led to trust between stakeholders. All stakeholders were included in the process – all concerns and comments were taken seriously and dealt with openly. Weekly in-person field meetings and monthly auditing meetings were held to keep team members apprised.

This strategy seems simple, but it was time consuming and at times slowed the progress of the work. However, in the end, it proved successful in establishing an iterative design process and resulted in several modifications that enhanced the overall project. Through multiple trade-off studies, technical gates, risk assessment discussions, rounds of reviews and regular meetings, the project advanced with fewer obstacles. This strategy led to the implementation of a phased excavation sequence that allowed the contractors to establish methodology for excavation and train workers in a less risky environment, reducing the learning curve while addressing the data gaps for the most critical phase of the project. With this approach, the observational method was applied during Phase 1 and Phase 2 that enhanced the design and excavation of Phase 3 (and the ongoing Phase 4 and 5).

There were challenges in characterizing the soils and tailings hydrogeologic and geotechnical parameters, but the results of the hydrogeological model have proven to be crucial for understanding the groundwater behavior and led to an improved 3D deformation model. A simpler 2D seepage model would

not have captured the geological complexity of the area. Calibration of the model against actual piezometric readings improved the confidence in the model results.

Finally, the 3D deformation model became a critical tool for predicting the behavior of the excavation and the potential for liquefaction during the works using a calibrated hydrogeologic model, site investigations and laboratory testing even though there was limited construction history for the site. Critical state laboratory tests were used to define the model constitutive relationships and predict the site performance during excavation. This was critical to successful completion of the works.

Conclusion

The decharacterization project of the high-priority upstream-raised dam presented in this case study demonstrates the effectiveness of a phased engineering approach. Key conclusions from this project include:

- The integration of technical innovation and rigorous modeling is essential for addressing the complexities of high-risk mining dams.
- A holistic and adaptive engineering and governance strategy, incorporating initiative-taking stakeholder management, is critical for successful project outcomes.
- Continuous evaluation and updates to the hydrogeological and deformation models are necessary to reflect the evolving conditions during the excavation.

Overall, this project underscores the importance of a comprehensive and flexible engineering methodology to achieve compliant and effective decharacterization of high-risk mining dams.

Design of a Co-disposal Facility for Thickened Tailings and Potentially Acid-generating Waste Rock

Patrick Williamson, INTERA Inc., USA
Wilson Muir, Knight Piésold Ltd, Canada

Abstract

Environmental and geotechnical risks and impacts from surface disposal of mine waste are increasingly becoming a source of concern for regulators, investors, operators, and communities within the potential area of influence of mining operations. Waste disposal strategies should implement the Best Available Technology and Best Available Practice for waste management, while considering specifics of the local topography, climate, foundation conditions, construction materials, and waste characteristics. The Alacrán Cu-Au-Ag Mine Project (the Project) in northwestern Colombia will need to manage potentially acid-generating waste rock during mining. The steep, rolling terrain limits disposal site options, and water management is challenging, with approximately 3 m of rain annually. Minimizing water in tailings storage facilities and reducing waste rock exposure to atmospheric oxygen and precipitation are common challenges at many mine projects. One emerging technology addressing both issues is co-disposal, which combines tailings and waste rock in a single engineered storage facility.

Co-disposal was selected as the preferred waste management strategy for the Project after multiple investigations. This waste management strategy will create a low-permeability waste deposit, reduce foundation seepage, and centralize the storage of all mining and processing waste. Co-disposal, in places where suitable, may reduce environmental risks and impacts, improve public perception, and lower costs and timelines for mining projects. Multiple lines of investigation are necessary for the effective design of a co-disposal waste management facility.

Introduction

Environmental and geotechnical risks and impacts from surface mine waste disposal are increasingly becoming a source of concern to regulators, investors, operators, and the communities within the potential area of influence of mining operations. Operational, financial, ecological, and reputational risks arise from drainage of mine-impacted water from waste rock storage facilities, reactive surfaces exposed by mining, and tailings storage facilities (TSFs). Recent TSF failures, resulting in the sudden release of large volumes

of tailings and solutions, include the Williamson Mine (Tanzania, 12.8 M m^3), Brumadinho (Brazil, 12 M m^3), and the Germano mine (Brazil, 32 M m^3) (WISE, 2024). These challenges have led the mining industry to develop Best Available Practices for waste disposal by minimizing water in tailings storage facilities and reducing the exposure of waste rock to atmospheric oxygen and precipitation. An emerging technology that addresses both issues is co-disposal, which is the placement of tailings and waste rock together in an engineered storage facility. Co-disposal, also known as co-placement, co-deposition, co-mingling, co-layering, or PasteRock®, ranges from heterogeneous co-placement of tailings with waste rock to very homogeneous blends (Figure 1). The proposed co-disposal strategy for this Project involves layered co-mingling as the best balance between effectiveness and feasibility. Due to the space limitations for this publication, only an overview of the details will be provided here. The complete Feasibility Study is available at Cordoba Minerals (Corboba Minerals, 2023).

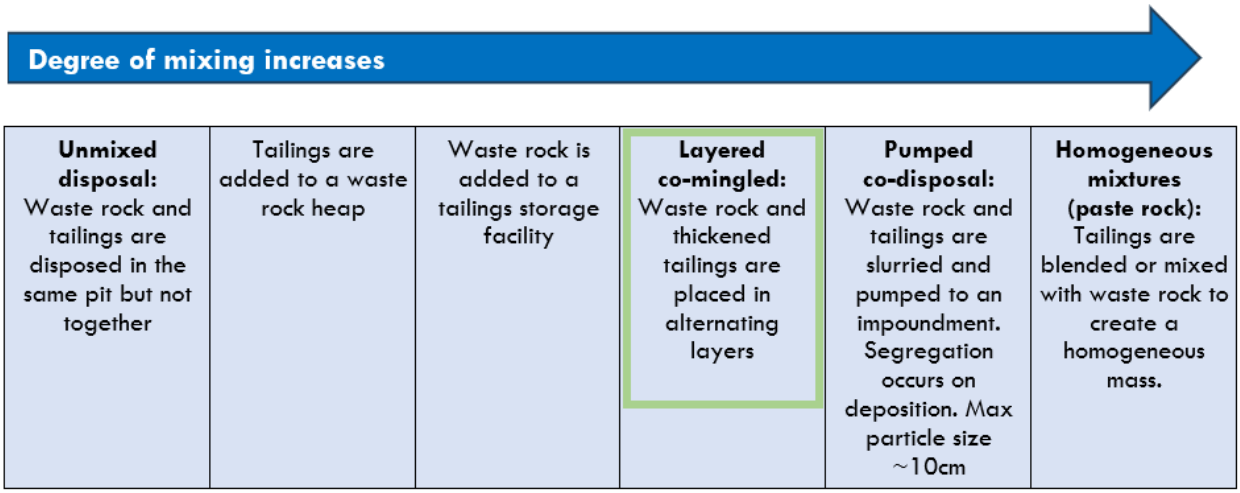

Figure 1: Co-disposal methods (after Pukkinen et al., 2019)

Research and mine site applications have demonstrated that co-disposal has the following benefits (Gowan et al., 2010; Habte and Bocking, 2012; Ulrich and Coffin, 2015; Wickland et al., 2006):

- Reduces oxygen flux and infiltration through mine rock (i.e., to control sulfide oxidation, acidic drainage, and metal leaching).
- Improves stability (static and dynamic) of a disposal facility and decreases probability of liquefaction.
- Reduces the footprint required for the disposal of two waste streams.
- Simplifies water management, monitoring, and closure.
- Accelerates tailings consolidation, improves permitting timeline, and facilitates earlier closure.
- Reduces the erodibility of tailings by either water or wind.

Critical factors for effective co-disposal include the moisture content of the tailings and waste rock placement practices. Oxygen diffusivity in a fine-grained porous media decreases sharply with increasing moisture content. Tailings at approximately 85% saturation form an effective barrier to oxygen diffusion (INAP, 2018), minimizing sulfide oxidation. In a homogeneous blend, the optimal ratio of rock to tailings required to fill the pore space in waste rock is 5:1 or less (Wickland et al., 2006). In co-mingling, the objective is not to fill the waste rock pore space, but to minimize oxygen diffusion and infiltration into the layers of waste rock using contiguous layers of tailings to isolate the waste rock from the atmosphere.

The selection of a specific co-disposal method depends on several factors, including:

- Site topography and ease of construction and operation.
- Climatic conditions (e.g., cold, extremely dry, extremely wet).
- Tailings characteristics (e.g., geochemistry, viscosity, grain size distribution, mineralogy).
- Mine rock characteristics (e.g., geochemistry, grain size distribution, mineralogy).
- The volume ratio of mine rock to tailings.
- Life cycle costs of the co-disposal facility.
- Risk potential (e.g., wind and water erosion, slope stability, liquefaction, closure).

Currently, several mines employ co-disposal, including Marmato (Colombia), Navachab (Namibia), Nunavik (Canada), Greens Creek (USA), Snap Lake (Canada), Caraíba (Brazil), Neves Corvo (Portugal), Mount Thorley (Australia), and Argyle (Australia) (Verburg, 2024; Gowan et al., 2010). All these mines have a daily production of less than 20,000 tonnes per day.

Site background

The Project is in the Department of Cordoba, Colombia, 390 km northwest of Bogotá and 160 km north of Medellín. The mine site lies in the northern foothills of the Western Cordillera of the Andes mountains, with elevations ranging between 100 m and 350 m above sea level.

The Project is in an accreted oceanic terrane of the Western Andean Cordillera. The El Alacrán deposit's mineralization is hosted by a west-dipping Cretaceous succession comprising mafic volcanic rocks overlain by a calcareous volcaniclastic sequence, capped by pre- to syn-mineralization sill-like diorite and felsic sub-volcanic bodies. Cu-Au-Ag mineralization occurs throughout the volcaniclastic package. Research by Manco (2020), in combination with previous work, suggests that the genetic model for the El Alacrán deposit is a hybrid between Iron Oxide Copper-Gold and Carbonate Replacement deposits associated with a porphyry source. The climate in the region is humid and warm, with average monthly temperatures ranging from 24.5°C and 27°C. The Project receives approximately 3,000 mm of rainfall annually, with rain occurring year-round and a wet season between April and November. The

evapotranspiration rate is approximately 1,500 mm/year. Due to the high rainfall and warm climate, the igneous and volcaniclastic rocks in the region have undergone extensive weathering, characterized by up to 11 m of saprolite (composed principally of quartz, chlorite and aluminous and lateritic clays), a transition zone (weathered bedrock), and then unaltered bedrock.

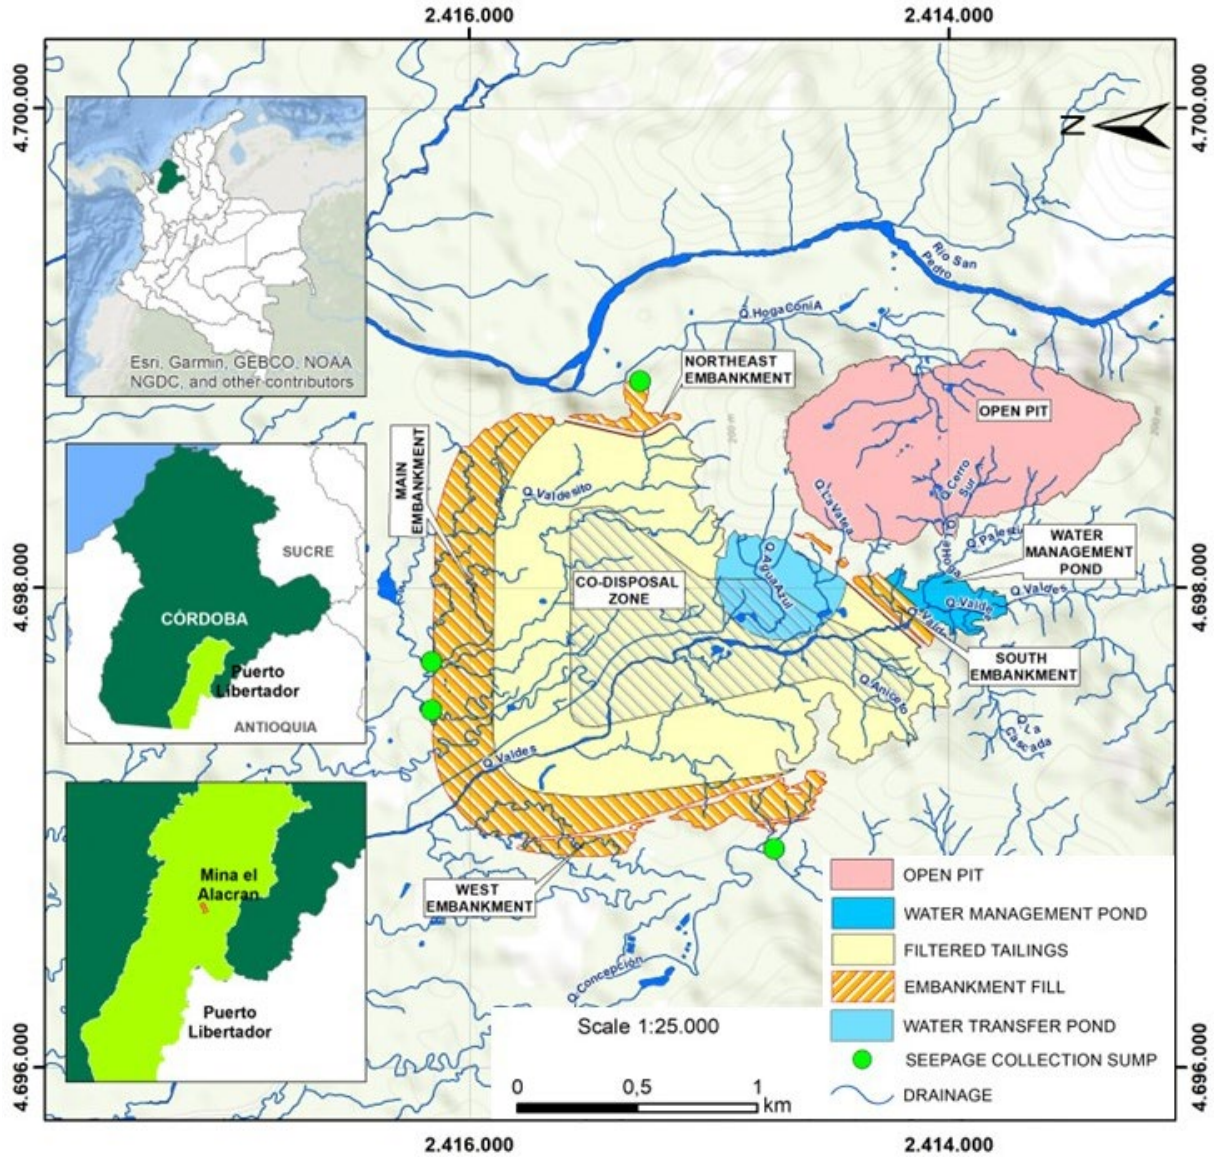

Figure 2: Site location and waste management facility features

Conventional open-pit mining methods will be used to extract ore from the El Alacrán deposit, with an anticipated production period of 14 years. The ore will be processed through crushing and a four-stage flotation circuit, which includes rougher, cleaner scalper, cleaner scavenger, and recleaner stages. Concentrate from the cleaner scalper and recleaner stages will be thickened and filtered to produce the final

concentrate. Tailings produced in the rougher and cleaner scavenger stage flotation (after passing through the gravity concentrator) will be sent to the tailings thickener, and subsequently to the waste management facility (WMF) at approximately 55% solids by mass. The mill throughput rate is set at 17,600 tonnes per day. It is anticipated that 34 million tonnes (Mt) of potentially acid-generating (PAG) waste rock and 102 Mt of thickened tailings will be stored in the WMF basin during mining and milling operations over the 14-year mine life.

Investigations

Studies supporting the design and operation of the WMF included foundation assessments, geochemical characterization of waste rock, tailings, and tailings decant within the proposed WMF area (described in more detail below), along with various hydrogeological and water chemistry studies of the valley where the WMF will be located.

Foundation characterization

The foundation characteristics at the WMF reinforce the suitability of co-disposal at the Project. Topsoil covers the entire WMF area, underlain primarily by saprolite, with isolated pockets of fine or coarse alluvium. The fine alluvium has very similar engineering properties to the saprolite. Beneath the soil units, weathered bedrock and bedrock are present. The saprolite will form the basin for tailings deposition and reduce seepage from the WMF. The saprolite typically consists of silt and clay with varying sand content and is classified as CH (inorganic clays of high plasticity) to MH (inorganic silts of high plasticity) according to the United Soil Classification System (ASTM D2487). Five permeability tests indicate that the permeability ranges from 4.2E-10 to 5.6E-08 m/s, which is at the low end of typical values for saprolite, effectively minimizing seepage (Blight, 1997).

Waste geochemical characterization

Geochemical characterization of the waste streams generated by a mine is an essential element of a Feasibility Study. Samples of mine waste to be deposited in the WMF included tailings (n=4), tailings decant (n=1), waste rock (n=80), and saprolite (n=20). These materials were characterized using a standard suite of geochemical static and kinetic analyses, including mineralogy, total elements (52 elements), shake flask extraction and leachate analysis, net acid generation, and acid-base accounting (ABA). Kinetic tests included site barrel (n=10) and humidity cell tests (n=14). A geochemical sampling and analysis program was developed and implemented to inform the Pre-Feasibility and Feasibility studies, as well as the Environmental Impact Assessment required to obtain a Colombian environmental permit. The program was based on a site-specific conceptual geochemical model, considering the range of anticipated waste rock

lithotypes (including lithology, alteration, and degree of weathering), expected volumes of each potential waste rock lithotype, and operational factors. Results from this geochemical program were correlated to the much larger exploration data set (n=47,231 for waste rock), which was used to generate a block model for the waste rock.

Results of the program indicate that the range of waste rock lithotypes from the mining operation at the Project are a mixture of PAG, uncertain acid generation, and non-acid-generating (NPAG). Most of the waste rock to be generated by the Project falls into the uncertain range (Figure 3) based on static tests.

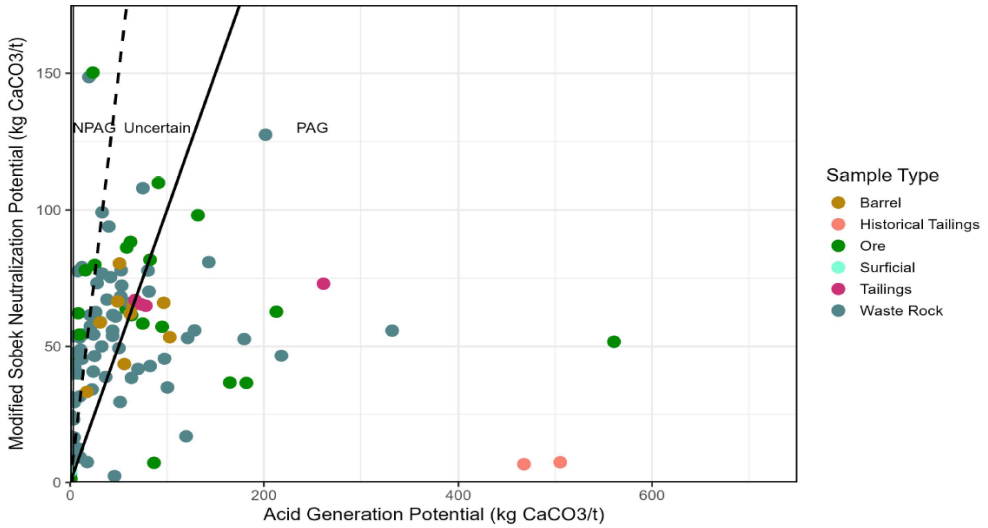

Figure 3: Acid-generation potential vs. acid-neutralization potential for Project waste.

Field barrel test results from 10 waste rock composites after 17 months suggest that mixed waste rock could produce drainage with pH < 6 drainage and elevated metal concentrations, indicating that it could have uncertain acid-generation potential in the long-term. Results for saprolite within the proposed WMF footprint had very low sulfide concentrations and were classified as NPAG. Decant samples were analyzed for the full list of organic compounds, metals, major ions, and potential mining by-products listed in the Resolution 0631 limits for mine discharge (MINAMBIENTE, 2015). The only parameter that exceeded the Resolution 0631 limits was pH at 9.5 (limit is 9). Sulfate concentrations in the decant were 300 mg/L.

Tailings geotechnical characterization

Laboratory physical characterization testing was completed on thickened tailings samples to estimate their Atterberg limits (index test), settling, consolidation, and permeability properties. The index test results suggest that the tailings are non-plastic, consist of 32% sand, 55% silt, and 13% clay, and have a specific gravity of 2.87. The P80 of the tailings is 150 micrometers (i.e., 80% of the particles are finer than 150 micrometers). The tailings are classified as an inorganic silt of slight plasticity.

Undrained, drained, and drained plus air-drying settling tests were completed on tailings slurry samples at 60% and 65% solids content by mass. The results indicate that the estimated settled density ranges from 1.34 to 1.36 t/m^3 under undrained conditions and from 1.45 to 1.50 t/m^3 under drained conditions. Air-dried settling test results at 60% solids content indicate that the solids content increased to 71% (11% increase) in 2 days and were fully dry after approximately 4 weeks.

Consolidation tests were conducted using a Rowe cell, allowing the tailings to settle and consolidate under their own weight. Confining stresses ranging from very low (10 kilopascals [kPa]) to high (800 kPa) were applied in incremental loading stages, while maintaining two-way drainage conditions. The measured Coefficient of Consolidation (Cv) values ranged from 31 m^2/year at low effective stress (10 kPa) to 5 m^2/year at high effective stress (800 kPa). The Cv values are considered to be at the low end of the range of typical values for copper mine tailings (Vick, 1990).

Permeability test results indicate that the hydraulic conductivity of the tailings decreases from 4.9x10^{-9} m/s at 200 kPa to 2.2x10^{-10} m/s at 800 kPa. This suggests that the hydraulic conductivity of the tailings will likely decrease with increased tailings depth and effective stress. Permeability tests on compacted saprolite yielded hydraulic conductivities ranging from 4×10^{-10} to 6×10^{-8} m/s, with a geometric mean of 4×10^{-9} m/s. These values are comparable to the permeability of high plasticity tailings silts and clays (Vick, 1990).

WMF design overview

The WMF will consist of a valley-type impoundment to provide permanent storage for PAG tailings and PAG/uncertain waste rock. A schematic of the proposed WMF is provided in Figure 4.

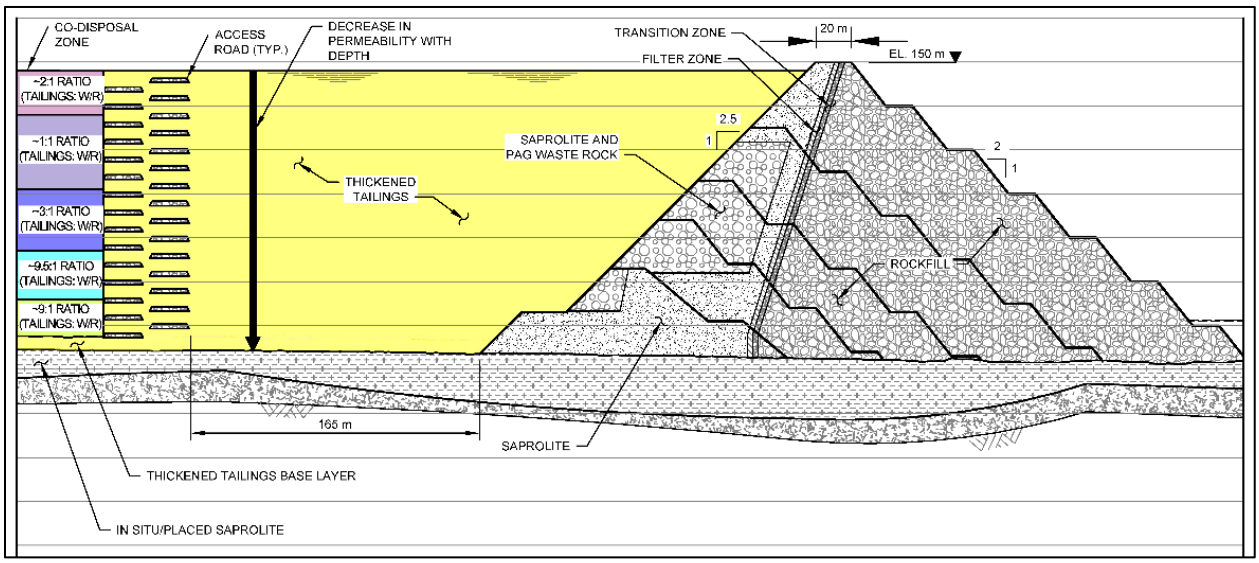

Figure 4: Typical WMF embankment and basin section (Cordoba Minerals, 2023)

Key components of the design of the WMF include perimeter embankments, a basin liner, and drainage.

Perimeter embankments

Perimeter embankments will be constructed using waste saprolite and waste rock from open-pit development to safely store the thickened tailings and PAG/uncertain waste rock. The impoundment will be developed by constructing embankments around the perimeter of the valley (Figure 2). The West, Main, and Northeast Embankments will be raised using the downstream construction method. The South Embankment will be constructed as a full-width divider embankment to establish a water management pond (WMP) in the southern portion of the valley. The embankments will be raised in five stages (Figure 4) to a maximum height of 68 m. The typical embankment cross-section from upstream to downstream includes saprolite to provide a low-permeability zone, filter and transition zones to provide drainage within the embankment fill, and a downstream rockfill shell zone.

Basin liner

The basin liner will consist of at least 3 m of saprolite within the WMF basin to reduce potential seepage from the facility. Saprolite, along with isolated areas of fine to coarse alluvium are present within the WMF basin. The WMF basin will be cleared and grubbed, and topsoil will be removed to expose the saprolite. In most areas, the foundation will consist of in-situ saprolite that is greater than 3 m in thickness, which will be grubbed, compacted and proof rolled. Additional saprolite will be placed and compacted following stripping and grubbing in areas of the WMF footprint with less than 3 m of in-situ saprolite.

Drainage

To manage water and maintain a low phreatic surface within the embankments, the design includes internal filter and transition zones, and a series of finger drains at approximate 200 m intervals in the Main, West, and Northeast Embankment foundations. The finger drains will connect to a conveyance drain along the ultimate downstream toe of the Main and West Embankments (parallel to the embankments) or directly to a collection sump (Figure 2). Multiple collection sumps will be located along the conveyance drain. The finger and conveyance drains will consist of gravel with a slotted CPT pipe wrapped in a filter sock and fully wrapped in non-woven geotextile.

WMF operation

Key aspects of the WMF operation will include water management, tailings deposition, PAG/uncertain waste rock placement, and basin filling.

Water management

The water management strategy for the WMF involves collecting supernatant and runoff for transfer to the WMP and maintaining a small water pond along the southeast side of the WMF basin (Figure 2). This will maximize the WMF basin surface area for drying and consolidation of the tailings and provide a suitable area to haul, place, and spread PAG waste rock.

Tailings deposition

The tailings will be pumped from the thickener at approximately 55% solids by mass to a series of centrifugal pumps and conveyed to the WMF via pressurized HDPE pipelines. Tailings discharge during operation will be rotated around the perimeter of the embankments and basin to achieve a tailings beach slope of approximately 2%. Multiple spigots will be used to maintain a low deposition velocity and the homogeneity and non-segregating properties of the tailings during deposition. Tailings deposition will be managed to route the supernatant liberated from the tailings and runoff towards the Water Transfer Pond located in the southern portion of the basin. This approach will facilitate the efficient transfer of supernatant and runoff to the WMP.

The tailings will consolidate over time due to the weight of overlying layers of tailings and waste rock. The dry density of the tailings will range from 1.3 tonnes per cubic meter (t/m^3) to 1.6 t/m^3, with a corresponding vertical hydraulic conductivity of 8.5×10^{-8} meters per second (m/s) to 1.1×10^{-10} m/s.

Waste rock placement and basin filling

The tailings deposition and waste rock placement strategy are illustrated in Figure 4. Prior to placement of PAG and uncertain waste rock within the WMF basin, tailings will be deposited in layers to develop a low-permeability deposit approximately 3 m thick immediately above the compacted foundation. The initial deposition of tailings will lower the hydraulic conductivity of the foundation and reduce potential seepage from the WMF basin into the underlying material.

Waste rock will be strategically placed at least 165 m from the Main, West, and Northeast Embankments and co-disposed with the thickened tailings. The waste rock will be placed in alternating layers and in such a manner as to avoid the formation of higher-permeability zones through the deposit. The waste rock will be continuously buried by subsequent tailings deposition to encapsulate the waste rock and minimize the potential for the onset of acid-rock drainage (ARD) and/or metal leaching (ML) conditions. The tailings in the co-disposal zone will partially fill the waste rock voids (estimated at 30%) and increase the overall dry density of the stored materials to an estimated dry density of 1.64 t/m^3 by the end of operations.

The ratio of tailings to waste rock placed in the co-disposal zone will vary over the five stages of WMF development. Initially, during Stage 1 operations, the ratio is estimated to be approximately 9:1. This ratio is expected to decrease to approximately 1:1 during Stage 4 operations and to approximately 2:1 during Stage 5 operations. Access roads constructed with waste rock will be incorporated into the WMF impoundment to facilitate waste rock placement. As each road is inundated with thickened tailings, a subsequent access road will be constructed, offset from the previous roads. This approach will prevent the formation of higher permeability zones in the WMF and help maintain the overall 2% tailings beach slope.

Closure

At closure, the WMF will be covered, and a spillway will be constructed to direct runoff from the WMF to the open pit. The WMF closure cover will consist of a 2 m thick, compacted saprolite layer covering the entire WMF basin, graded at 2% towards the closure spillway. Over this saprolite cover, a 0.25 m thick layer of topsoil will be applied and hydroseeded. This will minimize water and air infiltration into the tailings mass and provide controlled drainage from the surface of the WMF. This strategy will also help create a landform that will blend into the local topography, prevent standing water on the closed WMF and eliminate the possibility of uncontrolled embankment overtopping.

The infiltration of meteoric water through the WMF cover, mass of interlayered tailings and waste rock, and into the underlying saturated layer were estimated using a HELP model (USEPA, 2020). The model, developed for the final WMF arrangement, incorporated complex climate and land boundary conditions. The HELP model included parameters such as the saprolite cover layer, six fully saturated layers of tailings and waste rock, a final cover slope of 2%, local climate data, and evapotranspiration estimates, along with characteristics of the saprolite and tailings. The model was simulated for a period of 6 years. The results from the model suggest that the average infiltration rate through the bottom of the thickened tailings will be less than 100 m^3 per year. Based on the modelled flux through the WMF and groundwater flux under the WMF, the pore solution in the WMF will be diluted by a factor of approximately 12,000 by groundwater. Assuming the WMF source term chemistry reflects the pore water chemistry in the WMF that might eventually migrate into the underlying groundwater, mixing with groundwater will have a minimal effect on groundwater quality.

Conclusion

The combination of the compacted saprolite liner, the initial layer of consolidated tailings on the saprolite liner, and the tailings against the embankments will create a low-permeability waste deposit that minimizes oxygen diffusion and water infiltration within the waste. This waste management strategy is designed to reduce the oxidant and transport mechanisms that create ARD conditions. The following key additional

conclusions can be made based on the waste co-disposal strategies discussed above.

- The tailings and PAG/uncertain waste rock can be effectively co-disposed in a single facility over the life of the mine, with the waste rock fully encapsulated within the tailings.
- Partial ingress of tailings into the waste rock voids will increase the overall density of the waste deposit over time and reduce the overall height of the perimeter embankments.
- The WMF can become a landform at closure, while minimizing potential seepage to the environment post-closure.

A Study on the Possibilities, Constraints, and Motivation for Transitioning a Conventionally Designed TSF into a Full-scale Hydraulically Dewatered Stack Facility for Fine Residue Disposal in South Africa

N.W. Nxumalo, Jones & Wagener (Pty) Ltd, South Africa
P. Newman, Anglo American, UK
A. López, Anglo American, Chile

Abstract

Tailings dewatering and optimized water recovery are desirable objectives for owners and operators of tailings storage facilities (TSFs) in the mining industry. A large international mining firm has undertaken several studies and field-scale trials on the feasibility of hydraulically dewatered stacking (HDS) to improve water recovery from fine residue facilities. A concept study has been undertaken to transition a TSF designed to operate with conventional deposition and water recovery methods (ring feed pipe, spigots, penstock intake, and outfall system) into an HDS facility. This paper discusses the possibilities, constraints, and risks identified for full-scale implementation of the HDS methodology on a TSF. Findings on the preliminary preferred configurations from a high-level water balance and conceptual 3D numerical modeling are also presented.

Introduction

Conventional methods of recovering water from a tailings storage facility (TSF) comprise (i) a gravity penstock intake and outfall pipe,; (ii) a pumped decant system; and (iii) a network of basal drains. Gravity penstock and pumped decant systems drain supernatant water only. Basal drains collect water, which infiltrates through the settled tailings and reports to the bottom of the facility. This water must infiltrate through the very fine and cohesive silty material, through which water flow is impeded due to very low permeabilities. The process of draining water from the settled tailings occurs over extended durations and results in large volumes of water that are not recovered from the settled tailings. This water is undesirable, as it reduces the strength of the settled tailings material, increasing risks to mining operations, the environment, and surrounding communities.

The hydraulically dewatered stacking (HDS) deposition methodology enables recovery of both supernatant and interstitial water. Successful implementation of HDS is a significant deviation from current water recovery strategies and will substantially increase water reuse quantities in mining operations.

CPR and HDS process and definition

Anglo American (AA) has successfully implemented coarse particle recovery (CPR) at several of its assets. The technology generates a coarse reject material and creates a bulk concentrate for further processing (Filmer and Alexander, 2016; Filmer and Alexander, 2017, Filmer et al.., 2020). CPR uses a fluidized bed to enable valuable minerals, with as little as 1% mineral surface exposure, to be separated from gangue, a commercially valueless ore (Arburo et al., 2022). This process increases ore recovery rates, improves plant energy efficiency rates and reduces water consumption by recovering minerals at a particle size 2 to 3 times coarser than conventional flotation processes (Arburo et al., 2022). In the CPR process, underflow from the cyclones within the plant is recycled and reprocessed, increasing product recovery, while the overflow, a coarse graded reject sand referred to as CPR sand, is pumped directly to the TSF.

The CPR sands are characterized by low fines content (less than 5% particles <75μm) (Newman et al., 2022) resulting in relatively high permeability (Bustamante et al., 2024). The CPR sands are co-disposed with conventional tailings to form preferential and connected three-dimensional (3D) drainage paths within the tailings. When engineered correctly, such a configuration has the potential to change dewatering of freshly deposited tailings slurry (abstracting pool water via infiltration into pre-configured berms vs. penstock recovery), increases consolidation, and improves recovery of water from the in-situ settled tailings, thereby leaving a waste residue that is desaturated.

HDS trials and studies by Anglo American

Previous studies were undertaken by AA and WSP-Golder in Chile and by AA and SRK Consulting in South Africa. Both studies focused on: (i) material characterization through geotechnical testing programs in the laboratory; (ii) simulation of expected drainage behavior in the laboratory; and (iii) implementation of field-scale trials to characterize drainage behavior and verify laboratory test results.

El Soldado trial, Chile

Newman et al. (2022) highlighted that the El Soldado trial formed part of the laboratory test work carried out as part of the proof-of-concept study. The proof-of concept study was premised on the hypothesis that *"… placing interbedded layers of tailings with free draining sands (being a by-product produced by coarse particle recovery techniques from within the process flow sheet) will accelerate consolidation and increase the reduction in degree of saturation of the tailings mass. The purpose of this being to increase the tailings*

resistance to liquefaction." The El Soldado study therefore considered two main objectives: (i) laboratory characterization of tailings and CPR sand samples; and (ii) the design and implementation of a field-scale trial.

Mogalakwena trial, South Africa

A concept design for the BW2 TSF was undertaken by AA and Jones & Wagener (Pty) Ltd (J&W) in 2022, and a key finding of the study was that the options for implementing HDS on the BW2 TSF were dependent on the capabilities of the deposition equipment. This resulted in AA commissioning the Blinkwater 1 TSF trial (Murray et al., 2023). The primary objective was to assess the effectiveness of the sand placement unit. The focus of the field-scale trial was thus on advancing the knowledge base relating to operating a Self-Propelled Cyclone Unit (SPCU) and its performance in relation to: (i) sand thickness required to form a stable working platform; (ii) ease of preforming controlled deposition to form drainage channels; (iii) formation of blanket drains; and (iv) the potential erosion of CPR sand.

Contributions of present paper

The objectives and learnings of previous studies do not extend to the design of a full-scale facility for the HDS deposition method. The scope did not include assessment of appropriate spacing for CPR sand berms and the constraints that must be considered when the HDS method is implemented. This paper seeks to expand the knowledge base gained from previous studies and field-scale trials. The focus and objectives include: (i) documenting risks associated with design and full-scale implementation of the HDS methodology; (ii) identifying constraints associated with full-scale implementation of the HDS methodology; and (iii) evaluating water recovery performance of the platinum CPR sand berm configurations under high inflow rates.

Transitioning a conventional TSF design to HDS deposition

AA commissioned J&W to undertake the feasibility and detailed engineering for BW2 at the Mogalakwena Mine in Limpopo, South Africa. BW2 has a consequence classification of Extreme (ICMM, 2020) and is a waste rock impounded facility with a peak tailings throughput of 14.2 Mtpa, an annual rate of rise of 6.0 m, and a total capacity of 114 Mt. The conventional design, referred to as the "base case," comprises an embankment constructed in the downstream direction to a maximum height of 60 m, a Class C barrier, with an above and below liner drainage system as well as temporary and permanent penstocks. The penstock systems (temporary and permanent) are designed to accommodate the planned commissioning of the TSF in two phases.

Prior to commencement of the detailed engineering for the base case, AA commissioned the study to investigate transitioning BW2 from the conventional base case design into an HDS facility.

Three-dimensional numerical model

The influence of CPR sand berms on dewatering of tailings and the flow regime is omni-directional in nature and occurs in the 3D space. To understand the omni-directional flow properties and quantity of water reporting into the CPR sand columns, several 3D flow and seepage models were constructed in FEFLOW software.

FEFLOW uses finite element analysis to solve the groundwater flow equation for saturated and unsaturated conditions, which are critical for accurate modeling of the movement of water through tailings. All materials in the present study were modeled as saturated. Furthermore, consolidation of the tailings during deposition and cycling were not modeled. As a result, variability in saturation levels and the effect on permeabilities are not built into the model, resulting in conservative estimates of water reporting to the CPR sand berms. Permeabilities of the tailings slurry and CPR sand berm/outer embankment were specified as 0.0035 m/d and 1.7 m/d, respectively. The vertical permeability to horizontal permeability ratio of all materials present was specified as 0.1.

The FEFLOW models were used to evaluate ideal spacing (40 m, 60 m, 80 m, and 100 m) for the proposed CPR sand berm columns, evaluate inclusion of horizontal sand layers connected to the vertical sand columns, and to assess the impact of the hydraulic gradient on abstraction capacity of the drains. The models considered cyclic deposition through a series of paddocks.

This enabled simulation of the omni-directional flow regime and hydraulic interaction between the tailings and the CPR sand columns, both in the short term (i.e., during deposition), and in the long term (i.e., during consolidation) phases. Figure 1 illustrates a simplified TSF model with paddocks spaced at 40 m, 60 m, 80 m, and 100 m.

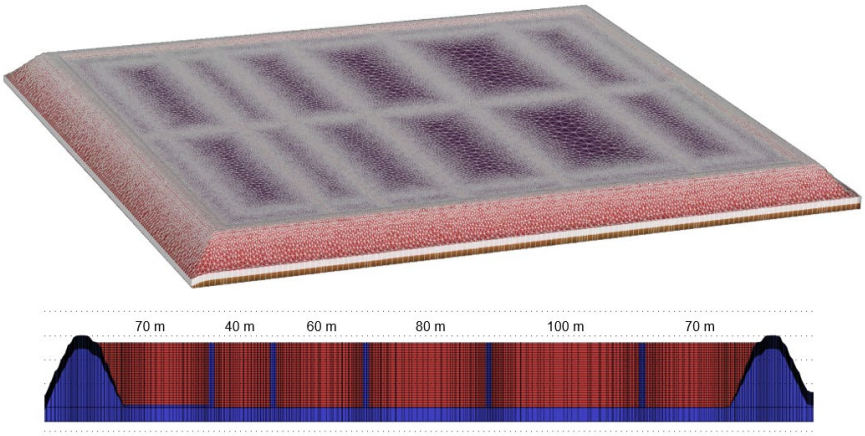

Figure 1: Simplified FEFLOW model with paddock spacings of 40 m to 100 m

Cases evaluated included CPR sand configuration for: (i) tailings only (base case); (ii) tailings with vertical sand drains only; and (iii) tailings with vertical sand drains and horizontal sand layers. Figure 2 presents schematic cross-sections of vertical sand columns only and columns with horizontal sand layers.

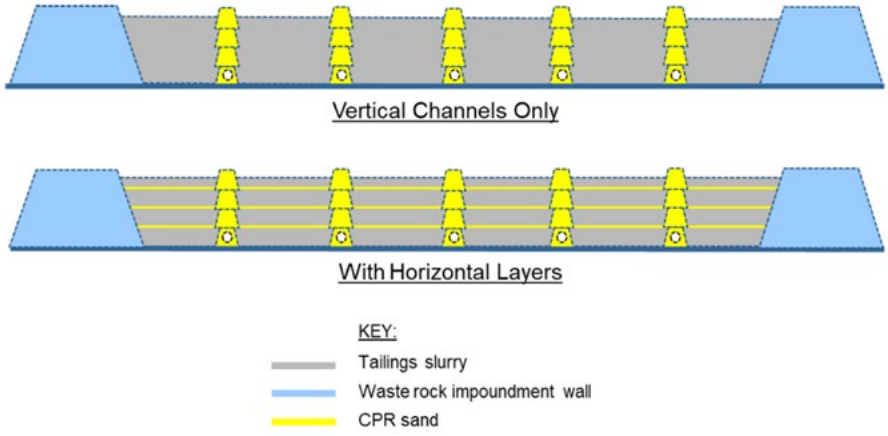

Figure 2: CPR sand configuration with horizontal and without horizontal layers

Typical results are presented in Figure 3 and demonstrate the influence of the of horizontal sand layers and CPR sand column spacing. The phreatic surface for Case 1 is located on the surface, indicating a pool, and for Case 2 and Case 3, the phreatic surface varied depending on the sand column spacing.

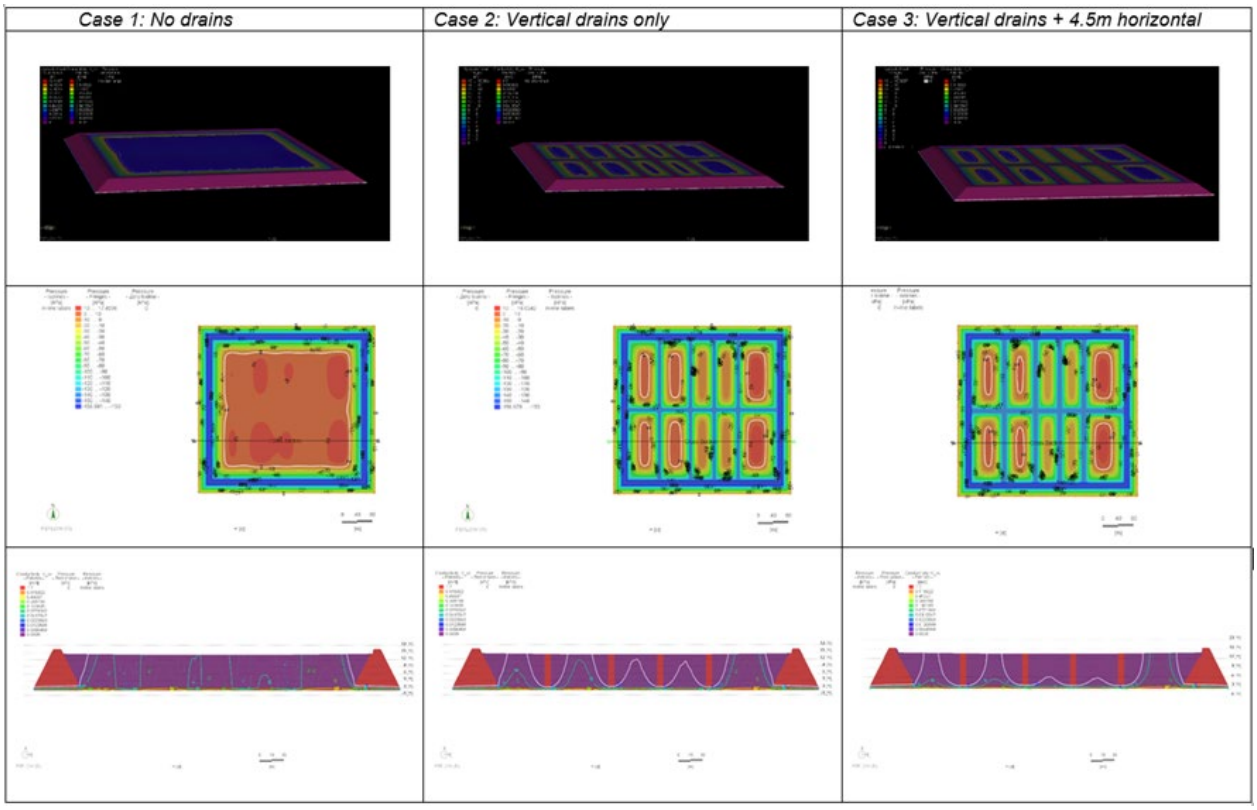

Figure 3: FEFLOW geometry and model results

Inclusion of horizontal sand drainage layers is ideal and improves recovery of water. The phreatic surface in Case 3 is lower compared to that of Case 1 and Case 2 as more water is intercepted and conveyed out of the facility. However, such a geometry increases the required volume of CPR sand, which is limited, and was regarded as a prohibitive constraint to implementing the horizontal drains.

The paddocks with 40 m spacing had lower phreatic surfaces and it was concluded that depending on availability of CPR sand berm spacing ranging between 40 m to 60 m is ideal.

Furthermore, abstraction of pool water via CPR sand berms depends on the hydraulic gradient, and it was found that in the early stages of deposition the hydraulic gradient is not adequate for recovery of pool water and results in a low outflow rate of the system. This results in larger supernatant water pools with a risk of overflow between paddocks. Inclusion of a penstock intake and outfall pipe must therefore be implemented to provide decant capacity in the initial stages of an HDS facility and for stormwater management.

High level water balance

Several options were identified for the CPR sand configuration and with iterative workshops and ratings, two options were selected, for which water balances were developed in order to undertake a comparative evaluation and selection of the preferred go-forward solution. The water balance was carried out at a monthly timestep, using stochastically generated rainfall data for the LoM duration (2028 to 2038), and is not intended as a detailed/final water balance. Figure 4 (on the next page) illustrates the schematic inputs, storage and output components considered in the water balance.

The comparative water recovery results are presented in Table 1. For Option 1, 70% of the total inflow water volume is recovered. Option 2 recovers 82% of the total inflow water volume.

Table 1: Comparative water recovery results

Scenario	Total water stored	Total water loss (evaporation)	Total water recovered	Recovery rate (m^3/t)
Option 1	24%	6%	70%	0.87
Option 2	16%	2%	82%	0.96
Base case	29%	11%	60%	0.57

The makeup of the recovered water volume in Option 1 is (i) 19,588 m^3/d (53%) from pool abstraction; (ii) 2,703 m^3/d (7%) from the settled tailings; (iii) 1,238 m^3/d (3%) through the above and below liner drains; and (iv) 2,577 m^3/d (7 %) through the waste rock (W/R) wall drains. The makeup of the recovered water volume in Option 2 is (i) 20,991 m^3/d (56%) from pool abstraction; (ii) 6,311 m^3/d (17%) from the settled tailings; (iii) 697 m^3/d (2%) through the above and below liner drains; and (iv) 2,577 m^3/d (7%)

through the W/R wall drains. The recovery via pool abstraction and from settled tailings is substantially higher in Option 2 compared to that achieved in Option 1.

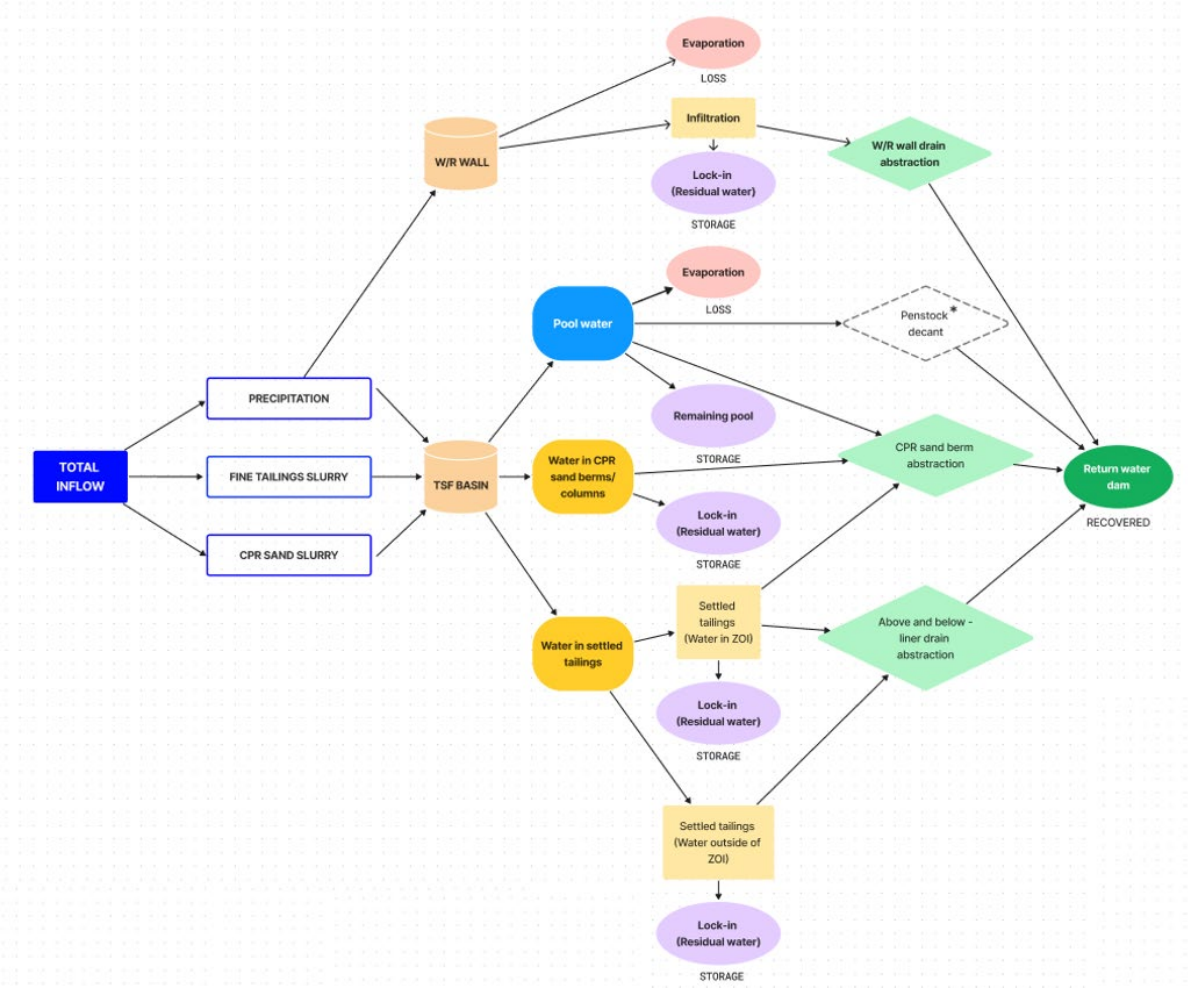

Figure 4: Water balance schematic diagram

These recoveries were also compared to the water balance undertaken for the base case. The comparison confirms that while both Option 1 and Option 2 will improve water recovery compared to the base case configuration, Option 2 is significantly better than Option 1.

Options identification and go-forward solution

Option 1 (Figure 5) comprises 8 compartments divided by CPR sand berms that intersect at the centroid of the TSF. A single penstock intake is located at this centroid position and all CPR sand berms are constructed radially from the outer embankment towards this centroid. Each compartment has additional inter-compartment CPR sand berms that are constructed to leave a minimum gap of ± 60 m to enable operational and storm water to flow unimpeded towards the centroid position where the pool will form. Potential erosion of the CPR sand berms during deposition is a risk due to narrowing of the flow paths. A second

drawback is that the CPR sand berms are concentrated on the outer footprint of the basin away from the pool area where saturation, and hence potential for abstracting interstitial water, is expected to be highest. Set-up and mobilizing of SPCUs to construct CPR sand berms is expected to require more effort during deposition since the berms are constructed from the outer basin perimeter and equipment must be moved continuously, over long distances, around the entire TSF perimeter to keep ahead of deposition.

Option 2 (Figure 6) comprises two penstock intakes located along a north-to-west divider road that will be constructed from waste rock material. The divider road will be raised continuously with deposition lifts as the facility rises. The basin footprint is divided into 6 compartments by CPR sand berms that intersect at the 2 penstock intake positions and extend to the outer perimeter of the basin. Each compartment contains CPR sand berms that do not extend to the perimeter and are constructed outwards from the divider road and penstock intake structure locations. The geometry is such that all CPR sand berms are not constructed from the outer perimeter of the basin and construction and set-up are therefore expected to be less onerous. This configuration is advantageous as CPR sand berms are concentrated centrally within the basin footprint and therefore are expected to be more efficient with higher water recovery from both the pool and interstitial water.

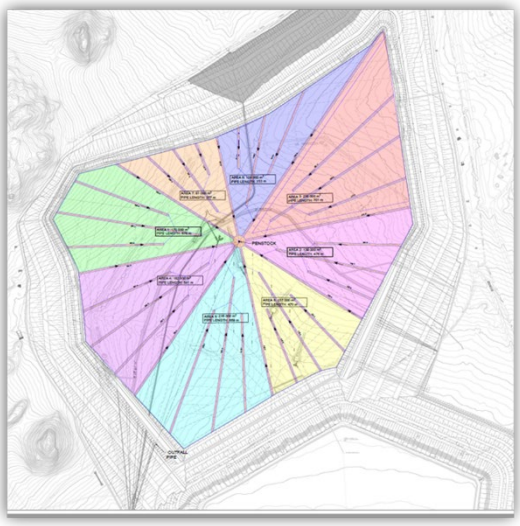

Figure 5: Option 1 configuration

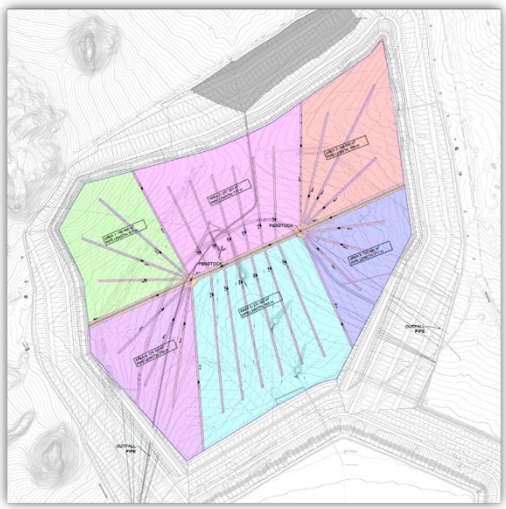

Figure 6: Option 2 configuration

A workshop was held during which advantages and disadvantages associated with each option were evaluated. Option 2 scored the highest with a weighted score of 115, compared to Option 1, which scored 77. Option 2 achieved the higher score due to: (i) advantageous berm location to optimize wicking and abstraction; (ii) easier operation with all berms constructed from the central divider road instead of along the TSF perimeter; (iii) higher operational safety; and (iv) the higher water recovery.

Infrastructure requirements

Compared to the base case, HDS is expected to increase costs substantially. In order to transition BW2 to an HDS facility an additional pipeline and pump station are required. Furthermore, since the base case engineering had been completed to feasibility level, modifications to the penstock, drainage system, and phase 1 containment infrastructure were required. Although the HDS solution delivers significant additional water, mitigates against the most likely failure mechanism (seepage driven) and enables a far lower closure cost, the business case for HDS is not yet positive.

Closure

The base case closure profile for BW2 comprises constructing a convex surface with waste rock on top of the TSF basin to allow surface runoff to drain towards the side slopes. The convex topography will have a final slope of 1:200, with the highest point being above the proposed base case penstock location. The constructability of the waste rock dome shape at end of life is improved significantly due to the "drier" tailings and additional access provided by the divider road. The CPR sand berms (with associated collector pipes) and divider road must therefore not be demolished at closure. A major risk associated with the base case closure solution is the potential ponding of water above the tailings level inside the waste rock dome after sealing the penstock. The ponded water due to infiltration will collect on top of the tailings and eventually infiltrate the tailings, feeding the phreatic surface within the TSF, thus delaying its desired drawdown.

Mitigation considered in the base case scenario comprised either a capping layer (barrier system with a liner), which must be placed over the dome to prevent infiltration, or the penstock should not be sealed, allowing ponded water to drain through it. The latter has safety risks related to an accessible penstock post closure due to potential access by unauthorized persons. The HDS system provides an advantageous alternative solution that is operable as a safe passive drainage system. This will reduce the risk of ponding above the tailings level inside the waste rock body, thereby allowing both penstocks to be sealed and negating the need for a capping layer.

Conclusion

The HDS deposition methodology is a significant deviation to current water recovery strategies and enables recovery of both supernatant and interstitial water. The CPR sand berms significantly improve the recovery, by shortening the drainage paths for seepage water and creating preferential drainage paths through which water including the interstitial water (which is not accessible in conventional deposition methods) is recovered. This leads to a TSF that is comparatively drier than a conventional facility. This paper documents salient considerations for the design and for transitioning a conventionally designed facility into an HDS

facility. Availability of CPR sand is a prohibitive constraint when considering the use of the more effective horizontal sand layer configuration. It was concluded that typical spacing of 40 m to 60 m is ideal for CPR sand berm configuration at BW2. Furthermore, implementation of HDS and recovery of pool water does not immediately replace the use of traditional penstock or pump recovery systems. Outflow through the CPR sand berms is driven by the hydraulic gradient, which is not adequate in the early stages of development, and this motivates for the inclusion of a secondary penstock or pump outflow system.

Abstract

Brazil is one of the largest iron ore producers in the world, and its major producing region mainly explores downgrade iron deposits. Thus, large volumes of tailings have to be stored daily. Although compacted filtered tailings disposal has long been used in arid areas, their use in tropical climate regions is still reduced and demands a deeper understanding of tailings behavior. Moreover, compacted filtered tailings storage can reach hundreds of meters in height, which introduces more complexities to the design of these structures, such as particle breakage.

Geotechnical engineering applications usually are restricted to pressures of 1 MPa, where particle crushing may have a less significant influence than for conventional materials. However, higher pressures may arise for high-rise tailings stackings. Particle breakage is known to affect the behavior of granular materials, regarding their volumetric response, critical state parameters, and stiffness. Therefore, this paper aims to investigate the relevance of grain crushing to the behavior of tailings in the usual range of pressures they might achieve in compacted filtered tailings stacking. Triaxial compression tests were conducted in distinct tailings specimens sheared at 1.2 MPa and 12 MPa, and the tailings' particle size distribution was evaluated after testing. It was found that particle breakage depends on the grading distribution of the tailings tested. Breakage increases the fines content and can change the coefficients of curvature and uniformity. The material with more breakage presented a greater reduction in M value. Also, particle breakage changes the stiffness trends with increasing pressures. Nonetheless, the observation of particle breakage in the tests highlights the relevance of crushing to the behavior of tailings and mandates further understanding of this clastic and anthropic material.

Introduction

Mineral exploitation is an essential economic activity. Yet, the large volume of tailings produced during the ore beneficiation requires finding options for their safe and appropriate storage (Hu et al., 2017). Regulatory limitations on the disposal of saturated tailings in upstream dams and advancements in dewatering technologies have encouraged the disposal of these materials in stacks (Crystal et al., 2018; Schaper et al., 2020). The tailings are then filtered and compacted to form a dry stack structure. Compaction reduces the risk of liquefaction and increases the stability of the stacks, allowing them to achieve elevated heights, even hundreds of meters (Davies, 2011; Wagner et al., 2023). During the stacking raising, the tailings may be exposed to much higher pressures than those experienced in typical geotechnical engineering applications, which can affect the tailings particles and their mechanical response (Consoli et al., 2024a).

Particle breakage is the most important mechanism observed in soils subjected to compression or shearing at high pressures. As pressure increases, the amount of particle breakage also increases. Simulations indicate that most of the particle breakage is due to the breakage of the fragments produced, resulting in the development of various particle sizes during loading (De Bono and McDowell, 2014). Then, particle breakage changes the material's grading, affecting its mechanical behavior and fundamental constitutive properties. The packing of particles can become more efficient when breakage occurs, leading to changes in the states achieved in a stress-density space observed in the position of the critical state locus (Muir Wood and Maeda, 2008). The strength and stress-strain behavior of soil are influenced by the degree of particle crushing during loading and deformation: particle breakage increases the volume reduction during compression and decreases the dilation rate during shearing (Hardin, 1985; Yamamuro and Lade, 1996). Beyond the stress state, the degree of particle crushing is influenced by other factors such as the grains' size, shape, and mineralogy (Mitchell and Soga, 2005). The lower the particle strength, the lower the pressure at which particle crushing starts to influence the material's response.

The breakage potential of an individual particle generally increases with its size, as larger particles tend to have more internal defects, resulting in lower tensile strength (Hardin, 1985). However, studies have shown that larger particles tend to survive during loadings (McDowell and Bolton, 1998; McDowell and Harireche, 2002), which indicates that the coordination number greatly influences particle failure. Particles with a higher coordination number (more surrounding particles = more contacts) experience better stress distribution and are less susceptible to break by tensile splitting (Muir Wood and Maeda, 2008). As stress increases, smaller particles created by breakage tend to surround the larger ones, increasing their coordination number and preserving them from breakage. The breakage is then predominant in the smaller particles with lower coordination numbers. In addition, soils that have higher fines content and are more well-graded will result in better grain arrangements and more contacts between particles, which increases the coordination number and reduces the breakage potential (Altuhafi and Coop, 2011).

The characteristics of iron ore tailings vary depending on the ore's nature and the beneficiation processes (Fourie et al., 2022). As a result, materials from the same mine may have different grading and mineral compositions (Consoli et al., 2024). Therefore, understanding the impact of grain breakage on tailings' behavior is crucial for safely designing compacted tailings stacks. Accordingly, the present work evaluates the breakage occurrence on two iron ore tailings with distinct characteristics obtained in different mines. The influence of particle breakage on stress-strain response, stiffness, and volume change is evaluated through triaxial compression tests conducted over two confining pressures representing typical stress levels (1.2 MPa) and higher stress that is possible to be achieved in dry stacks structures (12 MPa).

Methodology

Materials

Two iron ore tailings obtained from different mines in the Quadrilátero Ferrífero, located at Minas Gerais, Brazil, were studied herein. Figure 1 shows their particle size distribution (PSD) obtained via sieve and sedimentation analysis, considering the ASTM D7928 (ASTM, 2021). The materials present distinct geotechnical characteristics associated with their different origins, as summarized in Table 1.

Table 1: Characterization of the tailings

Parameters	Tailings A	Tailings B
D_{50} (mm)	0.17	0.08
Fines content (< 0.075 mm)	14.07	47.98
Uniformity coefficient- C_u	2.75	9.97
Curvature coefficient - C_c	0.87	1.89
ASTM-USCS Classification	SM	SM
Plastic index - PI	non-plastic	
Specific gravity – G_s	3.1	3.05
Quartz content (%)	78.69	78.44
Fe oxides content (%)	19.23	17.21

Tailings A is more uniformly graded (Cu = 2.75 and Cc =0.87) and has more coarse particles, while Tailings B is well-graded (Cu = 9.97 and Cc =1.89) and presents higher fines content. Despite the differences in tailings grading, their mineralogy is very similar, and both materials are predominantly composed of quartz (around 78%) and iron oxides (17 to 19%), resulting in similar specific gravity (Gs) values (3.10 for Tailings A and 3.05 for Tailings B). The mineralogical characterization was obtained using the Quantitative Evaluation of Minerals by Scanning Electron Microscopy (QEMSCAN®) system, and the specific gravity was evaluated using ASTM D7928 (ASTM, 2014). The differences in grain size

distribution and mineralogy of particles can be observed in Figure 2 for Tailings A and B. Also, the tailings are non-plastic and classified as silty sand (SM) by ASTM-USCS Classification (ASTM, 2017).

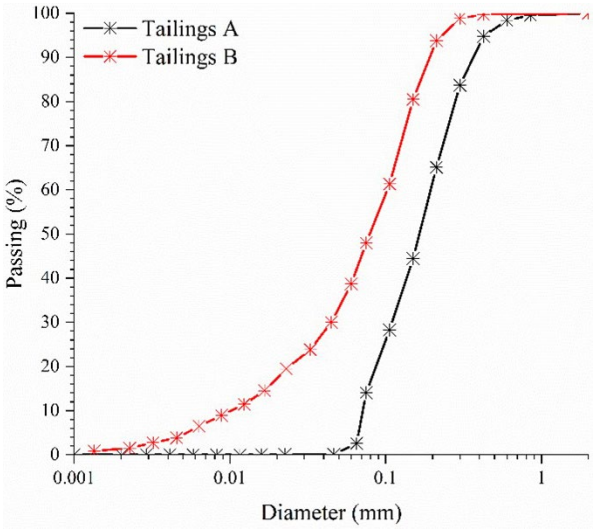

Figure 1: Particle size distribution of the tailings

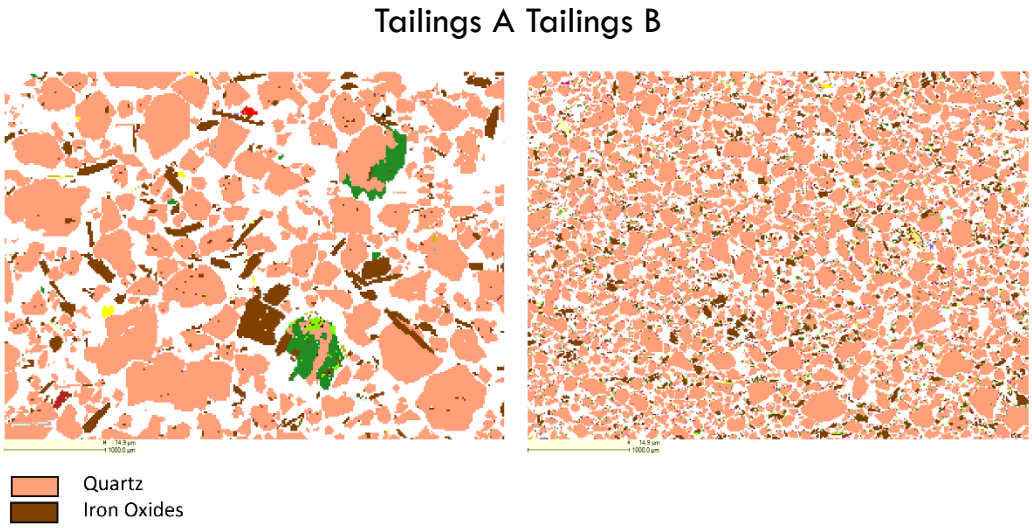

Figure 2: Mineralogy of tailings particles

Testing

The tests were performed using a high-pressure triaxial device typically used in rock mechanics' practice. Dry samples were used to avoid suction effects, and the volumetric change was calculated using internal measurements and the variation in the triaxial cell chamber confining fluid volume. Cylindrical specimens (50 mm in diameter and 100 mm in height) were molded using the dry funnel deposition method (Shi et al., 2021; Silva et al., 2024; Yamamuro and Lade, 1996), aiming to obtain dense specimens with similar states of compacted tailings stacks. The confining pressure was incremented to the target value (1.2 or 12 MPa)

during the isotropic compression stage. Then, the shearing phase was strain-controlled and performed at 1.5 mm/h. Consoli et al. (2024) described the triaxial equipment and procedures adopted herein. Table 2 summarizes the performed tests.

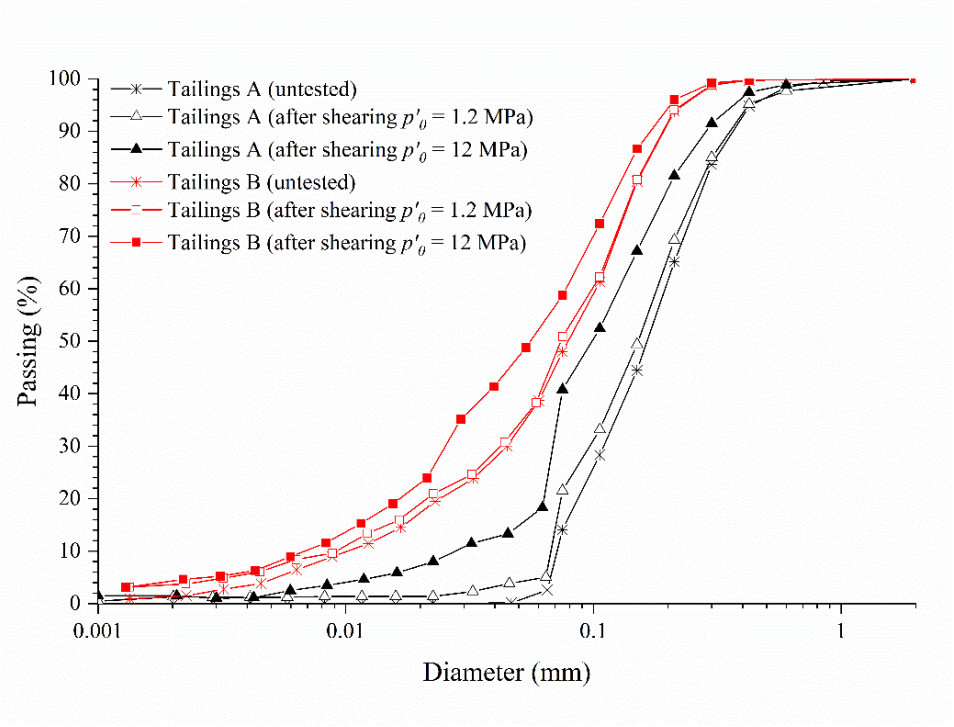
Table 2: Triaxial testing

Material	Confining pressure (MPa)	After shearing	End of test		
		v_c	v_f	q/p'	ϕ'_{cs} (°)
Tailings A	1.2	1.57	1.43	1.43	35.3
Tailings A	12	1.53	1.33	1.33	33.0
Tailings B	1.2	1.52	1.57	1.45	35.7
Tailings B	12	1.46	1.36	1.43	35.4

Results

Particle breakage and grading changes

Representative samples were retrieved at the end of each test from specimens sheared at distinct confining pressures to assess the occurrence of grain breakage. The PSD curves obtained are shown in Figure 3 and can be compared with the respective untested tailings. As expected, the amount of breakage increases with the confining pressure, and the PSD curves offset upwards from the untested material.



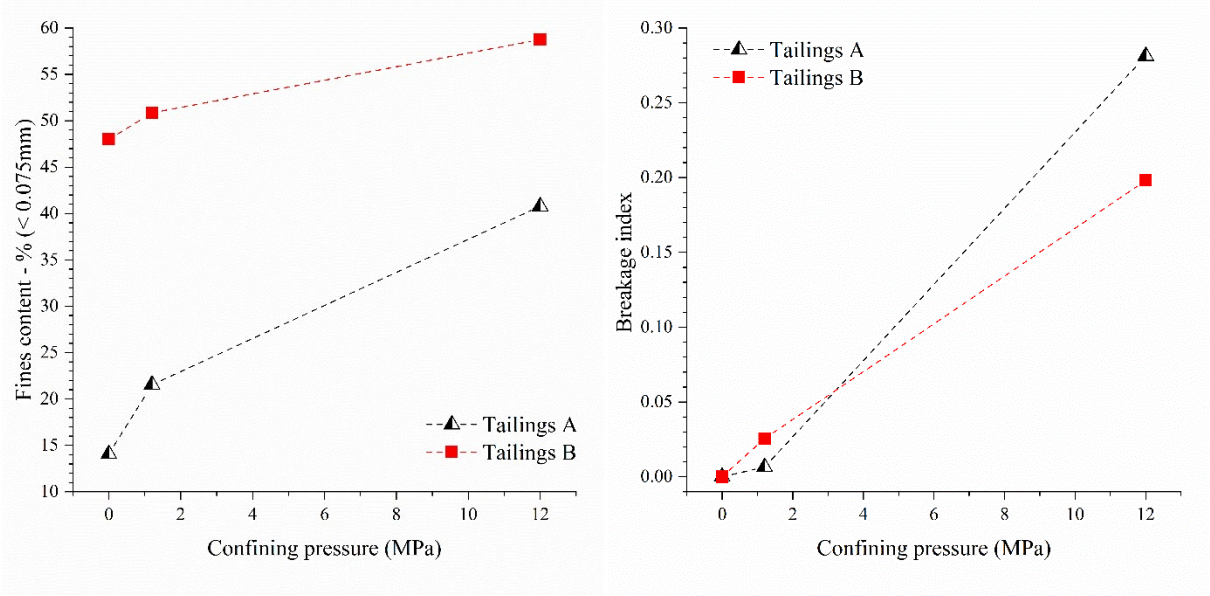


Figure 3: Particle size distribution after testing

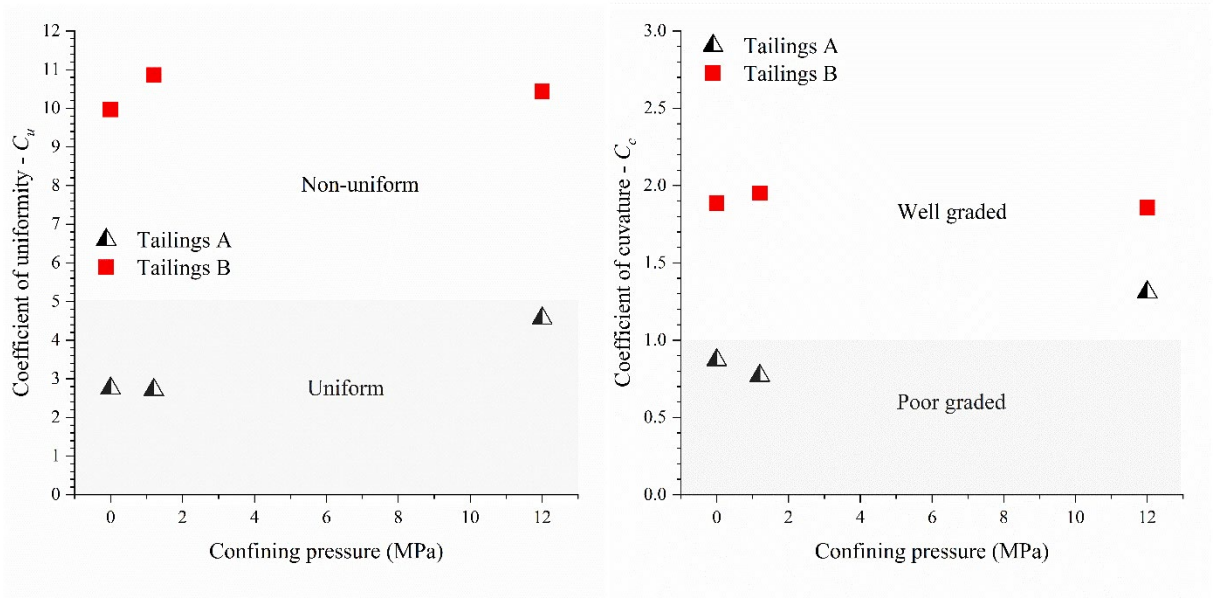
Figure 4a shows that the fines content increases with confining pressures, and the changes become more pronounced for the specimens shearing with 12 MPa. Additionally, it is observed that the rate of increase in fines content is higher for tailings A, suggesting that there is more particle breakage for tailings with a coarser initial particle size.

The relative breakage parameter proposed by Hardin (1985) was employed to quantify the particle breakage. However, all grain sizes of the PSD curves were used in the calculation, differently from the Hardin index, which set a lower limit for grain size at 0.074 mm. Figure 4b shows the breakage indexes obtained for each confining pressure. The particle breakage of the two tailings was very similar up to 1.2 MPa, with Tailings B being slightly superior. However, at 12 MPa, the breakage of Tailings A was significantly greater than Tailings B. This result demonstrates how the grain size distribution affects the tailings breakage: well-graded tailings with higher fines content (Tailings B) result in better arrangements with higher coordination number, reducing the average stress in the contact points and particle breakage.



(a) (b)

Figure 4: Particle breakage measure (a) fines content (b) breakage index

Particle breakage creates smaller particles that tend to alter the original PSD. For this reason, Figure 5 evaluates the change in C_u and C_c of the PSDs obtained. Tailings A, which was initially well-graded, does not exhibit much difference in grain distribution. The coefficients are similar to those of the untested material, suggesting only a shift in the PSD and a slight change in its format. Conversely, the coefficients of Tailings B changed significantly after the shearing under 12 MPa, and the addition of fine particles

reduced its uniformity, making the PSD more well-graded. These changes in grading certainly impact the grain arrangements and may affect the mechanical behavior of the tailings.

(a) (b)

Figure 5: Influence of particle breakage on (a) coefficient of uniformity (b) coefficient of curvature

Stress-strain behavior

Figure 6 exhibits the normalized stress-strain behavior and the volume change response for the tailings sheared at distinct confining pressures. Table 2 summarizes the data about the tests. The specimens sheared at 1.2 MPa confinement showed an initial compression followed by dilation, accompanied by a brittle behavior with a defined peak strength (Tailings B) or no defined peak strength (Tailings A). On the other hand, both specimens sheared at 12 MPa presented a ductile response accompanied by a fully contractive behavior.

The higher peak value observed for Tailings B can be attributed to the lower void ratio and the better grain packing formed during molding for the well-graded material, resulting in a higher contribution from interlocking. The more compressive behavior observed at 12 MPa is due to significant particle breakage, which allows for a new grain arrangement and greater volume reduction compared to 1.2 MPa.

The specimens presented practically constant volumetric strain rate values and deviatoric stresses at the end of the tests, indicating they were close to reaching the critical state. For Tailings A, the stress ratio at critical state (M) achieved at two different confining pressures is very similar (1.45 for 1.2 MPa and 1.43

for 12 MPa), suggesting that grain breakage may have slightly influenced *M* value. In the case of Tailings B, the *M* value varies from 1.43 at 1.2 MPa (similar to Tailings A) to 1.33 at 12 MPa. This result indicates a stronger influence of higher pressure for Tailings B, which can lead to more particle breakage, possible particle shape alterations, and changes in particle size distribution towards a more well-graded condition.

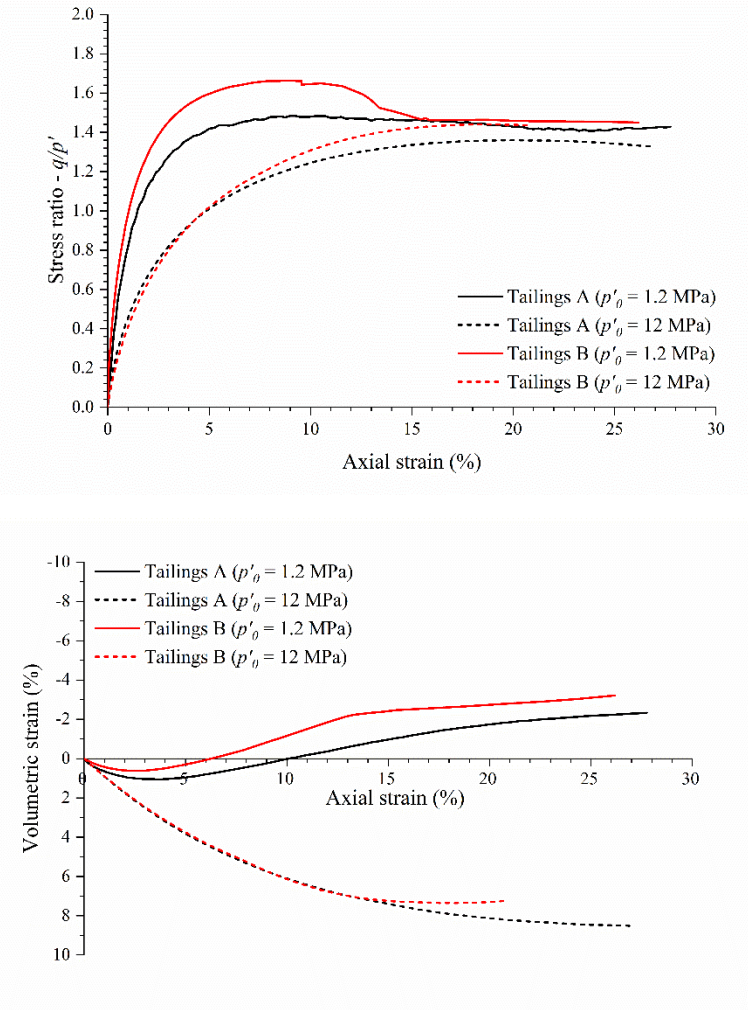


Figure 6: Stress-strain response of tailings

Figure 6 shows a change in stiffness trend for lower and higher stresses, and Figure 7 presents the Secant Young modulus degradation for each test during the axial strain development. At a lower confining pressure (1.2 MPa), Tailings B shows higher stiffness compared to Tailings A. This is expected due to the lower void ratio and well-graded state of Tailings B, leading to a higher particle contact number and better stress distribution. However, when the pressure is increased to 12 MPa, Tailings A became stiffer than Tailings B. This difference can be explained by the increased breakage in Tailings A, resulting in finer particles that alter the grain contacts and improve stress transmission. Moreover, at higher strains, the stiffness of both Tailings A and Tailings B is quite similar under the two stress conditions.

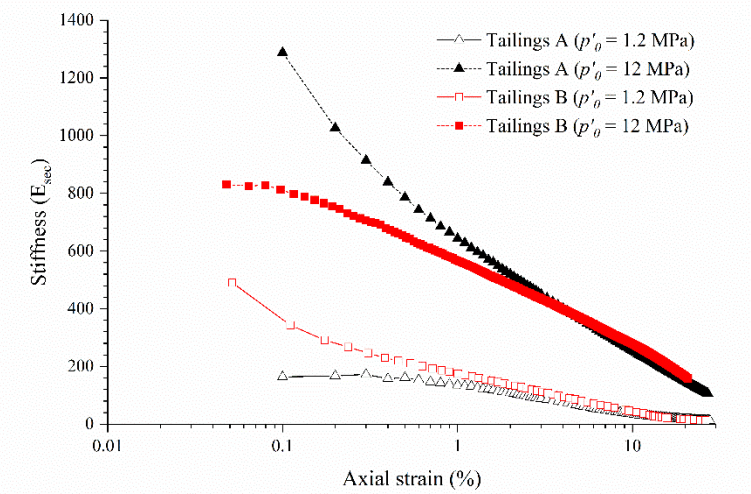

Figure 7: Stiffness degradation curves of tailings

Conclusion

This paper examined the mechanical behavior associated with the particle crushing occurrence of two iron ore tailings under two different confining pressures (1.2 and 12 MPa) through triaxial tests. Considering the boundaries of this work, the following conclusions can be drawn.

Particle breakage is most significant in tailings sheared with a confining pressure of 12 MPa. This stress level can be achieved in very high stacks (up to 600 m, for example).

Tailings with coarser grain size distribution and more uniform grading tend to present more particle breakage due to the lower coordination number and greater stresses in the particle contacts.

Particle breakage generates new small particles that can alter the original PSD, changing the fines' content, coefficient of uniformity, and coefficient of curvature.

The change in PSD due to particle breakage can impact the mechanical response of the tailings. The present study showed that particle breakage can increase compression, reduce the *M* value, and increase the stiffness.

Finally, the results demonstrate the importance of considering the correct stress level in laboratory analysis corresponding to the expected height of the structure. This is essential for assessing particle breakage and its influence on the PSD, as well as the strength and stiffness properties of the tailings, which can impact the design of storage facilities.

Abstract

Brazil has been one of the top world iron ore suppliers, generating vast amounts of tailings which are usually stored in upstream heightened dams. These rising embankments are supported on the deposited tailings, often saturated and loose. This, combined with the uncertainties associated with the tailings' characterization within the reservoir, leads to unsafe structures. Thus, Brazilian regulatory agencies have introduced novel legislation requiring the closure of the upstream heightened tailings storage facilities (TSFs) by decommissioning or de-characterization. Such procedures demand the removal and reallocation of a significant volume of tailings that must be characterized to provide necessary data for its upcoming use. An option is piling up the removed tailings in stacks to prescribed design specifications. Nevertheless, laboratory testing is mandatory to characterize the material. Accordingly, the present research's main goal was to assess the small-strain stiffness (G_0) and the stress-strain behavior of four samples of iron ore tailings retrieved from distinct locations of a dam that was about to be de-characterized. Before mechanical testing, each material was thoroughly characterized, revealing gradation, mineralogical, and morphological differences. The mechanical testing consisted of consolidated drained triaxial tests, in which G_0 was evaluated using bender elements during the consolidation phase. These tests were conducted on specimens of the four materials compacted at two relative density values (D_r = 20% and 100%). In general, the stiffness results have shown that, by adopting a proper void ratio function $f(e)$, the same power-type relationship can express the G_0 of the same material, regardless of molding D_r value. It was also demonstrated that $f(e)$ depends on the material's gradation and can be expressed as a function of the effective particle size (d_{10}). Moreover, despite the differences between the four materials, they tended towards the same stress ratio at larger strain values.

Introduction

In the past decades, upstream heightened dams have prevailed in storing iron ore tailings in Brazil. The stability of such structures relies on embankments raised above the hydraulically disposed tailings, which are often saturated and loosely disposed of; that is, the material is prone to liquefy (Bedin et al., 2012; Silva et al., 2024). The recent episodes concerning upstream heightened tailings storage facilities (TSF) have starkly highlighted the risks and potential damage associated with their collapse, compelling the governing agencies to introduce a set of new rules regarding tailings storage to mitigate these risks and increase safety in the mining sector (Islam and Murakami, 2021; Rodrigues Leão and dos Santos Santiago, 2022).

Essentially, those rules forbid the construction of new upstream heightened tailings dams and demand the shutdown of existing ones via decommissioning and/or de-characterization (Schaper et al., 2020). Decommissioning includes the closure of the TSF and denotes the beginning of the de-characterization process, in which the structure completely loses its dam characteristics and is safely reincorporated into the landscape.

These actions involve the withdrawal and reallocation of significant amounts of tailings, whose geotechnical characteristics are essential data for ensuing use, which may include tailings dewatering with subsequent compaction into piles with specified design requirements (Lupo and Hall, 2010; Wagner et al., 2023). Understanding the compacted tailings response under distinct boundary conditions is essential in this context, particularly when considering the variability of the tailings within the same reservoir (Velten et al., 2024).

In this context, the present work evaluates the small-strain stiffness (G_0) of four iron ore tailings samples collected from different areas within a reservoir that was to be de-characterized. The tailings were previously dewatered, and the tests were conducted using two relative density (D_r) values for each sample: G_0 was evaluated during the isotropic consolidation stage of a triaxial test using bender elements. The intrinsic variability of the tailings, associated with the uneven tailings distribution during the dam's operation time, resulted in samples differing in gradation and mineralogy. As a result, this study helps to enlarge understanding of the effects of gradation and mineralogy on the small strain stiffness of compacted iron ore tailings for dry stacking purposes.

Experimental program

The experimental program comprises the geotechnical and mineralogical characterization of the four iron ore tailings samples (termed materials 1, 2, 3, and 4) and the conduction of eight drained triaxial tests with coupled bender element analysis during the isotropic consolidation stage. Tests were performed on specimens compacted at two relative density values (D_r = 20 and 100%) using the moist tamping technique

(Quinteros and Carraro, 2023), with a moisture content of 10% for materials 1, 3, and 4, and a moisture content of 14% for material 2.

Materials

The samples were collected in an undisturbed state from a dam located at the Iron Quadrangle (Minas Gerais, Brazil). Table 1 summarizes the main physical characteristics of each tailings. All the materials are non-plastic silts, except material 2, a non-plastic silty sand. Also, only material 3 is well-graded (CU > 5); the others are uniformly graded. Mineralogically, QEMSCAM® tests revealed that tailings 1, 2, and 4 are mainly composed of quartz (~47%) and iron oxide (~49%), with minor amounts of minerals such as chlorite, biotite, and gibbsite. In contrast, tailings 3 presents a smaller quantity of quartz (~24%) and more significant amounts of feldspar (1.5%), chlorite (11.3%), and iron oxide (~58%). Table 1 also displays four particle shape parameters calculated based on SEM micrographs. Despite the differences in gradation and mineralogy, the morphology of the four tailings is similar because of the beneficiation processes they underwent. These resulted in angular to subangular particles with intermediate sphericity and elevated surface roughness.

Table 1: Physical characteristics of the tailings

Parameters	1	2	3	4
Specific gravity – G_s	3.70	3.52	3.71	3.64
Medium sand: 0.425 mm < d < 2.00 mm (%)	0.10	3.70	0.10	0.20
Fine sand: 0.075 mm < d < 0.425 mm (%)	34.00	71.20	1.60	34.20
Silt: 0.002 mm < d < 0.075 mm (%)	64.40	23.70	86.90	63.20
Clay: d < 0.002 mm	1.50	1.40	11.40	2.40
d_{10} (mm)	0.025	0.05	0.002	0.03
Coefficient of uniformity – CU	2.6	2.4	9.0	2.2
Coefficient of curvature – CC	0.98	1.10	1.36	0.82

Sphericity	0.60	0.45	0.61	0.57
Convexity	0.82	0.75	0.77	0.78
Overall regularity	0.67	0.56	0.66	0.65

Triaxial testing

The ASTM D7181 (ASTM, 2020) underlined the procedures of the consolidated drained (CID) triaxial tests carried out on fully automated triaxial equipment using saturated specimens. These were previously flushed

with de-aired water and saturated under backpressure until a B-value greater than 0.95 was obtained. The isotropic consolidation took place in stages; at the end of each stage, bender elements tests were carried out to assess the shear wave velocity (V_s) by ASTM D8295 (ASTM, 2019). The small strain stiffness (G_0) is the product of the square of V_s and the bulk density of the specimen (ρ). The shearing was strain-controlled (1% per hour) and conducted under an effective confining pressure (σ'_3) of around 805 kPa for the loose specimens (D_r = 20%) and 610 kPa for the dense ones (D_r = 100%). Table 2 contains the characteristics of the tested specimens: molding void ratio (e_0), void ratio after consolidation (e_c), and void ratio after shearing (e_{final}).

Table 2: Characteristics of the tested specimens

Material	σ'_3 (kPa)	e_0	e_c	e_{final}
1	808	0.93	0.80	0.70
1	610	0.52	0.52	0.59
2	809	0.93	0.86	0.74
2	606	0.61	0.54	0.63

4	808	0.90	0.80	0.71
4	605	0.58	0.56	0.62

Results

Bender elements

Figure 1 displays the evolution of the small strain stiffness (G_0) during the consolidation stage of each tested specimen (each plot contains the data of the loose and dense samples of the same material). The increase in the confining pressure compresses the sample, diminishing the void ratio and augmenting the interparticle contact area, which causes the G_0 to increase (Santamarina et al., 2001). The same mechanism accounts for the higher stiffness values amongst the dense samples within each material. Equation 1 captures the relationship between G_0 and the mean effective stress (p') through a power-type format.

$$G_0 = A \cdot \left(\frac{p'}{p'_{ref}}\right)^{\beta} \quad \text{(Equation 1)}$$

Where A is a scalar (expressed in MPa) depending on the grain characteristics and the packing properties, β is the adjustment exponent dependent upon the material's compressibility, and p'_{ref} is a reference pressure taken as 1 kPa.

Parameters A and β are inversely proportional because denser packing implies stiffer (and less compressible) material. The fabric differences decurrent from compacting the same tailings at different D_r

values justify a unique relationship for each tested specimen. Yet, it is possible to express A by the product of two terms: a scalar α (expressed in MPa) and a void ratio function $f(e)$ that captures the features of particle packing (He et al., 2019). Therefore, Equation 1 becomes:

$$G_0 = f(e) \cdot \alpha \cdot \left(\frac{p'}{p'_{ref}}\right)^{\beta} \quad \text{(Equation 2)}$$

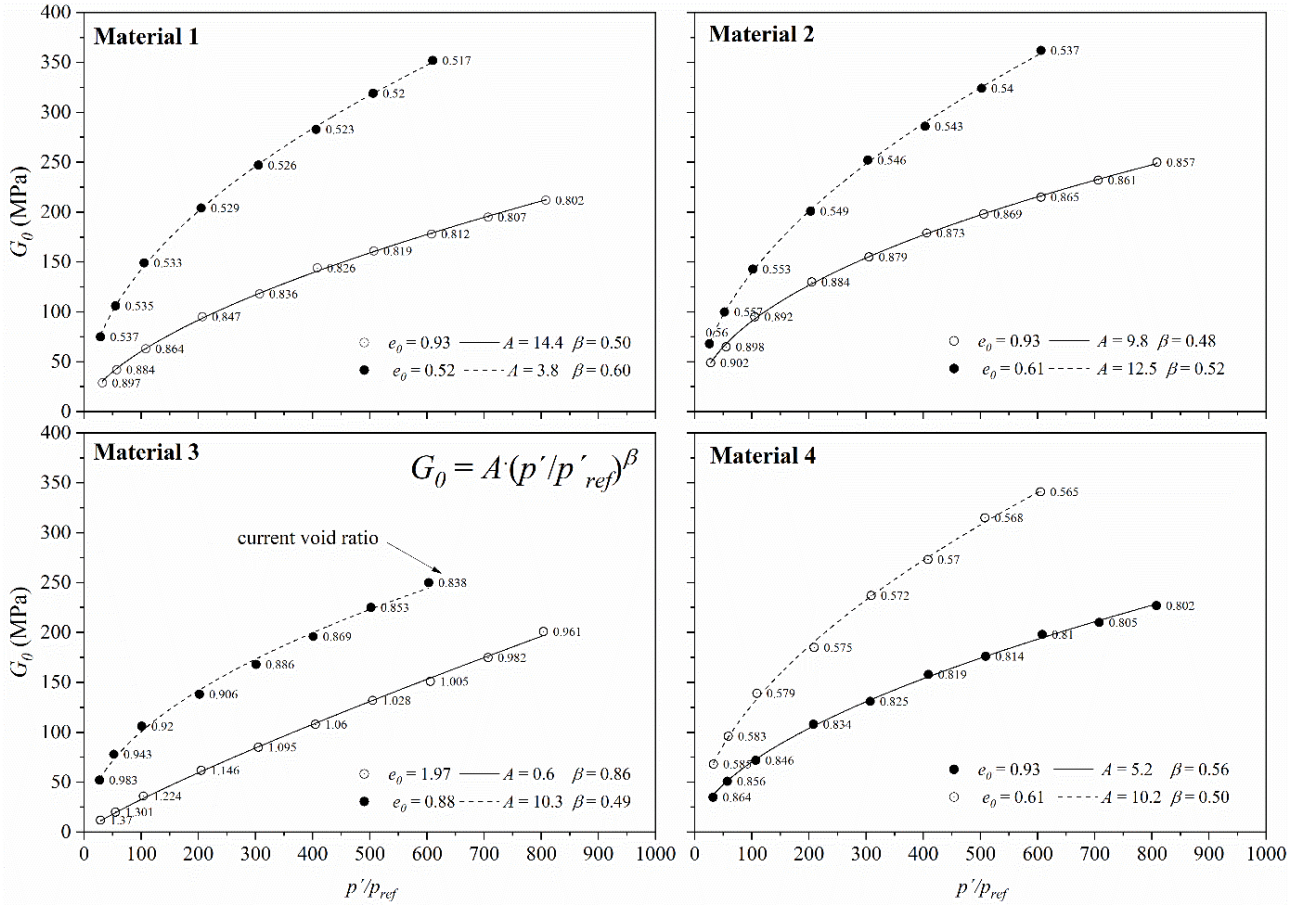

Figure 1: G_0 variation during the consolidation phase

Despite the existence of several forms of the function $f(e)$ (Goudarzy et al., 2016; Lo Presti et al., 1997), a simplified form of $f(e)$ was used to adjust the stiffness results within each material. It is given as follows:

$$f(e) = e^{-a} \quad \text{(Equation 3)}$$

Where a is an exponent depending upon the particle's characteristics.

Figure 2 shows the normalized small strain stiffness data $G_0/f(e)$ versus p'/p'_{ref} for all the tested specimens. When using the adequate a value, the specimens molded at different D_r collapsed onto the same

trend (Equation 2) within each material. In other words, this permits the mathematical description of the G_0 for a series of void ratios and pressure combinations.

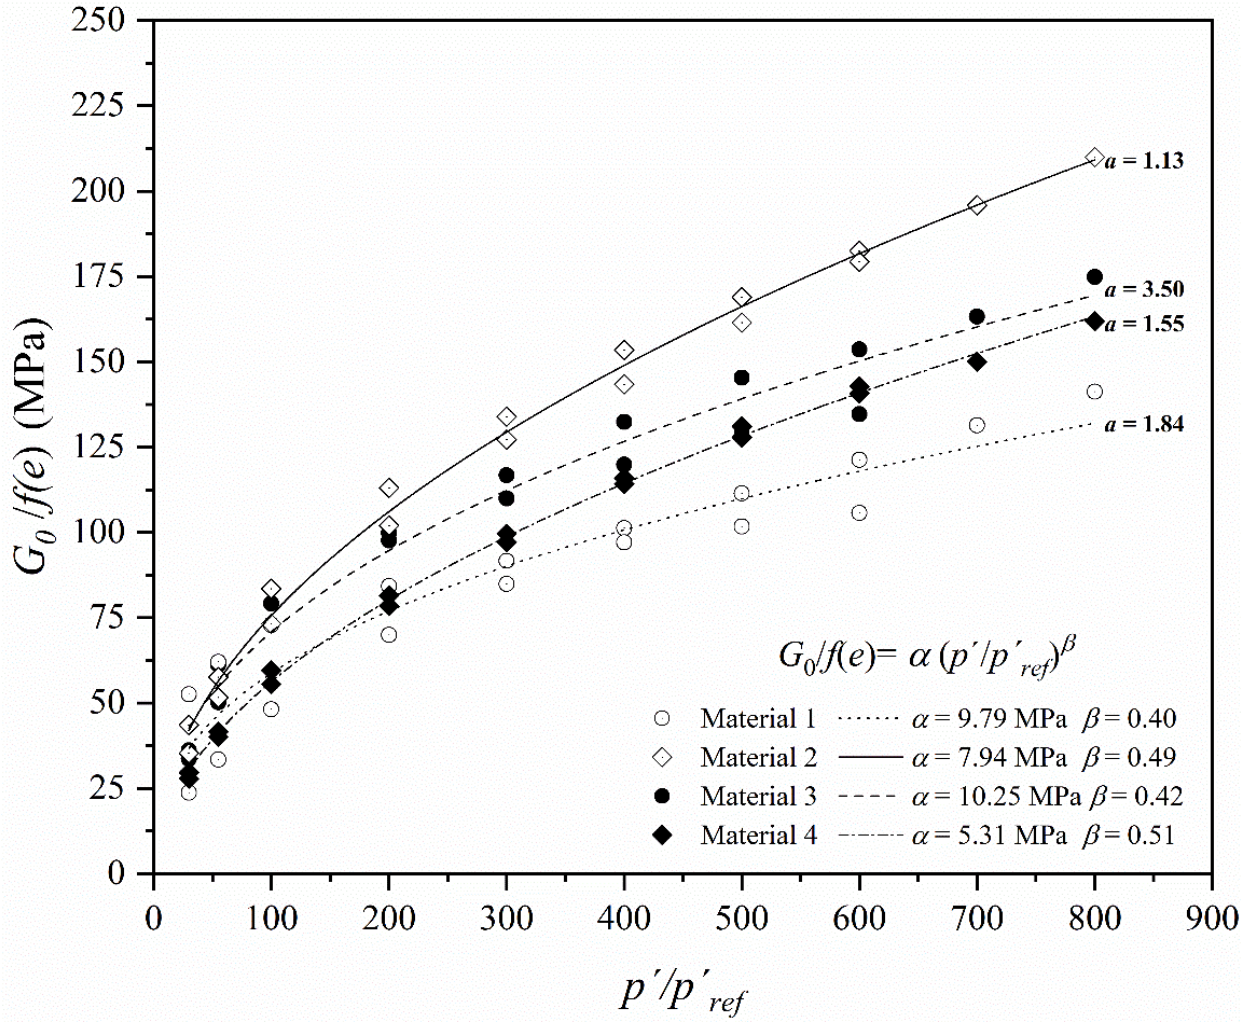

Figure 2: Normalized G_0 data

The four materials are generally similar but differ slightly in grading, mineralogy, and particle morphology, especially material 3. Those distinctions affect the particle packing-related characteristics (i.e. fabric), influencing the stiffness at the interparticle contact (Fernandez and Santamarina, 2001; Shi et al., 2021), which explains individual equations for each material.

Nonetheless, a relationship between exponent a and the effective particle size (d_{10}) appears to exist, accounting for the influence of the particle size on the value of a. Figure 3 displays such a relationship, fitting a power-type equation that portrays an inverse trend between the value of a and the effective particle diameter – higher a values occur for finer tailings. A coefficient of determination (R^2) of 0.97 was obtained.

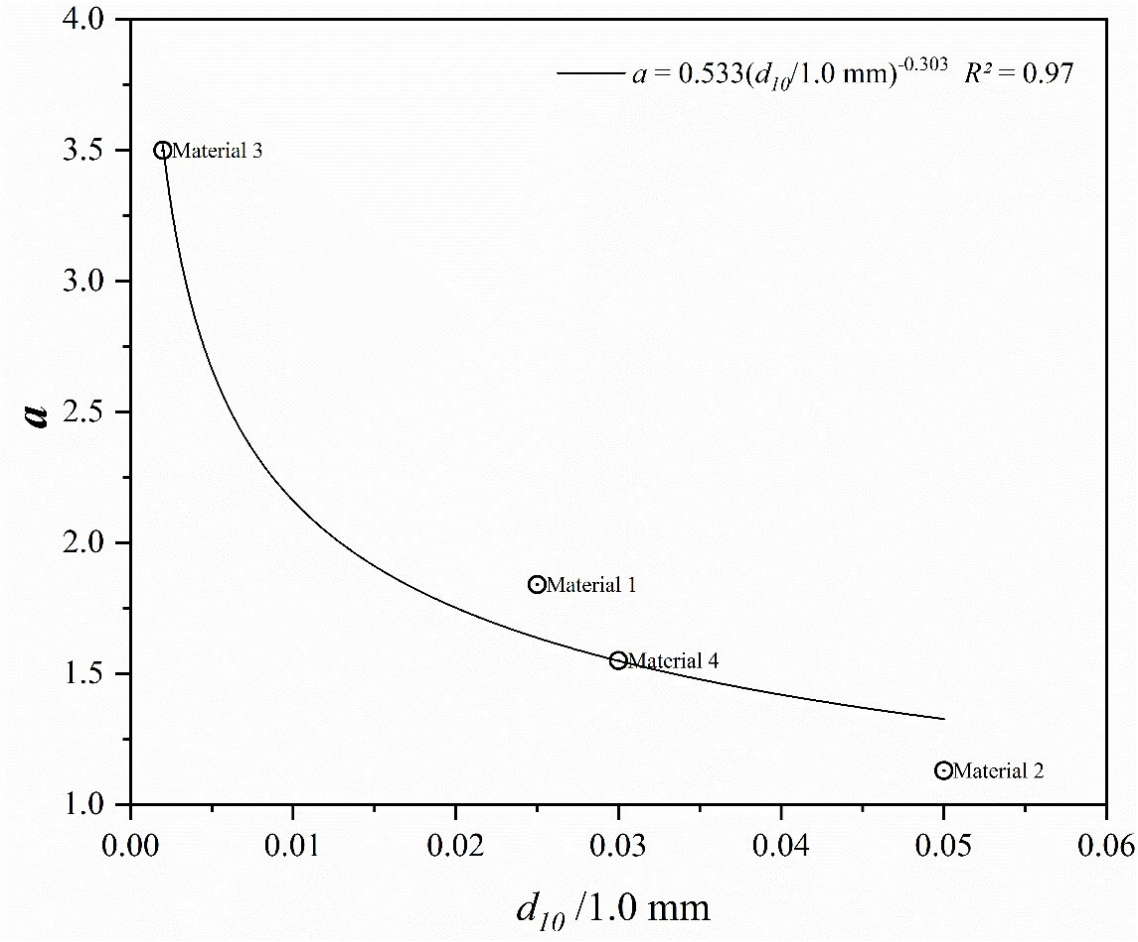

Figure 3: Coefficient of void ratio function

Triaxial testing

Figure 4 displays the normalized stress-strain behavior and the volume change response of the loose and dense samples of the four materials. All the loose specimens presented a ductile behavior and a fully compressive response in which the amount of compression was proportional to the void ratio at the beginning of the shearing (e_c value). All the dense specimens but the material's A exhibited a slightly fragile response: defined peak strength, post-peak strain softening, and initial compression followed by dilation. At the later stages of shearing, the specimens that have solely compressed stabilized in volumetric strain and directed towards the same stress ratio value ($q/p' = 1.33$), indicating that the fabric differences arising from gradation, mineralogy, and D_r values erased because of shearing.

In other words, the differences that influence the interparticle stiffness at small strain values are erased; the same critical state line can fit the data in the effective stress plane $q{:}p'$, denoting a critical state friction angle (ϕ'_{cs}) of 33°.

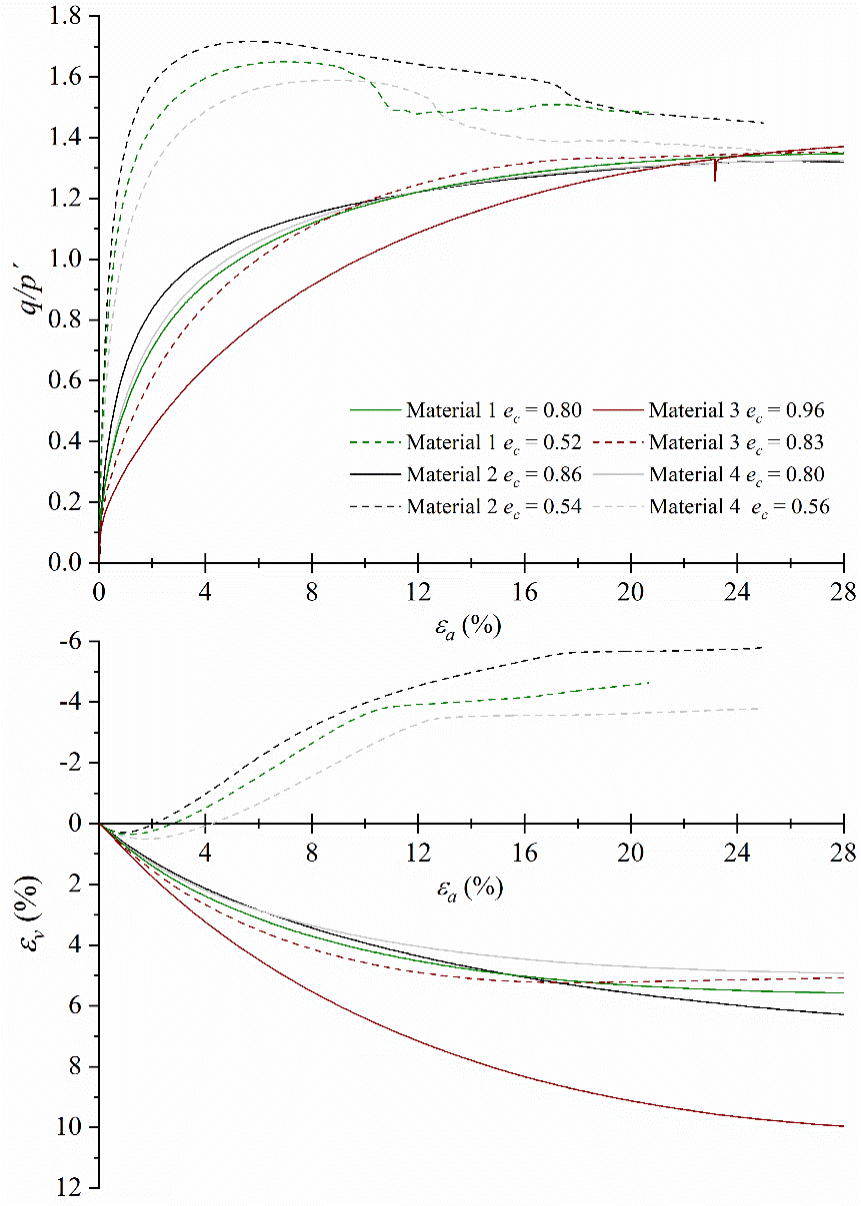

Figure 4: Shearing response

Conclusion

This study assessed the small-strain stiffness of four iron ore tailings through bender elements tests carried out during the isotropic consolidation phase of triaxial compression tests. The tailings were tested considering two initial relative density values (D_r = 20 and 100%). Therefore, considering the boundaries of the present work, the following conclusions can be drawn:

- The small strain-stiffness was shown to be proportional to the effective confining pressure and to the void ratio, which influences the interparticle contact stiffness.

- A power-type equation, depending on parameters A and β, can express the relationship between G_0 and the mean effective stress for each tested specimen. Yet, within each material, the data of the loose and dense specimens solely fall towards the same relationship by splitting A into two parameters and adopting a proper void ratio function $f(e)$.
- The grading and mineralogy characteristics influence the fabric, and thus the interparticle contact stiffness, explaining the existence of individual normalized relationships for each material.
- The value of the parameter a, related to the adopted $f(e)$, was shown to be dependent on the grain size characteristics of the tailings; it could be correlated with d_{10} of each material.
- Shearing appears to remove the fabric differences related to initial density, gradation, and mineralogy, as all the samples reached the same critical state stress ratio at the later stages of shearing.

This study has provided valuable insights into predicting small strain stiffness, considering aspects depending on the tailings gradation and state (void ratio and mean effective stress), which are relatively easy to measure within the context of dry stacking facilities.

Abstract

The Rainy River tailings management area (TMA) in Northern Ontario is situated above highly plastic, normally consolidated glacial clay soils of variable thickness. The TMA consists of clay core dams, with chimney and blanket filters, constructed upwards of ~30m in height. The clay foundation soils govern the design and construction of the dams. The design of the TMA requires large upstream and downstream rockfill buttressing combined with extensive monitoring to ensure continued performance is maintained.

The design and construction procedures attempt to best employ the observational method (Peck, 1969) to complete each raise safely. Construction raises are completed yearly to facilitate additional storage capacity and deposition. Dissipation of excess pore water pressure allows for the optimization of rockfill buttress placement after each construction season prior to the next raise. The design of the dams is completed using conventional methods to meet or exceed the minimum Canadian design standards.

Over 400 piezometers, 30 slope inclinometers, numerous settlement plates, and magnetic extensometers are used to monitor the site. Displacements (both lateral and vertical) and excess pore water pressures are observed throughout the year in response to additional loading. Monitoring of the instrumentation is ongoing by both the owner and the Engineer of Record (EOR).

The successful construction and operation of the site has benefited from continuous improvements to the monitoring and reporting system, yearly field investigations, interrogation of the most-probable and unfavorable conditions through numerical modelling, and open communication between the EOR and owner/site operations. This case-study paper describes the continued improvement and challenges of applying of the observational method. Specific emphasis is on the lessons learned with respect to the

importance of the governance structure, continuous improvements to the instrumentation monitoring and reporting system, and communication between stakeholders.

Background

The Rainy River mine site is located ~160 km south of Kenora, in the Lake of the Woods area of Northern Ontario, Canada, as shown in Figure 1. The site is operated by New Gold Inc., an intermediate Canadian-based mining company with core assets based in Canada. The mine is estimated to have an average annual processing rate of approximately 25,000 tonnes per day (tpd) and the TMA currently stores approximately 38 Mm^3 of tailings, with projected life of mine estimates around ~80 Mm^3. Tailings containment is currently provided by natural topography to the north and three perimeter dams to the northwest, southwest, and southeast.

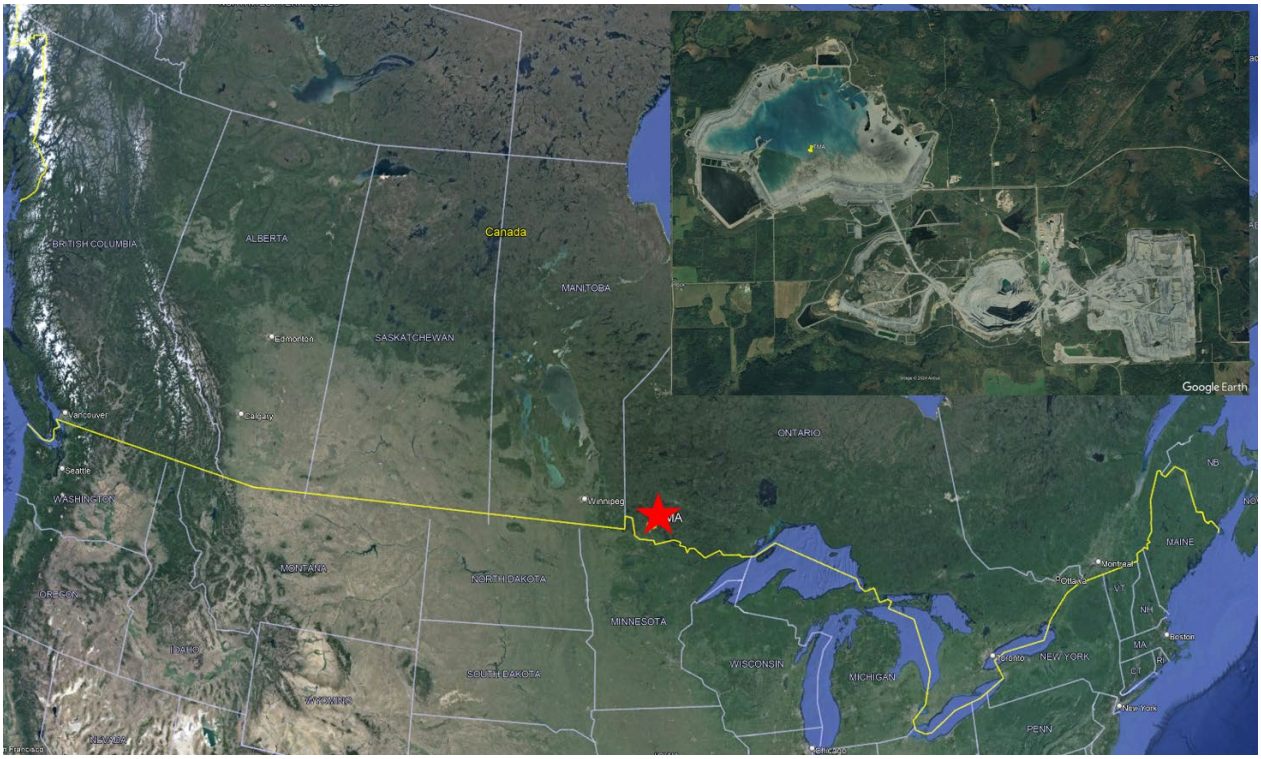

Figure 1: Location of the Rainy River Mine

Geological setting

The quaternary geology of the area is based on glacial deposition from the Laurentide ice sheet. Starting from the lowest unit, undulating bedrock of the Canadian Shield is present on site and visible from surface outcrops (390 m), or as low as ~310 m below overburden soils within the tailings management area (TMA). Soils within the TMA were deposited because of two main glacial advances: the Labradorean and Keewatin

sectors of the Laurentide ice sheet (Ontario Geological Survey, 2001; BGC, 2021). Sequencing of the geological units is provided in Figure 2, as shown in SRK's 3D geological model.

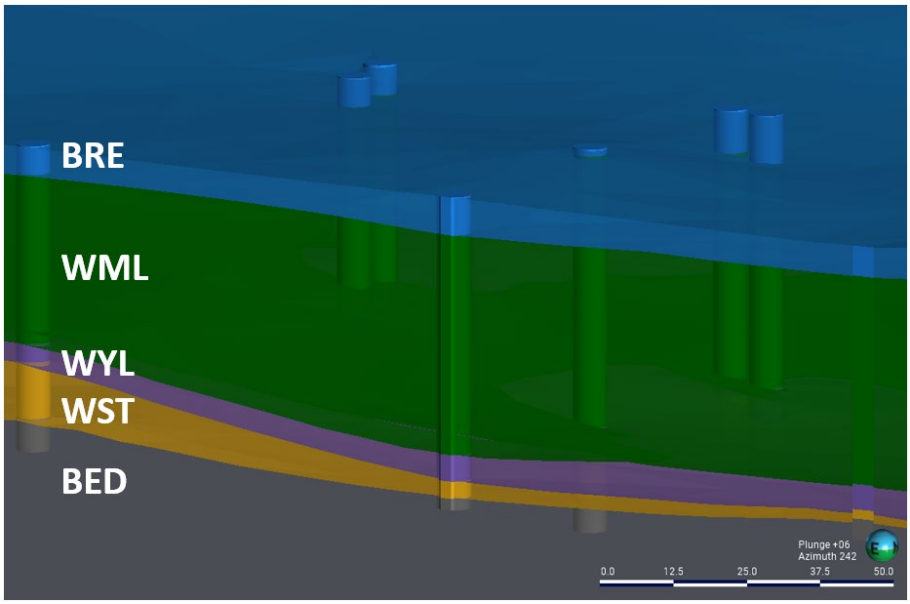

Figure 2: Generalized geotechnical geology of the tailings management area at the Rainy River Mine

The geological history of the TMA area on site is as follows (from bedrock to surface):

WST: The Labradorean ice sheet advanced towards the southwest, depositing coarse Whiteshell Till (WST) along the bedrock. The WST is variable in thickness and is found in bedrock troughs or depressions crosswise and on the leeward side of the bedrock highs. Thicknesses within the site area typically range from 0 to ~15 m. The WST can be observed to daylight at bedrock highs around the site and acts as a confined aquifer – artesian conditions are observed in some locations.

WYL: The retreat of the Labradorean ice sheet likely resulted in a pro-glacial lake over the site area in the period prior to the Keewatin ice advancement. The unit, coined the Wylie formation (WYL) is rhythmically layered sediments, progressing from sands and silts near the bottom (Labradorean sourced) to increasingly more Keewatin ice-derived clays near the surface, reflected by a change in mineralogy (Keewatin clays contain a high volume of expansive clay minerals).

WML: Movement of the Keewatin glacier from west to east resulted in the deposit of Whitemouth Lake Till (WML) across the site in a buoyant environment. The clay is a highly plastic montmorillitic soil and is typically overconsolidated (OC) from depths of 4–10 m, likely due to desiccation/weathering or grounded glacial advance, and normally to lightly overconsolidated at greater depths.

BRE: The Brenna layer, deposited within the retreat of the Kewaatin ice and emergence of the Lockhart Phase Glacial Lake Agassiz, has variable grain size and characteristics due to its dynamic

depositional environment. It has generally been observed to be spatially continuous below elevation 375 m, with thickness ranging from 0.5 m to 6 m. The depositional environment varied both temporally and spatially, resulting in different types of BRE – classified as low or high plasticity clay.

Organics: Thick fibrous peat deposits and topsoil can be observed around site.

At the Rainy River mine site, organics and BRE are removed to construct the dam core. The WML is used for dam core construction due to its consistency and low hydraulic conductivity. Meanwhile, the WST acts as a confined aquifer, recharged from areas with bedrock highs and daylighting WST. Groundwater is present at or near the surface as observed in piezometers, boreholes, and many local lakes and streams evident in the area. Although the WST has been observed to be artesian in some areas disconnected from the open pit, the transmissivity has generally been observed to be low.

Cross-section and design basics

The TMA is constructed as a centerline raise clay core dam with chimney and blanket filters, as shown in Figure 3. Due to the weak, compressible foundation soils, large rockfill buttresses and tailings are placed on both the upstream and downstream sides. As the foundation varies over the length of the dam (~7.6 km), the dam is segmented into 18 critical cross-sections. Each cross-section buttress is optimized to meet CDA (2019) requirements based on the interpreted foundation conditions.

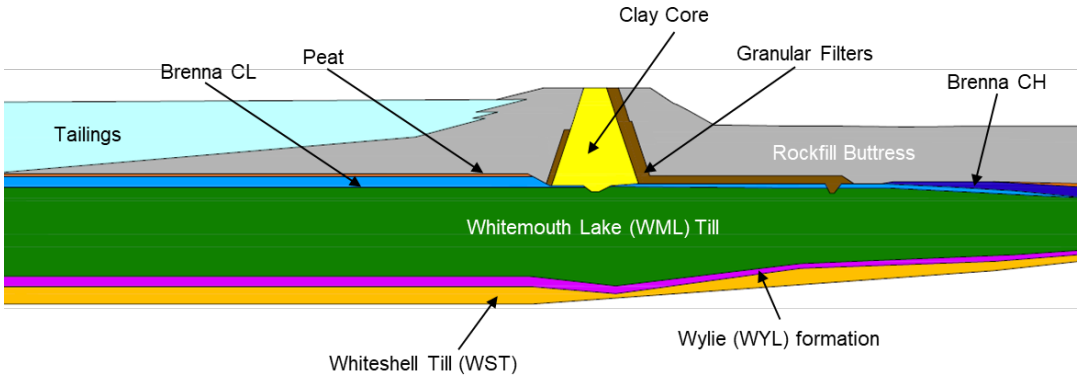

Figure 3: Typical cross-section of a tailings management area dam

The dam height varies from tying into the bedrock outcrops to a maximum dam height of ~27 m (as of 2024). The downstream buttress varies in width depending on the foundation conditions (described below) but can range from ~8H:1V to ~20H:1V, resulting in buttresses exceeding 400 m offset from the centerline of the crest.

Foundation conditions

The plastic clay foundation soils at Rainy River result in low strength clays that generate high excess porewater pressures upon loading. Extensive work has been performed characterizing both the BRE and

WML units as they relate to TMA performance (BGC 2019, 2021; SRK, 2023). New Gold has supported several site investigations, which have been conducted for both the TMA, waste rock, and overburden stockpiles. Additionally, test embankments and numerical modelling has been undertaken on site (Etezad et al., 2019, 2022). Examples of triaxial testing on the WML and BRE CH as shown in Figure 4, with a sample with a pre-sheared slickenside failure given in the photo. Design strengths lines of 15° and 12° are provided for reference.

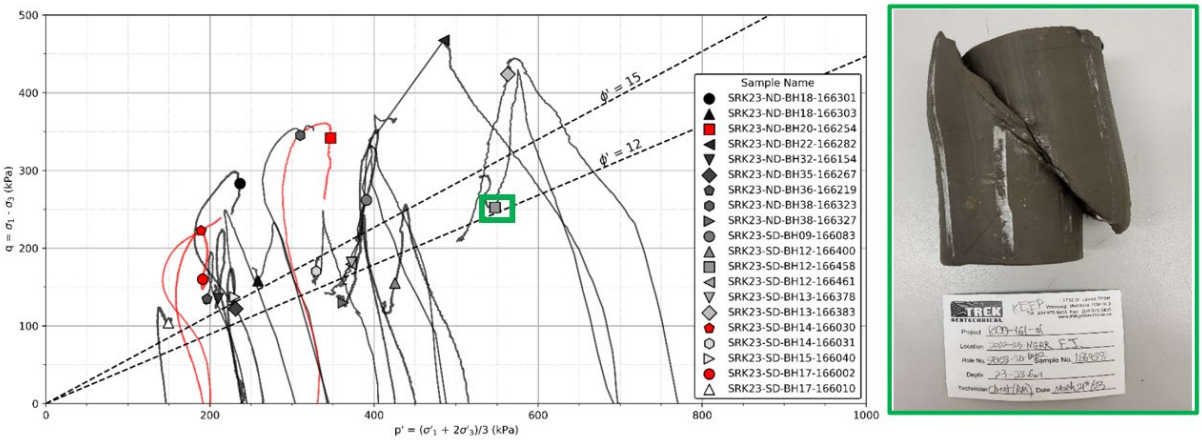

Figure 4: Triaxial test results on WML (grey) and BRE CH (red) samples

The Whitemouth Lake Till has been identified to contain discontinuous shear zones "slickensides" present across the site. The slickensides vary in size from ~10 mm to ~10,000 mm in size. They are assumed to be discontinuous and occur at several angles, as shown in Figure 5.

Figure 5: Examples of slickensides surfaces observed in borrow pit development

The pre-sheared slickensides are a function of the depositional history of the lodgement till (BGC, 2019). The shear strength along the slickenside is assumed to be at or near residual, although the bulk strength is assumed to be a combination of the peak-post-peak-residual value (i.e., "operational")

(Skempton, 1985; Lo, 1972). Observations and numerical modelling of the clay borrow pits indicate the clay reduces in strength with increasing strain (Marcotte et al., 2023).

Observational method in design and construction

To keep the buttresses a reasonable size (and not overdesign), the observational method is employed. Many historical tailings facilities are not well suited to the observational method due to the potential for brittle strain-weakening behavior of loose tailings deposits. However, the limit equilibrium critical downstream stability sections during design do not predict failure through the tailings mass even when fully liquefied tailings are assumed to occur.

The buttress requirements at Rainy River were initially based on stability assessments developed from preliminary site investigations. A higher operational strength for the WML and a lower minimum required factor of safety (FOS) (1.3) were adopted during construction and were used during the initial construction, but unfavorable displacements led to additional buttressing as the dams grew in height.

After further data collection and review, the geological and geotechnical models were updated, adopting a lower operational shear strength (φ'=12°) and a higher FOS requirement (1.5) for the following dam raise (2020). The additional rockfill buttressing that was required to satisfy the new parameters led to reduced lateral displacements and controlled movement rates during construction.

A comprehensive site investigation during winter 2021 refined the geological model (BGC, 2021), enhancing site understanding. Improved performance and increased confidence in the geotechnical model provided confidence for a 3° increase in operational strength of the WML, reducing buttressing requirements for select design segments. Using Peck's observational method, the lower-bound operational strength was applied if unfavorable movements occurred.

If unfavorable instrumentation readings indicate that additional rockfill buttressing may be required, the mine has a fleet of construction equipment that can be immediately mobilized. Additional rockfill is stored at the toe of the TMA for both convenience during construction and expediency should it be required.

The third raise (2022) with the increased clay strength demonstrated satisfactory performance, improving understanding of clay behavior. Consequently, a φ'=15° was adopted for the 4th, 5th, and 6th raises across all design segments.

The design assumptions, instrumentation, and construction are reviewed on an ongoing basis, and adjusted to reflect the actual site conditions. Modifications are made yearly to the stability assessments and detailed design for the next raise to best reflect the current interpretation of the dams. Stability assessments on an adverse foundation using the observational method require the engineer to continually measure and observe conditions, and test them against the current design assumptions.

Monitoring

To successfully apply the "observational method" to the Rainy River site, an extensive suite of monitoring instrumentation is employed by the mine, as shown in Figure 6. This includes:

- 486 active VWPs at the TMA and associated water management structures;
- 36 installed slope inclinometers;
- 2 Shape Array accelerometers;
- 13 settlement plates;
- 29 magnetic extensometers;
- 19 standpipe piezometers;
- regular InSAR surveys and reporting;
- regular photogrammetric drone flights;
- regular LiDAR surveys; and
- regular dam inspections.

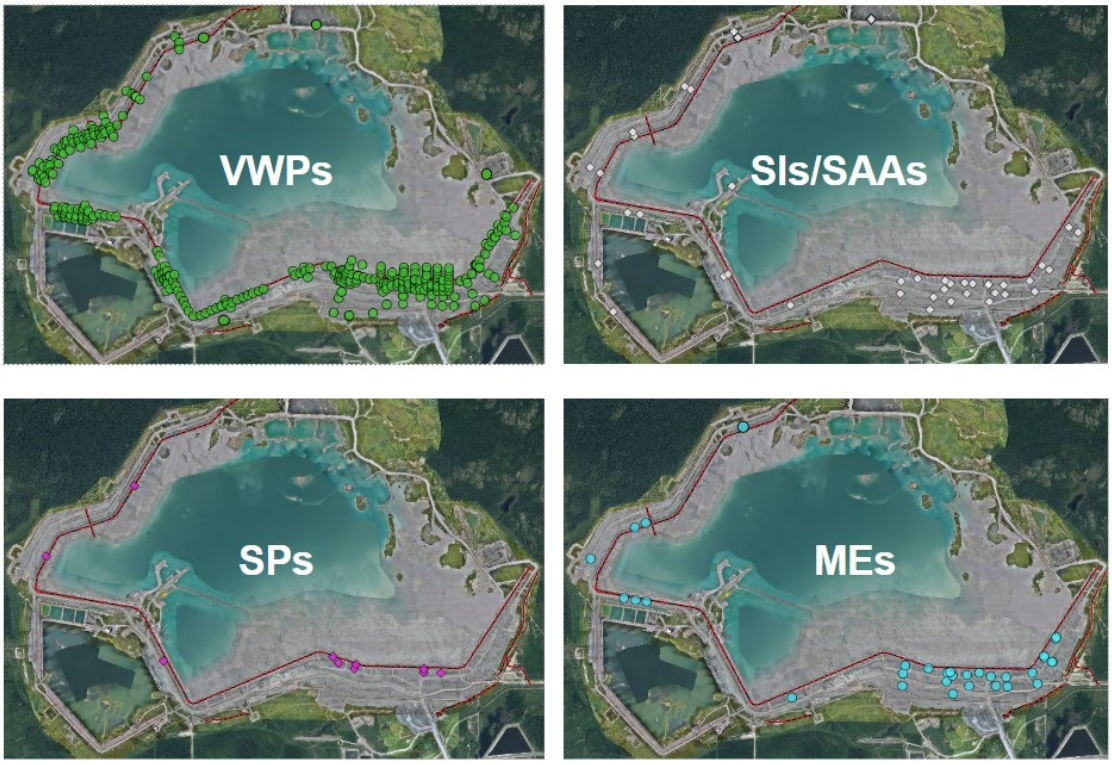

Figure 6: Instrumentation at the Rainy River tailings management area

To accommodate the significant data collected, New Gold has developed in-house geographic information systems (GIS) and stores all data within a SQL server. As communication between the EOR and client is a critical component of the monitoring system, the SQL server is provided directly to the EOR.

From the SQL database, the EOR can download specific data, develop custom interpretation visualizations, and keep up to date with the latest readings. The developed system can track and timestamp changes made, to aid in any future troubleshooting and help address any discrepancies that may arise. The GIS system developed by New Gold collects and stores the following key information used by the EOR for interpretation and performance monitoring:

- VWP metadata, readings, health (battery, signal) and any changes that occur;
- slope inclinometer readings, azimuth directions, configurations, and any changes that occur;
- tailings spigots that are active, elevation of tailings at spigot;
- weather; and
- pond water levels.

The ability to have unrestricted access to real-time site data has allowed the EOR team to create visuals to expedite data review and performance monitoring. For example, a capture of the monitoring data output is given in Figure 7.

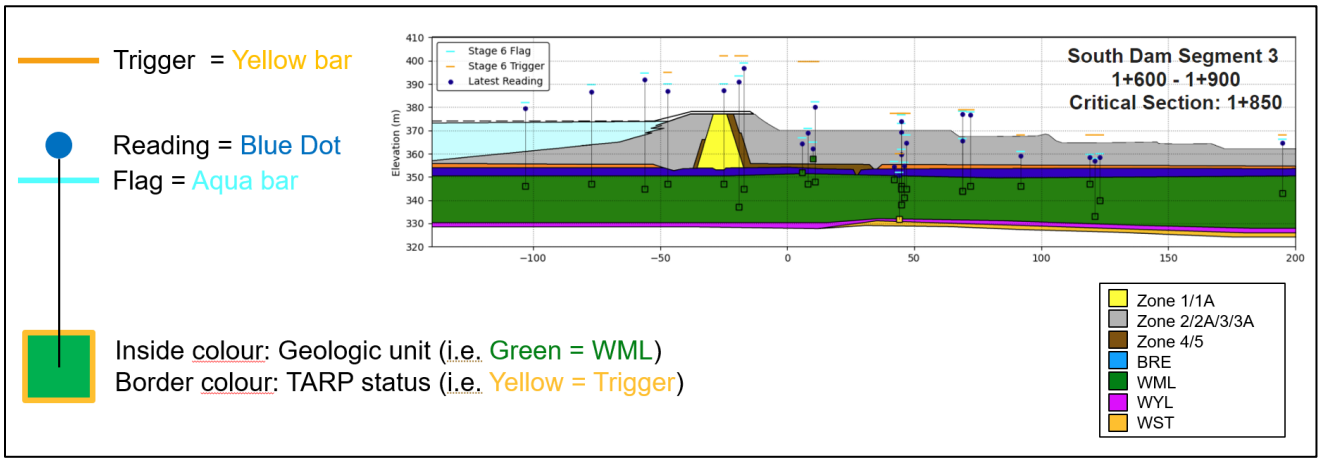

Figure 7: Real-time plots of total head superimposed on critical cross-section

The visual quickly communicates information to the engineer inspecting the data about the current total heads within the foundation, any "Trigger" or "Flag" alerts that are noted, as well as time-series data that can be inspected further.

TARPS and governance

SRK revised the sitewide trigger action response plans (TARP) in 2024 to be more in line with the Mining Association of Canada (MAC) tailings guide TARPS (MAC, 2021, 2022). As outlined in the example by MAC, a clearly defined risk-management plan for specific indicators is required. Although just an example,

MAC provides a four-level risk-framework. A similar framework was developed to fit the site conditions, as shown in Figure 8.

Segment Status	Potential Actions	Notified Personnel
Green	Standard surveillance activities and frequencies.	-
Yellow	Halting construction; Additional buttressing; Reduce pond volume; Increased instrumentation reading frequency; Increased survey and inspection frequency; Adjustments to instrumentation thresholds.	EOR Team; Tailings Dam Engineer; Responsible Person.
Orange	All applicable activities in Yellow; Preparation for unfavorable conditions; EOR site visit; Reassess thresholds and conditions that may result in a high-risk situation.	SRK internal review panel; NGRR ITRB; Emergency Response Personnel; Accountable Executive.
Red	All applicable activities in Orange; Mandatory EOR site visit; Prepare to activate the Emergency Response Plan; Evacuate areas of concern and notify Communities of Interest.	All stakeholders. Communities of Interest; Regulators.

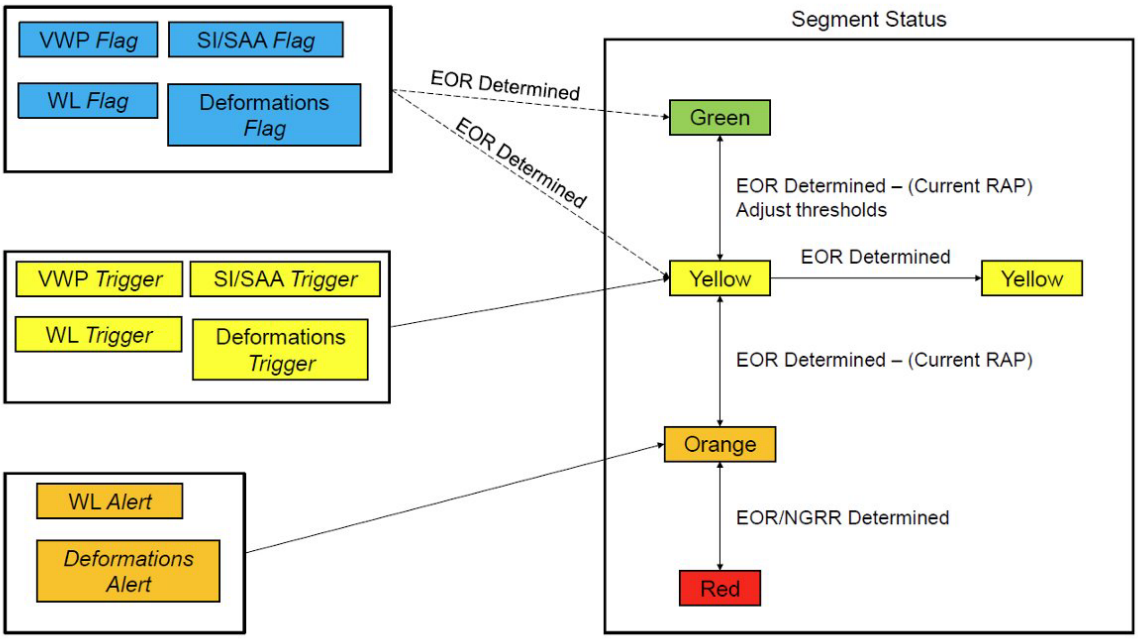

Figure 8: TARPs framework for the Rainy River Mine site

For each of the 18 individual dam segments, an operational status is assigned based on current observations or instrument readings. If the segment moves into a new operational status predetermined actions are initiated, as depicted in Figure 8.

As described previously, the Rainy River site employs the observational method to construct the dams in stages. The dams are expected to move, with upwards of 1–2 m of total vertical settlement expected over

the decades, primarily due to consolidation. Lateral displacements and high excess porewater pressures are anticipated due to the nature of the foundation and consolidation of the materials. The instruments inform the engineer of the movement/responses of the structure, but in isolation, may not directly correlate with a "Yellow" or "Orange" status.

Importantly, based on the spirit of the observational method as described by Peck (1969) a "Flag" level was adopted for data with quantitative values, such as SIs and VWPs, representing the anticipated response of the instrument. This varies instrument to instrument, based on previous history and expected fill placement near the instrument. A flag in isolation may not be indicative of a problem, but rather notifies the engineer that an instrument should be reviewed. If the EOR determines that a flag (or several flags/observations) is a symptom of a larger or developing problem, the engineer may increase the segment status and initiate actions to be taken. Flag values are evaluated on a weekly basis.

Trigger values represent observations that require a formal EOR response to the mine. For example, if a VWP total head exceeds the total heads used during the design, the EOR must reevaluate stability using the current conditions and geometry. Once this is complete, the EOR may determine that the segment can return to "green" or an acceptable status if the stability is acceptable (along with consideration for other observation instrumentation at that section). If other instrumentation indicated a potentially worsening problem, the EOR may determine that the segment should remain at the "yellow" status, or be moved to the "orange" status, and begin actions associated with that stage. The outcome of these actions is summarized and communicated with NGRR.

Conclusion and recommendations

The Rainy River TMA is located on thick, high plasticity, soft clay foundation soils that make construction and monitoring challenging. To keep the buttresses a reasonable size (and not overdesign), the observational method is employed. This involves developing a plan based on the expected conditions, having action plans developed if unfavorable conditions arise, and implementing continuous monitoring to assess the actual behavior during construction.

To support the observational method approach, extensive instrumentation has been deployed at the site to measure displacements, porewater pressures, settlement, and any movements that have occurred. The significant effort taken by the mine to fully digitize and automate the data collection and distribution has reduced the time spent troubleshooting errors, allowing the EOR to spend more time analyzing and interpreting the data.

The TARPs system was developed strategically to capture the spirit of the observational method. The site employs "Flag" and "Trigger" threshold levels to indicate responses to instrumentation. Notably, in

2024, the initial threshold level was renamed "Flag" to properly reflect the response of any flag threshold levels that may occur.

Unusual behavior and movement are expected when foundations are founded on clays with an undrained shear strength of ~30 kPa. It is expected that "Flag" thresholds will occur throughout the year. For this particular site, it is important to set the initial threshold low enough that deviations from expectations can be observed prior to them progressing to a more significant problem, allowing time to properly assess and react.

Lessons are learned each year by the EOR. The instrumentation thresholds and expectations are revised annually, and these lessons are incorporated into the new thresholds. During the 2024 construction season, SRK has observed less "Flag" threshold responses as the site understanding was increased and adjusted after the 2023 season.

There can be a tendency in engineering to set thresholds high enough that they are only triggered in cases of serious concern, reducing the overall workload. However, if the observational method is truly being used, the thresholds should be set to alert the engineer when something outside of expectations occurs, so that further learnings of the foundation and subsequent fill can be assessed. Care must also be taken to ensure that false alarms are not set off frequently, as this can lead to complacency. Often (at this site), false alarms may be as simple as a temporary stockpile being located above a handful of piezometers.

Acknowledgements

The authors would like to acknowledge the continued support of New Gold Rainy River (NGRR) mine for the support in development of this paper. NGRR has been highly supportive in initiatives such as this paper, and previous papers (Etezad et al., 2019, 2022; Marcotte et al., 2023).The greater geotechnical committee benefits from their transparency and willingness to participate in more academic activities.

Compaction Sensitivity in Tailings Stack Infiltration Modeling: Unsaturated Properties Uncertainty Analysis

Letícia B. L. Garcia, Knight Piésold Consulting, Brazil
Marcos A. Lemos Júnior, Companhia Brasileira de Metalurgia e Mineração (CBMM), Brazil
Guilherme J. C. Gomes, Universidade Federal de Ouro Preto (UFOP), Brazil

Abstract

Filtered tailings stacks have become increasingly prevalent in the mining industry since the 1990s, particularly in regions with arid climates. However, the adoption of filtered tailings technology has expanded globally, regardless of climatic conditions, as mining operations seek to reduce water in tailings to improve safety. Nonetheless, the implementation of tailings stacks in high-rainfall areas contradicts conventional practices, as filtered tailings operations are typically associated with regions of low precipitation due to compaction challenges during rainy periods. This poses significant challenges for tailings stacking in high-rainfall conditions, including their unsaturated characteristics and the absence of specific guidelines tailored to such environments.

Consequently, numerical modeling of infiltration under the principles of Unsaturated Soil Mechanics offers a promising approach to optimize recharge calculations, enabling more precise assessment of various factors such as moisture content, compaction, and drain sizing for these stacks. While optimized values are expected through modeling, inherent uncertainties exist in calibrating soil water retention curves (SWCC) and permeability functions, which involve Van Genuchten parameters, thereby affecting both parameter definition and model results. This study utilized tailings properties from a Brazilian mine, along with site climatic data, and employed a Bayesian approach to address calibration uncertainties. A hypothetical two-dimensional (2D) section of a test pad was considered for the study, and a software that simulates the movement of water and solutes in variably saturated media, for obtaining infiltration rates by solving the Richards Equation, was employed. In addition to calibration uncertainties, the simulation assessed the compaction sensitivity (different void ratios) on the SWCC, revealing that both factors influenced infiltration rates and pressure head fluctuations. These findings underscore the critical importance of proper compaction control and suitable drainage system design.

Introduction

The mining industry is a cornerstone of many economies, significantly contributing to employment, income generation, and the supply of raw materials to various industrial sectors. Understanding the entire mining production process is crucial to ensure the adoption of the best technologies and operational practices for more sustainable mining. As part of this effort, companies are continuously seeking innovative solutions to improve their ore treatment processes, enhance recovery rates, and extract minerals that were previously regarded as waste.

Waste and tailings management is a vital aspect of mining operations, and extensive research is being conducted to find better uses for these materials. However, these applications are often limited by the physical and chemical properties of the materials and the high costs associated with their logistical deployment. Given the technical and economic limitations of repurposing a large portion of mining tailings, it becomes imperative to dispose of these materials in geotechnical structures such as dams and stacks. Traditionally, tailings dams have been the preferred method in high-rainfall regions due to established engineering practices, regional topography, and climate conditions. However, recent changes in legislation and licensing processes, particularly after several catastrophic tailings dam failures in Brazil, have led to a growing interest in alternative methods, such as tailings filtration and stack disposal.

In some mining operations, filtered tailings stacks have gained prominence due to their potential for safer and more efficient waste management. As mentioned by Davies (2011), the installation of tailings stacks has grown significantly since the 1990s, particularly in countries such as Australia, Zambia, Chile, Mexico, and the United States (Ulrich and Coffin, 2013). However, areas with substantial annual rainfall require careful evaluation of this method. Considering operational criteria during the rainy season is essential, and understanding how these stacks behave given the variability in geotechnical parameters influenced by the moisture content of the filtered tailings from industrial processes is crucial. According to Patterson et al. (2016), the success of filtered tailings stacks depends on site conditions, operation scale, and the geotechnical and geochemical properties of the tailings.

Therefore, the implementation of tailings stacks in high-rainfall areas poses significant challenges, including their unsaturated characteristics and the absence of specific guidelines tailored to such environments. Key factors influencing this scenario include: (i) the moisture content of dewatered tailings, influenced by processing plants and precipitation; (ii) high infiltration and transient anisotropic seepage associated with precipitation, compaction, and tailings properties; and (iii) evaporation rate. Moreover, the constant need for tailings disposal exacerbates operational difficulties in compaction during rainy seasons.

Consequently, numerical modeling of infiltration under the principles of unsaturated soil mechanics offers a promising approach to optimize recharge calculations (Watson et al., 1995), enabling more precise assessment of various factors such as moisture content and drain sizing for these stacks. While optimized

values are expected through modeling, inherent uncertainties exist in calibrating soil water retention curves (SWCC) and permeability functions, which involve van Genuchten (1980) parameters, thereby affecting both parameter definitions and model results.

This paper proposes to address calibration uncertainties using a Bayesian approach and discuss their implications for the results of numerical infiltration modeling in tailings stacks based on sensitivity analyses of the compaction void ratio. Tailings properties from a mine in a high-rainfall area in Brazil were used as a case study, along with site climatic data. A fictional 2D section of a test pad was considered for the study, and a software that simulates the two-dimensional movement of water and solutes in variably saturated media, for obtaining infiltration rates by solving the Richards Equation (1931), was employed.

Methodology

This research focuses on a hypothetical filtered tailings stack located in a high-rainfall region. Data for the tailings were obtained from a mining company. Although tailings stacks are typically raised progressively, this study considers a three months long simulation in a test pad with a single raise.

While classical soil mechanics assumes that saturated pores between soil grains are completely filled with liquid below the water table and with gas above it – simplistically filled with water or air, respectively – unsaturated soil mechanics studies the simultaneous presence of water and air in different proportions between soil grains. Thus, a soil can present three distinct zones of saturation above the water table: the capillary zone, the two-phase zone, and the dry zone (Fredlund, 2017). The potential variation in the degree of saturation in the "two-phase" zone highlights the need to define the properties of unsaturated soil through functions.

The determination of the soil-water characteristic curve (SWCC) is the fundamental distinction between the behavior of saturated and unsaturated soils (Morgenstern, 2012). The SWCC is a curve that represents the nonlinear relationship between moisture content and pressure head in a given soil under a specific compaction state. In laboratory settings, the SWCC is obtained by measuring the soil suction at different moisture contents. A mathematical fit is then used to calibrate the curve. The following van Genuchten (1980) equation is one of the most widely used models for the SWCC (Gitirana et al., 2023) and it was adopted for the current study calibration.

$$\theta_w(\psi) = \theta_r + (\theta_s - \theta_r)\frac{(1 + (\alpha \cdot \psi)^n)^{\frac{1}{n}}}{1 + (\alpha \cdot \psi)^n}$$

Where: θ_w is the volumetric moisture content; θ_r is the residual volumetric moisture content; θ_s is the saturated volumetric moisture content; ψ is pressure head; α is the air-entry value; and n is a fitting parameter of the model that determines the curve inclination.

The van Genuchten parameters are calibrated using a Bayesian approach via the Markov Chain Monte Carlo (MCMC) method with the DREAM algorithm (Gomes et al., 2017). Calibration involves data collection through hanging column tests on different void ratio compactions. The MCMC calibration is implemented in MATLAB, involving the generation of one hundred combinations of possible van Genuchten parameters for each one of the three void ratio specimens that will be analyzed. With the volumetric moisture content function, the hydraulic conductivity function can be obtained as per the following equation (van Genuchten, 1980).

$$K(\theta) = K_s \cdot S_e(\psi)^L \left\{1 - \left[1 - S_e(\psi)^{\frac{1}{m}}\right]^m\right\}^2$$

Where: K_s is saturated hydraulic conductivity; S_e is effective saturation; ψ is pressure head; m is 1 – 1/n; and L is a pore-connectivity parameter (commonly equal to 0.5).

In possession of the parameters input, the flow can be simulated with Richards Equation (1931). Based on Darcy's Law (1856), Buckingham (1907) developed an equation for flow in unsaturated porous media, also known as the Darcy-Buckingham Equation, which relates hydraulic conductivity, suction, and moisture content. Later, Richards (1931) developed a differential equation that describes water movement in unsaturated soil using the Darcy-Buckingham Equation and Bernoulli's Equation. Due to its complexity, the Richards Equation (1931), presented below, is typically solved through numerical modeling.

$$\frac{\delta\theta}{\delta t} = \frac{\delta}{\delta z}\left[K(\theta) \cdot \left(\frac{\delta\psi}{\delta z} + 1\right)\right]$$

Where: θ is the volumetric soil moisture content (m/m); t is time (s); z is gravitational potential (m); ψ is pressure head (m); and K(θ) is the hydraulic conductivity (m/s) function based on soil moisture content.

The numerical modeling of infiltration presented here is conducted using Hydrus-2D software (Šimůnek et al., 2008), which simulates the bidimensional movement of water and solutes in variably saturated media by solving the Richards Equation. Input data for the model include the one hundred sets of van Genuchten parameters derived from soil-water retention curves (SWCC) calibration for each void ratio compaction, saturated hydraulic conductivity, relevant meteorological data, and the physical dimensions of the tailings stack.

The sets of one hundred infiltration results from these simulations are analyzed to assess the impact of parameter uncertainty arising from the calibration of the non-linear SWCC. This analysis involves comparing infiltration rates, moisture contents, and pressure heads while evaluating the variability introduced by the different combinations of possible van Genuchten parameters for each one of the three void ratio specimens that are being analyzed. Average values and 95% confidence intervals were calculated

for each set of one hundred simulations, facilitating meaningful comparisons of the impact of different void ratios. A 95% confidence interval is widely used in statistical analysis because it offers a balance between precision and reliability. This interval means that if many samples were taken and an interval estimate were built from each, 95% of these intervals would contain the true population parameter. A 95% confidence level is considered a standard in many fields because it provides reasonable certainty without excessively wide intervals, which can occur with higher confidence levels (Moore et al., 2017). This comprehensive methodology aims to account for inherent uncertainties in soil properties in infiltration modeling, providing optimized results for recharge calculations within the framework of unsaturated soil mechanics.

Data and discussion

Tailings characterization

The tailings investigated in this study are produced from niobium beneficiation, resulting from a flotation process. The particle size distribution testing, provided by the mining company, indicates that the tailings are primarily sand (~60%), with the remainder consisting of fines that pass through a No. 200 sieve. According to the Unified Soil Classification System (USCS), the authors classified the material as silty sand (SM), as the Atterberg limits testing indicates that the material exhibits non-plastic behavior. The selected sample for this study yielded a specific gravity of 4.44 g/cm³. Flexible wall permeability tests were conducted, according to ASTM D 5084, on the tailings sample at various stress levels and void ratios, and the results are presented in Table 1.

Table 1: Saturated hydraulic conductivity test results

Confining stress (kPa)	Void ratio (e)	K_{20} (cm/s)
400	0.89	9.15E-05
800	0.88	6.42E-05
100	0.73	1.91E-04
400	0.73	8.61E-05
800	0.73	5.33E-05
	Average:	1.22E-04

As a simplification of the treated uncertainties, and considering the available data and significant variability often encountered in hydraulic conductivity values, a saturated permeability input of 10^{-4} cm/s was uniformly defined for all simulations. Therefore, calibration of different hydraulic conductivity functions was not performed and the uncertainty was evaluated based on the SWCC parameters (θ_r, θ_s, α and n).

Parameters calibration

Three specimens from the same filtered tailings sample were compacted to achieve saturated void ratios (e) of 0.85, 0.71, and 0.69. The hanging column test, specified by ASTM D6836, was conducted for each specimen, and the results are presented as data in the SWCC calibration shown in Figure 1.

Since volumetric moisture content is the volume of water divided by the total volume, in a saturated condition, the volume of water is equivalent to the volume of voids. Therefore, since soil porosity is defined as the volume of voids divided by the total volume, θ_s is equivalent to the porosity of saturated soil. In this context, truncating saturated moisture content could be considered for the calibration presented here, given that porosity is determined by a straightforward indexing formula using void ratio as input. However, the curves showed the best fit when no truncation was applied to the SWCC parameters, as shown in the calibration results presented in Figure 1. Therefore, from the obtained uncertainty limits, one hundred sets of parameters (θ_r, θ_s, α and n) were generated to perform 100 simulations for each analyzed void ratio.

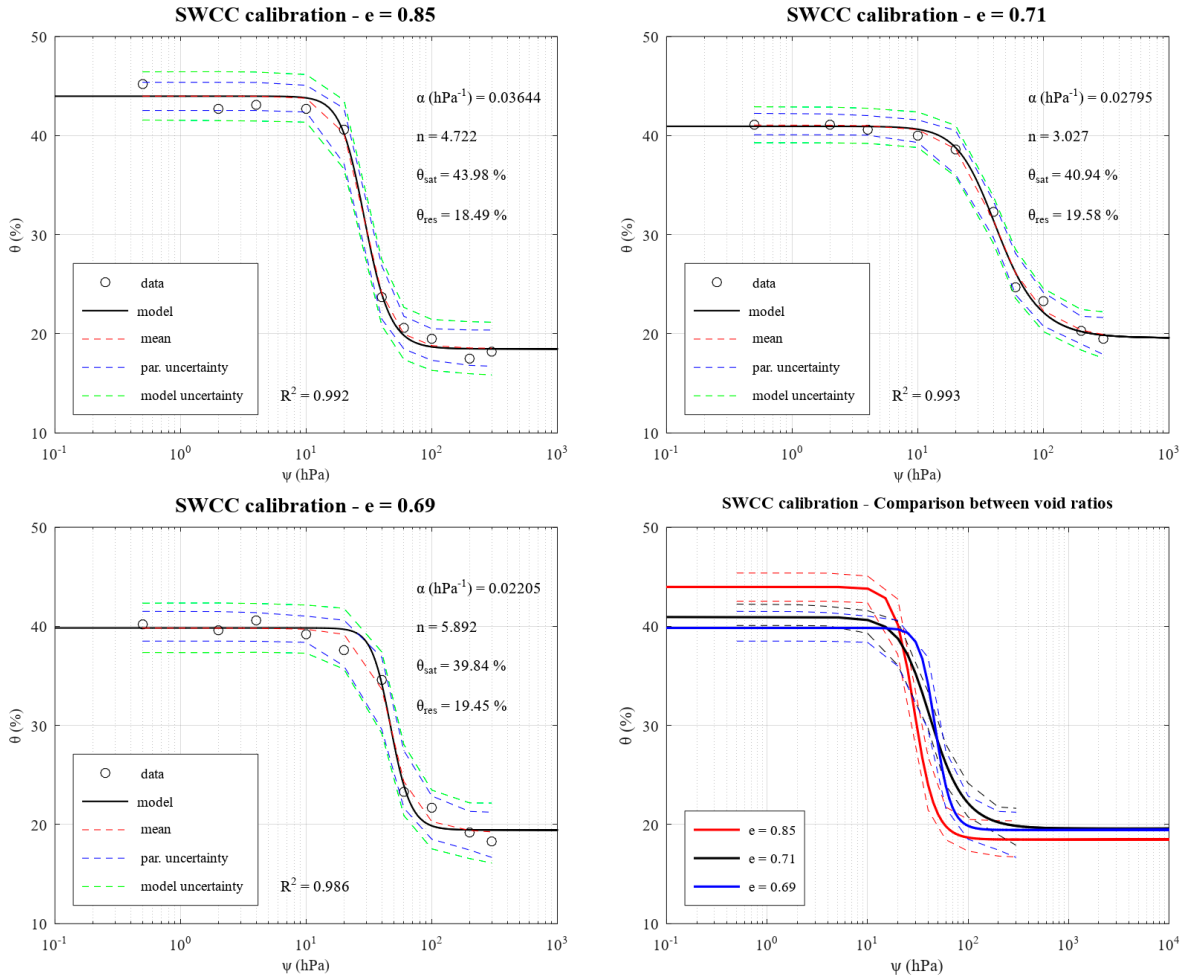

Figure 1: Calibration of van Genuchten parameters

As can be observed from the calibration results, in which each curve corresponds to a specimen with a specific void ratio, there is a noticeable relationship between the decrease in void ratio and the reduction in saturated volumetric moisture content. This relationship is attributed to the correlation between void ratio and porosity, which, as mentioned, corresponds to θ_s. Furthermore, the decrease in the parameter α when there is a decrease in void ratio can be explained by its role as the air-entry value. In saturated conditions, a smaller volume of voids hinders air entry, thereby influencing the observed decrease in α. However, the obtained parameter n does not clearly exhibit a direct relationship with void ratio. Since this parameter represents the curve's inclination, it suggests that, from an unsaturated perspective, moisture content may not necessarily increase with larger void ratios as typically observed in saturated conditions, indicating that it depends on the suction conditions at the time.

Hypothetical filtered stack and climatic conditions

The hypothetical filtered stack section shown in Figure 2 was developed to support the current study. The boundary conditions include an atmospheric boundary, where rainfall and evaporation are applied, and a seepage face at the stack bottom, indicating the location for drain installation. Observation nodes were placed at the bottom, top, and middle of the stacks. These nodes are specific points in the mesh marked to evaluate variations in moisture content and pressure head. To simulate the compaction process, an optimum moisture content of 33% was selected and used as the initial condition for all simulations.

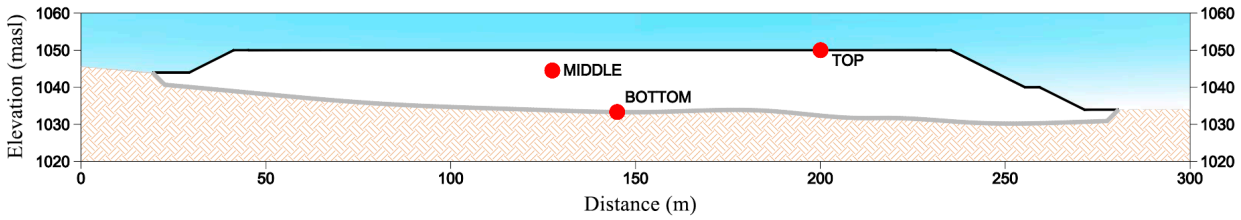

Figure 2: Hypothetical filtered stack

The climatic conditions used as input data included rainfall and evaporation, sourced from a specific location in Triângulo Mineiro (the Minas Triangle), Minas Gerais, Brazil. Evaporation was standardized to a daily value of 3.7 mm/day due to data availability. Actual daily rainfall data from the rainy season (January through March) of a particularly wet year (2013) in Minas Gerais were provided by the mining company's own weather station. This data was utilized in the simulations and is presented alongside the results in the following section.

Results

A total of 100 sets of parameters were simulated for each void ratio (0.85, 0.71, and 0.69). Some numerical

models did not converge and were excluded as outliers. The flux across the seepage face and the average head pressure at the seepage face were obtained for each simulation. From the results, the average and 95% confidence interval were calculated for each set of void ratio results, as presented in Figure 3.

The results indicate that uncertainties exert a greater influence on the bottom of the stack during the initial stages, immediately after the simulation begins, prior to saturation. Additionally, the differences in void ratio are evident from the beginning, as each calibrated SWCC exhibits unique behavior, leading to variability in the three sets of simulations before reaching saturation. The numerical model results align with the obtained SWCC, particularly highlighting the variability of the parameter n mentioned previously. This variability indicates that, depending on the head pressure, different void ratio inputs can result in significantly different moisture content. Notably, saturation at the base of the stack under high rainfall is anticipated by the model, emphasizing the need for a suitable drainage system installation. As the initial peak of flux diminishes when saturation is achieved at the bottom, the variability between the results of different void ratios and uncertainties limits also decreases, resulting in similar outcomes. This indicates that over time, after operational phases, the variability resulting from compaction and parameter uncertainties for infiltration levels becomes less significant.

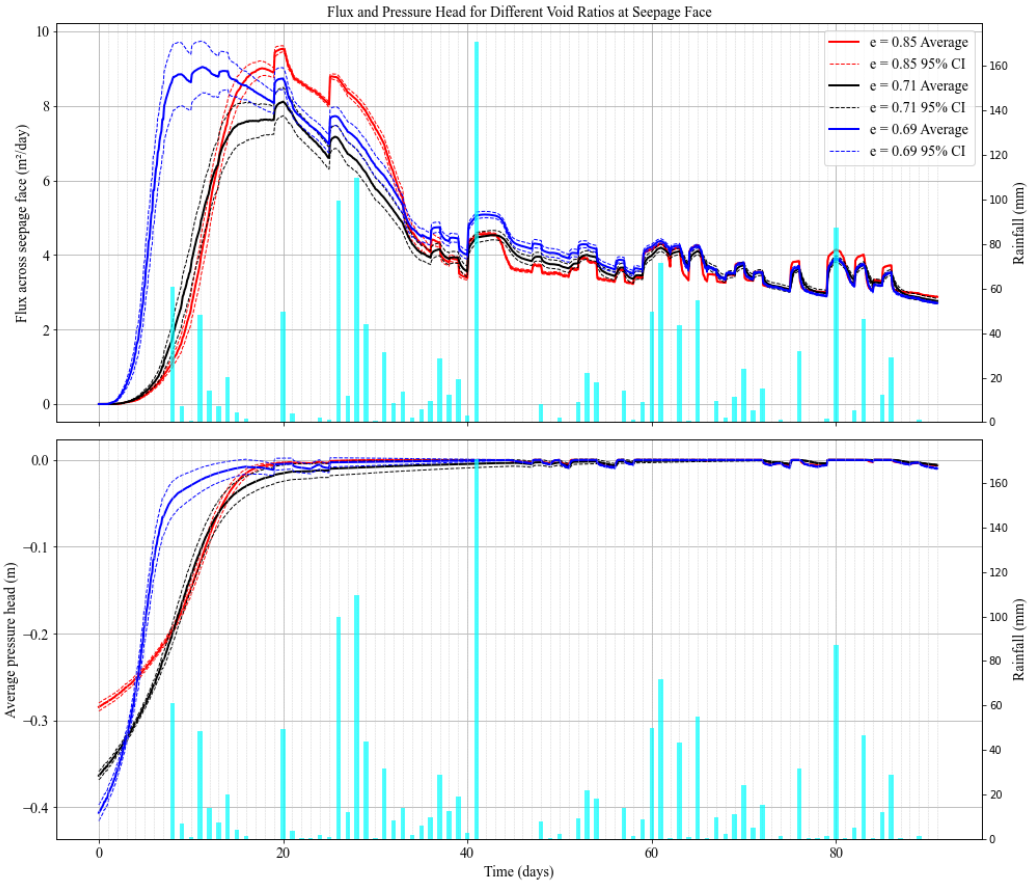

Figure 3: Seepage face results

The same data treatment applied to the results of the seepage face was also applied to the results of the observation nodes from each of the 100 simulation sets. Based on the results, presented in Figures 4, 5, and 6, it is noticeable that nodes at higher elevations are more significantly affected by climatic conditions than expected.

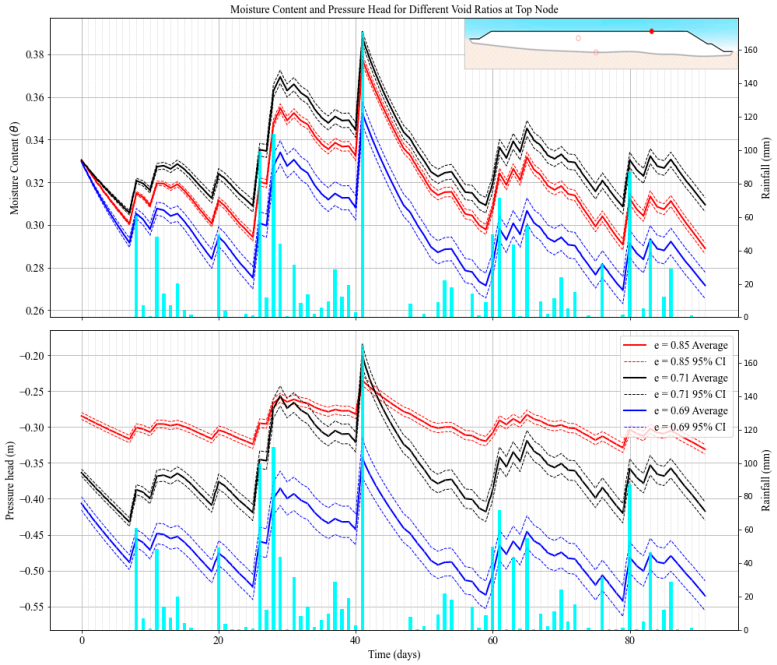

Figure 4: Top node results

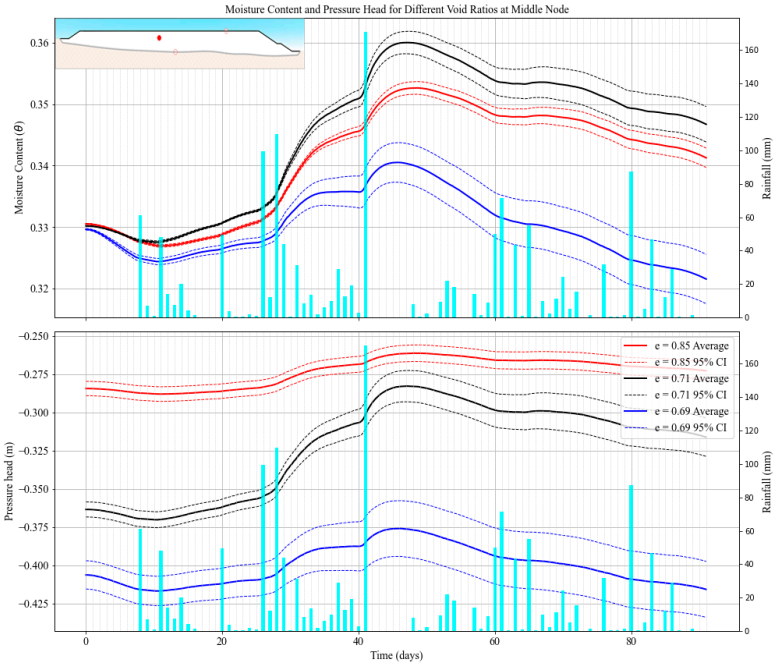

Figure 5: Middle node results

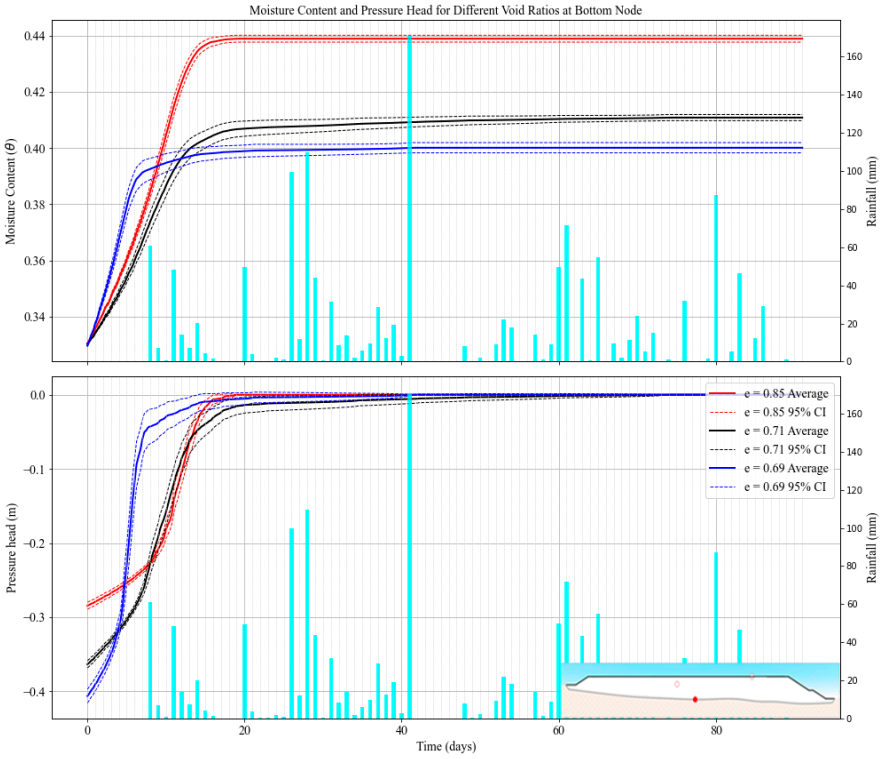

Figure 6: Bottom node results

The top node begins drying almost immediately, likely due to evaporation and drainage of the moisture used for compaction, and never reaches saturation, fluctuating with rainfall events. This lack of saturation results in greater variability influenced by both the initial void ratio and uncertainties from the calibration process, which are observable throughout the analyzed period.

The middle node exhibits an intermediate behavior, showing a delayed peak and smoother fluctuations with rainfall events. Like the top node, it also does not achieve saturation, presenting similar variability in behavior. Considering this variability and the possibility that a slip surface could pass through a similar middle area, it is important to further evaluate the potential impact of these uncertainties on Factor of Safety evaluations. As for the lower node, installed at the seepage face, its behavior closely resembles that of the seepage face, as anticipated, and it was monitored for validation purposes.

In this case study, due to the complexity of the simulation, it was assumed that a single lift would be constructed. However, in reality, the stack undergoes continuous raising during its operational phase. Therefore, the modeling highlights the critical importance of the operational phase, emphasizing the necessity for accurately sizing drainage with a suitable factor of safety and ensuring proper compaction control. This approach addresses both the inherent uncertainties in the model's design aspects and the variability encountered in field conditions, ensuring a more robust and reliable outcome.

Conclusion

In conclusion, this study emphasizes the significant challenges and complexities associated with implementing filtered tailings stacks in high-rainfall regions. The research employed advanced numerical modeling techniques underpinned by unsaturated soil mechanics principles to evaluate the infiltration behavior of tailings stacks, particularly focusing on the calibration of van Genuchten parameters using a Bayesian approach. The results underscored the significant influence of uncertainties in parameter calibration on infiltration rates and moisture content fluctuations during initial compaction stages. However, over time, these impacts diminished considerably. This comprehensive approach not only highlighted the variability introduced by different void ratios but also demonstrated the critical role of appropriate drainage design in managing saturation risks, particularly at the bottom of the stack during intense rainfall events.

Moving forward, further advancements in understanding the interactions between tailings properties, climatic conditions, and drainage systems will be essential for enhancing the reliability and efficiency of filtered tailings stacks in such challenging environments. This includes refining the impact of continuous raising on simulations and incorporating real-time data feedback mechanisms to improve predictive accuracy. Additionally, evaluating the impacts of uncertainties on stability analyses will be crucial. By addressing these complexities, future research can contribute to more sustainable mining practices that mitigate environmental risks and optimize operational outcomes in regions prone to high rainfall.

In summary, while the implementation of filtered tailings stacks in high-rainfall areas presents formidable engineering hurdles, integrating sophisticated modeling approaches and empirical data offers promising avenues for advancing the field of tailings management towards greater sustainability and resilience in diverse geographic contexts.

Stay and Fight, or Flee? Assessing the Risks of Intervention Leading up to a Catastrophic Failure

Justin Willis, BHP, Australia

Abstract

How much time exists between the signs of potential failure of a TSF, and full catastrophic release? Should the focus during this time be on remedial works to prevent the failure, or on ensuring the safety of workers and public? This paper assesses this decision by reviewing past failures where timelines of the events leading up to failure are available. The timelines are assessed for the signs of impending failure, providing an estimate of the time available between these signs and failure during which an evacuation or intervention response could be initiated. An estimate of the likelihood of a successful evacuation or intervention is provided based on this assessment.

This paper also looks at examples and practices in other settings and industries, where the choice between intervening to prevent a catastrophic failure versus the risk to workers' lives exists. Consideration is also made of the advice for managing fires, including residential/commercial and wildfires, where the guidance between staying and fighting and evacuating has evolved over time.

Introduction

According to the Good Practice Guide (ICMM, 2021), the key document for managing an emergency at a Tailings Storage Facility (TSF) is the Emergency Preparedness and Response Plan (EPRP). The goal of an EPRP is to prevent, or mitigate, or reduce impacts in the event of an emergency, and the Good Practice Guide notes the EPRP should describe procedures or actions to be taken to prevent an upset or unusual condition from becoming an emergency. These aims can be in conflict, as addressing upset and unusual conditions and preventing failure may involve actions and activities around the tailings storage facility (TSF) that can expose personnel to hazards or place them in the line of fire. It is possible that at some point a decision will need to be made to send personnel into an escalating situation to prevent failure or remove personnel to prevent loss of life, acknowledging that failure of the TSF may result, with this decision likely to be made based on the judgment of the management and technical staff at the site.

This paper seeks to support that decision by providing data on timeframes at TSFs and water dams that did result in failure and providing estimates on the likelihood of success of evacuation or intervention

to prevent failure. This paper can also be used to support assigning likelihood of a successful intervention to prevent failure used in risk assessments such as event fault trees or FMECA (Failure Mode Effects Criticality Assessment) (ANCOLD, 2022).

Method

Approach

This paper assesses how much time exists between the early signs of potential failure and when the failure occurs by reviewing available failure reports and records and noting the elapsed time between the signs of potential failure and when the failure occurred. This elapsed time is the period in which a decision can be made on intervention or evacuation. The failure timings have been grouped based on failure mode, and the different signs within those failure modes. The timings associated with each failure mode/observed signs were assessed to assign a likelihood of successful evacuation or intervention, considering examples of evacuations and intervention attempts sourced from the failure reports and available literature, along with reflections on the likely timeframes of evacuation and intervention.

Notes on the approach

This paper does not seek to comment on the decisions made in past failures, nor on whether a successful intervention could have prevented failure. This paper also does not seek to comment on the recognition or otherwise of the signs of failure noted in the reports, or the actions taken in response to those signs of failure. Upset conditions and emergencies are complex, high-pressure situations, and all assessment in this paper is made with the benefit of hindsight that the TSF did progress to failure.

Discerning whether the signs of an upset or unusual condition will lead to failure is difficult, and even more difficult is understanding the time frame available, or when the point of no return is reached. This paper does not indicate that failure should have been obvious from the signs adopted as the indicators of potential failure. TSFs and water dams often exhibit seepage, cracking, movement etc., and not all signs of this nature lead to failure; in fact, some level of cracking, movement, and seepage can expected. It is for this reason that signs recorded in the failure reports that could be considered normal behavior by TSFs and water dams have not been considered as a sign of potential failure.

Regulatory and industry guidance

Tailings Industry Guidance is largely silent on the choice between evacuating and intervening to prevent failure, with the tailings guidance from ANCOLD, CDA, ICMM, and ICOLD making no comments on the choice. For water dams, FEMA (Federal Emergency Management Agency) funded the development of a Dam Owner Emergency Intervention Toolbox (Gannett Flemming, 2016). This toolbox suggests

intervention to prevent or delay failure should be taken after notification to regulatory agencies, local authorities and emergency personnel, and only if working conditions are safe. Public safety should be the primary concern, followed by downstream property, with the dam itself being the lowest priority. The toolbox notes that the upset condition may have progressed too far to prevent failure, in which case the intervention could be to delay the breach and provide additional time for evacuation. A controlled breach may be the safest intervention in some situations.

Within Australia, the Commonwealth Work Health and Safety Regulations (2011) for major hazard facilities require procedures to be developed for the safe evacuation of and accounting for all people on site. It is expected that other jurisdictions will have similar requirements. Matters relating to the prevention of events are to be covered in the preparation of a Safety Case for the major hazard facility.

Dataset

Table 1 presents the TSF failures assessed, based on failures where a published failure report or paper providing details on the timing and circumstances of the failure was available.

Table 1: TSF failures assessed in this paper

TSF name	Date	Location	Failure type
El Cobre Old and New Dams	28 March 1965	Valparaiso, Chile	Seismic liquefaction
Middle Fork Dam 3	26 February 1972	West Virginia, USA	Liquefaction/overtopping
Mochikoshi Dikes 1 and 2	14 January 1978	Izu, Japan	Seismic liquefaction
Prestavel upper and lower basin	19 July 1985	Trentino-Alto Adige, Italy	Static liquefaction
Tapo Canyon	17 January 1994	California, USA	Seismic liquefaction
Merriespruit TSF	22 February 1994	Virginia, South Africa	Overtopping
Omai TSF	19 August 1995	Cuyuni-Mazaruni, Guyana	Internal erosion
Aznalcóllar	25 April 1998	Seville, Spain	Foundation failure
Baia Mare	30 January 2000	Maramures County, Romania	Overtopping
Baia Borsa	10 March 2000	Maramures County, Romania	Overtopping
Big Branch Refuse Impoundment	11 October 2000	Kentucky, USA	Internal erosion
Reservoir 10 Ajka Alum	4 October 2010	Veszprem County, Hungary	Foundation failure
Mount Polley TSF	4 August 2014	British Columbia, Canada	Foundation failure
Fundão Tailings Dam	5 November 2015	Minas Gerais, Brazil	Static liquefaction
Harmony Waste Pond	3 June 2016	Mississippi, USA	Foundation failure*
NTSF Cadia Operations	9 March 2018	NSW, Australia	Foundation failure
Dam 1 Córrego do Feijão	25 January 2019	Minas Gerais, Brazil	Static liquefaction

* Failure was due to excavation at the toe of the embankment

In addition to the TSF failures in Table 1, a select number of water dam failures were reviewed (Table 2), where a detailed record of the failure is available. These were chosen to include internal erosion and overtopping failure timings, as these are failure modes with a clear progression to failure without intervention.

Table 2: Water dam failures assessed in this paper

Dam name	Date	Location	Failure type
Baldwin Hills	14 December 1963	California, USA	Internal erosion
Teton	5 June 1976	Idaho, USA	Internal erosion
Big Bay	12 March 2004	Mississippi, USA	Internal erosion
Taum Sauk	14 December 2005	Missouri USA	Overtopping
Edenville	19 May 2020	Michigan USA	Liquefaction/Overtopping

Indications of potential failure

The signs of potential failure listed below were used to identify the timing to failure. These were chosen based on a typical operator accepting these as unusual or upset conditions or an escalating situation, or events that may trigger a response as part of a trigger action response plan (TARP).

- Fresh seepage that developed rapidly, or rapid increases in seepage.
- Cloudy or discolored seepage, or seepage carrying sediment.
- Rapid saturation of the embankment or toe.
- Initial overtopping of embankment (wave action or other).
- Large or intense rain event.
- Inflow into the TSF/Dam greater than the spillway capacity.
- Earthquake.

The timing has been taken as the moment of observation or recording of the metric, as this is when the opportunity for intervention would have commenced. For a number of TSFs the failure was unexpected, and there is little or no detail on the signs of potential failure. In these instances, the timing is based on the last inspection or observation of the TSF where conditions were noted as normal.

The indication of potential failure does not consider any underlying assessment of TSF or water dam integrity, including out of target factors of safety, inadequate design, inadequate characterization or investigation, excessive pond size or inadequate spillway capacity. This paper is not commenting on the conditions that led up to the failure, rather it is focused on signs that indicated an upset or escalating situation.

Intervention

Successful intervention

The datasets in Tables 1 and 2 only include TSFs that have progressed to failure, and as such only represent a portion of the TSFs and water dams that have experienced signs of potential failure. Examples where the signs of potential failure were recognized and the response successfully avoided failure, or where conditions changed such that the TSF did not progress to failure (e.g. overtopping that ultimately did not lead to failure as the rainfall ceased), are largely absent from the public record.

Only one paper could be located that contained detail on an intervention that was believed to have prevented a larger failure; this was for a platinum TSF in the (then) Transvaal Province of South Africa (Fourie and McPhail, 1993). In this instance the TSF embankment failed but did not result in a loss of containment, and a dewatering program using vertical wells stabilized the TSF sufficiently that it was able to be used until a new TSF was constructed. The exact timing of the dewatering program was not specified, however it was inferred to be 6 months to a year, and the TSF was operated during this time with additional controls in place.

According to the Samarco failure report, on 27 August 2014 extensive cracking at the crest and toe of the left setback was observed, accompanied by saturation at the setback toe (Morgenstern et al, 2016). An equilibrium berm was constructed at the toe within two weeks of the cracks being observed. This appears to be a second example of a successful intervention to prevent failure.

It is difficult to judge if an intervention prevented a failure, as even in cases where a clear failure progression could be expected, there are often too many variables (rainfall, uncertainties in material properties and geometry, uncertainties in phreatic condition, etc.) to say with confidence a catastrophe was averted. None the less, it is considered highly likely that there have been multiple occasions where early signs of potential failure were noted, and intervention successfully prevented a catastrophic failure. The lack of examples in the literature is attributed to a reluctance to share details of potential failures for fear of how this would be perceived by stakeholders.

Unsuccessful intervention

During the development of the internal erosion failure at Teton Dam, two bulldozers were dispatched to push material into the downstream expression of the erosion pipe (Wallace et al., 1976). Both bulldozers were lost in the rapidly growing outflow, with the operators abandoning their machines and escaping on foot (Johnson and Flynn, 1977). An attempt was also made to place large material into the upstream inflow of the developing erosion pipe; however, this was also unsuccessful. No machines were lost in the attempt to block the upstream expression of the pipe.

The Baldwin Hills failure report details an unsuccessful intervention to prevent failure (Jansen et al, 1964). When the upstream expression of the erosion pipe was observed it was small in size and onsite personnel believed that placing sandbags into the hole would slow or block the flow. A worker was lowered by rope above the hole, and sandbags were placed. This was quickly realized to be futile and abandoned, as the hole was significantly larger than first believed.

At Middle Fork Dam 3, a plan was developed to install additional spill capacity at the TSF as the water level rose. Surplus pipe was available nearby and bulldozers were being mobilized, however the TSF failed before the additional capacity could be installed.

While not resulting in a failure, an intervention was attempted at Oroville Dam, USA in 2017. Water overtopping the emergency spillway rapidly eroded the hillside, threatening the integrity of the spillway (France et al, 2018). Helicopters were mobilized and dropped bags of rock into the erosion gullies to reduce the rate of erosion (Associated Press, 2017). An evacuation order was issued concurrently and remained in place until the water level reduced and the threat to embankment stability had passed.

Increased fatalities from attempted intervention

Notably none of the failures assessed (TSF or water) included fatalities of workers sent into the line of fire in an attempt to prevent the failure. This extends to less well documented failures not included in Tables 1 or 2, as while there are a number of failures where workers have lost their lives, none have been identified where the loss of life was directly attributable to an attempt to prevent the failure.

Response timing

Evacuation

The time for successful evacuation can vary greatly depending on factors such as the size and geographical distribution of the population at risk, the means of notifying the population at risk, and the maturity of the evacuation procedures. Minesite personnel may be able to be evacuated in under an hour, while larger public populations may take several hours or longer. The reduction in population at risk during an evacuation is typically progressive, so even a brief warning time may save lives.

Within the assessed dataset there are several examples of public evacuation. A formal evacuation order was requested approximately two hours before the Baldwin Hills failure (Jansen et al., 1964), with approximately 1,600 people evacuated before the failure occurred (Barnes, 1992). At Teton Dam, the evacuation order was placed approximately 1½ hours before the dam failed (Johnson and Flynn, 1977). As the Cadia TSF failure developed, a decision was made to evacuate workers in the vicinity of the TSF two to three hours ahead of the failure.

Intervention

The time required to successfully intervene and prevent a failure is equally highly variable. Once an upset or deteriorating situation has been escalated within the chain of command, there are a further number of steps that would likely occur before a decision to intervene is made. These include understanding the current status of the TSF and how the situation is evolving, understanding the failure mode, and designing a suitable response. Responses may be described in the EPRP, along with details on resources and equipment, which may reduce the time required to intervene. Not all interventions may be technically feasible, and instead may exacerbate an escalating situation, such as involving additional loading.

Typical interventions are a reaction weight buttress, additional spill capacity, additional embankment height, or a reverse filter. These are difficult without placing personnel in danger, even if remote equipment is used. If the intervention requires placing personnel in the line of fire, additional approvals and controls may be required. While some of these activities may be completed concurrently, the estimated timeframe from escalation of the situation to implementation of the remedial measures is likely days, and based on the two examples of intervention in the assessed dataset that may have prevented failure, may take weeks .

Results

Failure timings

Tables 3 and 4 present the timings to failure for TSFs, separated based on whether there were recorded signs of upset conditions or an escalating situation noted ahead of the failure. Table 5 presents the failure timings for the water dams assessed.

Table 3: TSF failure timings based on observed signs

TSF name	Sign of potential failure	Time to failure from sign
El Cobre Old and New dams	Earthquake	< 90 seconds
Middle Fork Dam 3	Flow into TSF greater than spill capacity	40 hours
	Cracks on embankment, saturation of embankment	2–9 hours*
Mochikoshi Dike 1	Earthquake	≈10 seconds
Mochikoshi Dike 2	Earthquake	24.5 hours
	Cracking on TSF (following earthquake and aftershocks)	4.5 hours
Tapo Canyon	Earthquake	≈ 10 in es
Merriespruit TSF	Water overtopping embankment	2 hours
Reservoir 10 Ajka Alum	Large volume of flow through cracks in embankment	≈ 1 in es
Fundão Tailings Dam	Dirty water discharge from drains	≈ in es
Cadia TSF	Extensive developing cracking	9–11 hours**

* Conflicting eyewitness accounts

** Exact moment of failure not observed

Table 4: TSF Failure timings where signs were not observed ahead of failure

TSF name	Timing point	Time to failure from timing point
Prestavel upper and lower basin	Movement recorded on seismograph	< 1 minute
Omai TSF	No sign of failure at last inspection of TSF (southern end)	< 9 hours
	No sign of failure at last inspection of TSF (northern end)	< 10 hours
Aznalcóllar	No sign of failure at last inspection of TSF	< 12 hours
Baia Mare	Rapid increase in temperature leading to snowmelt	< 72 hours
	40 mm of rain	< 24 hours
Baia Borsa	Extreme rainfall and failure of pumping system	< 60 hours
Big Branch Refuse Impoundment	No sign of failure at last inspection of area	< 15 minutes
Mount Polley	No sign of failure at last inspection of TSF	< 1.5 hours
Harmony Waste Pond	Excavation at toe of embankment	< 1 minute
Dam 1 Córrego do Feijão	No sign of failure visible in video	< 1 minute

Table 5: Timing of water dam failures

Dam name	Sign of potential failure	Time to failure from sign
Baldwin Hills	Large seepage through underdrains	4.5 hrs
	Rapidly developing seep on embankment	2.5 hrs
Teton	Large seepages at embankment toe	19 hours
	Rapidly developing seep on embankment	2.5 hrs
Big Bay	Muddy seepage from drainpipe	21 hours
Taum Sauk	Overtopping of embankment	≈ 0 minutes*
Edenville Dam	Flow into reservoir greater than spillway capacity	26 hrs
	Slump and depression in embankment	≈ 0 minutes

* Failure sign was not observed, and back calculated from pumping data

Failure modes

Table 6 presents the failure timings grouped based on failure mode and for both TSF and water failures.

Table 6: Timings based on failures modes

Failure mode	Observed sign	Min. time to failure	Max. time to failure
Foundation failure	–	< 1 minute	9-12 hours
Static liquefaction	–	<1 minute	30 mins
Overtopping	Large inflows commenced	26 hours	72 hours
	Flow over embankment commenced	30 minutes	2 hours
Internal Erosion	Unusual seepage observed	4.5 hours	21 hours
	Pipe observed	2.5 hours	2.5 hours
Seismic Liquefaction	–	10 secs	24.5 hours

Likelihood of successful response

Table 7 presents the estimated likelihood of a successful response for each of the failure modes, based on the timings in Table 6 and the considerations for evacuation and intervention discussed previously.

Table 7: Estimated likelihood of successful response based on failure mode

Failure mode	Observed sign	Successful Evacuation	Successful Intervention
Foundation failure	–	Possible	Unlikely
Static liquefaction	–	Unlikely	Highly unlikely
Overtopping	Large inflows commenced	Likely	Possible
	Flow over embankment commenced	Possible	Highly unlikely
Internal Erosion	Unusual seepage observed	Likely	Unlikely
	Pipe observed	Likely	Highly unlikely
Seismic Liquefaction	-	Unlikely	Highly unlikely

Examples from other industries and situations

TSFs and water dams are not the only instances where a failure could have serious consequences, and a decision between intervention to prevent failure and evacuation to prevent loss of life may be required. Landslides and pit slopes share a common reliance on geotechnics and hydrogeology with their associated uncertainties and can be materially affected by rainfall. However, for these situations, once the signs of an unusual or escalating situation are observed, the options to prevent failure are limited and evacuation is the preferred action, such as at Bingham Canyon Mine (FEMA, 2018; Pankow et al., 2014).

Major hazard facilities such as oil refineries, oil rigs and nuclear facilities also face serious consequences in the event of a failure, leading to a conflict between preventing an escalating situation from developing into failure and ensuring the safety of the personnel. A search of available literature revealed

no information on incidents where failure had been averted, while major failures such as the 2005 explosion at BP's Texas City refinery happened without warning (CSB, 2007). The Piper Alpha disaster in 1988 warrants mentions, as after the initial explosion the remaining workers moved to the accommodation area furthest from the fire and waited for instructions that never came. It is believed that lives could have been saved with an attempt to evacuate (Human Factors 101, 2024).

The guidance for fires in public buildings is based on prioritizing evacuation to minimize the potential for fire-related injuries (OSHA, 2024). While there are a variety of sources of guidance around fires with slight differences, a broad consensus can be summarized as raise the alarm/evacuate before attempting to fight the fire (MFS, 2024; Fire and Rescue NSW, 2024; Weekly Safety, 2024). Once the evacuation is underway or complete, the guidance recommends fighting the fire if the type of fire is understood and can be tackled with confidence, including having the correct fire extinguisher, making sure the atmosphere is safe, gauging the size and how quickly the fire is spreading, and ensuring you have a safe evacuation route.

Of interest is the evolution of messaging relating to fighting wildfires. In 2006 the AFAC (Australasian Fire and Emergency Services Authorities Council) position was people should either stay and defend their property or leave early (AFAC, 2006). Following the 2009 "Black Saturday" fires in Victoria, Australia, when 173 people lost their lives, the position was revised with more weight given to leaving early (McLennan et al., 2014). The current position is that leaving early is always the safest action and may be the only safe option when wildfires are burning on days when weather conditions are extreme, or the topography or fuel load may create intense fire behavior (AFAC, 2019). The Camp fire (2018) and Lahaina fire (2023) tragedies in USA and the Valparaiso fire (2024) in Chile all resulted in mass fatalities, in part attributed to a failure to evacuate early (Koop, 2024; Zebratski, 2023).

Discussion

All the failures assessed had a relatively short duration of elapsed time between the signs noted or last observed stable condition, with 43% of failures occurring in under an hour, 35% between 1 hour and 1 day, and 22% greater than a day. This is a rapid progression from signs of an escalating situation to failure, with little opportunity for intervention and requiring a quick evacuation response to prevent or reduce loss of life. This dataset is comprised of TSFs and water dams that did ultimately progress to failure, and if that progression had not been as rapid it is likely that a successful intervention would have been made that might have prevented failure. It is likely there are examples where similar signs were recorded and catastrophic failure did not result, either without intervention, or as a result of intervention. This leads to the inference that if the TSF is progressing to failure, this progression can be expected to occur quickly, and if conditions stabilize after a period of time, then failure is less likely.

The lack of an example in the dataset of a failure that has resulted in the fatalities of workers attempting an intervention does not necessarily mean that this will not occur in the future. Considering the bushfire example, it may simply be that the combination of conditions has not been encountered yet and such a circumstance may be encountered in the future.

Evacuation and intervention do not need to be mutually exclusive, and as per the intervention toolbox for water dams it is possible to pursue an evacuation of non-essential workers and public while concurrently attempting to delay or prevent the failure. This is similar to the guidance for fires in buildings, ensuring the alarm is raised and evacuation has commenced before tackling the fire.

Conclusion

A review of the timings associated with past TSF and water dam failures indicates that a rapid progression to failure is possible. This makes evacuation possible in such scenarios, but makes intervention less likely to be successful. This information can be assessed with professional judgment, considering the circumstances when deciding whether to intervene in the situation or keep personnel out of the line of fire. Considering the guidance provided for water dams and fighting fires, the most prudent approach is likely to be prioritizing evacuation, and considering intervention once the evacuation is underway or substantially complete.

Bayesian Networks Application and Analysis of Failure Mechanism and Triggers in Tailings Dams: A Case Study

Keith Mandisodza, The University of Queensland, Australia
David J. Williams, The University of Queensland, Australia
Chenming Zhang, The University of Queensland, Australia

Abstract

Learning from past dam failures can help us to understand failure mechanisms, which can be instrumental in future tailings storage facility designs or improvement of existing operational and management processes through a better understanding of input parameters, failure triggers and contributing factors, and inherent uncertainties. Historically, when tailings dam failures occur, concerted efforts, time, and resources are channeled into understanding the failure mechanisms and triggers, sometimes more than what is input during initial geotechnical site investigations for designing and constructing a tailings storage facility. Such efforts aim to deduce failure mechanisms and triggers through forensic investigations conducted through expert panel reviews. Industry experts exhaustively analyze the system's and sub-system's events and decisions that potentially lead to failure. The failure event sequence analysis is often qualitatively or quantitively conducted through static logic methods such as event tree analysis (ETA) and fault tree analysis (FTA), or other less frequently used techniques such as fuzzy analysis or artificial intelligence neural networks (ANN), which have limitations in dynamic risk evaluations. Tailings dams are complex and dynamic systems that go through phases from design, construction, operation and transitions to closure and post-closure into perpetuity. The inherent system complexities in tailings dams depend on system variables, which can be exposed when the weakest variable link leads to failure. In this paper, we:

- Discuss some of the significant past tailings dam failures.
- Introduce Bayesian networks (BNs).
- Show how BNs can be applied to review the failure mechanism as reported in past expert panel reports by reproducing and analyzing the applied FTA and conversion to BNs.
- Show how this information can be used to examine variables that influence tailings dam failures comprehensively.
- Determine variable dependencies.

- Formulate a model for risk assessment.
- Conduct inference updating of the prior probability of events on obtaining new information under uncertainty, and application as an accident or predictive analysis for system processes.

Introduction

Mineral recovery improvement, commodity demands, and technological advances enable the processing of low-grade orebodies as they become economically lucrative, generating more waste processing and storage requirements. The demands of the global economic and energy transition are the main drivers for the market (Cacciuttolo and Atencio, 2022; Kossoff et al., 2014). Most of this mine waste is stored in tailings dams whose construction and depositional processes are a function of geographical location, topography, climatic conditions, seismicity, and jurisdictional and regulatory requirements, most of which are influenced by uncertainties. In addition to these uncertainties are the design, construction, and operational uncertainties that compound the complexities in the analysis of tailing dams (ICOLD, 1989; Klohn, 1972; McLeod et al., 2003; Ramon and Hinks, 2023). The result of such complexity, primarily from the applied conditional stability, a function of blended analyses for geotechnical, hydrology, hydraulics and seismic loading conditions, and associated uncertainties, are not considered explicitly in practice and hence the associated risk is not considered explicitly (Phoon et al., 2022; Phoon and Ching, 2018). This gap induces time-dependent structural issues in the embankment shell and the overall behavior and response of the contained tailings due to aging effects, causing significant failures.

Considering that the probability of failure and resulting consequences (i.e., estimates of loss of life or environmental damages) are used for risk quantification (Feinberg et al., 2016) as an empirical approach based on failure case histories, the differences in the case history's geographic location, topography, climate, and seismic conditions mean that the consequence approach might not suit other regions that do not have conditions similar to those in the applied case histories. However, since this approach is widely accepted in the dam design industry, it implies that the risk analysis and quantification for tailings dams might be compromised on these premises of the probability of the information used to determine the risk (Borovcnik, 2015).

Based on professional expertise and subjective judgements, expert panel reviews are undertaken when tailings failures occur (Jefferies et al., 2019; Morgenstern et al., 2014; Morgenstern et al., 2016; Robertson et al., 2019) to "exhaustively" analyze the system and sub-systems' events and decisions that might have caused the failure. The hierarchical and sequential causation of the failure is determined forensically and through qualitative and quantitative analyses, through static logic methods such as failure modes and effects analysis (FMEA), fault tree analysis (FTA), event tree analysis (ETA), bowtie risk analysis (BTA) and other methods such as fuzzy analysis (FA) and artificial intelligence neural networks (ANN), though less

applicable. Case history records for tailings dam failures indicate an increased failure rate in the last two decades, partly attributed to the abovementioned issues regarding improved processing methods due to technological advancement allowing for lesser grade ore to be processed. Hence, more waste is mined for ore recovery, as well as time-dependent storage growth and aging effects of tailings dam structures as more volume is mined and processed. Figure 1 shows recorded global tailings dam failures and some of the significant failures that have led to significant changes in the governance and management of tailings dams.

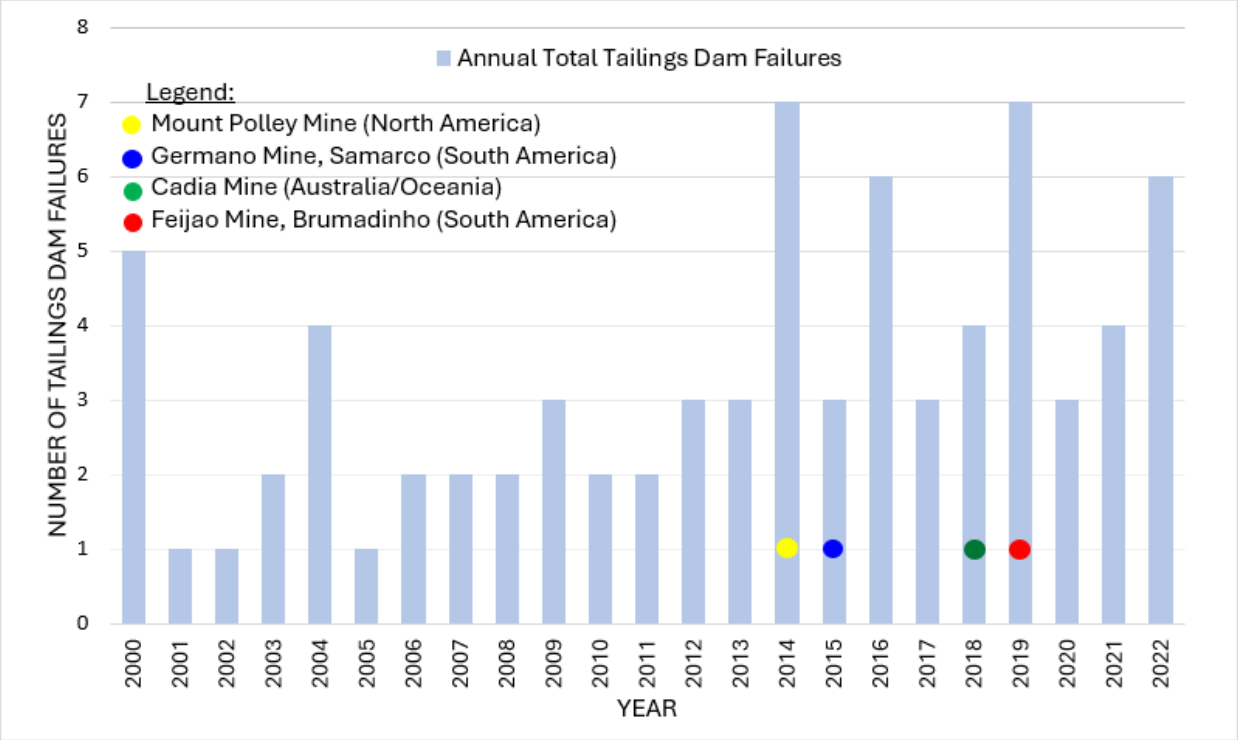

Figure 1: Tailings dam failures in the last two decades, with four significant failures that have contributed to significant governance changes in the tailings management

The static logic risk analysis methods mentioned above have limitations in analyzing the dynamic and complex nature of tailings dam failures and inherent dependencies of failure triggers. Hence, another paradigm is needed to analyze many continuous random variables without discretizing their probability. Bayesian networks (BNs) have slowly gained popularity in different industries through their capability to incorporate uncertainty analysis and conditional probabilities in the analysis models (Bobbio et al., 2001) and their ability to update model distributions following observations (inference modeling) and have been successfully applied in dam risk analysis (Delgado-Hernández et al., 2014). Risk analysis is characterized by natural variability, knowledge, and decision-model uncertainty (Baecher and Christian, 2005). These are characteristic of generic dam risk analysis and are more specific to tailings dams.

Literature review

Bayesian networks

BNs represent high-dimensional modeling using graph theory to model uncertainties and random variable dependencies. They are characterized by a directed acyclic graph (DAG) with conditional probability distributions, with nodes representing the random variable and the arcs the dependence relationship between nodes. Hence, they express a simplified representation of joint distributions and their dependencies (Hanea et al., 2015; Morales-Nápoles et al., 2013).

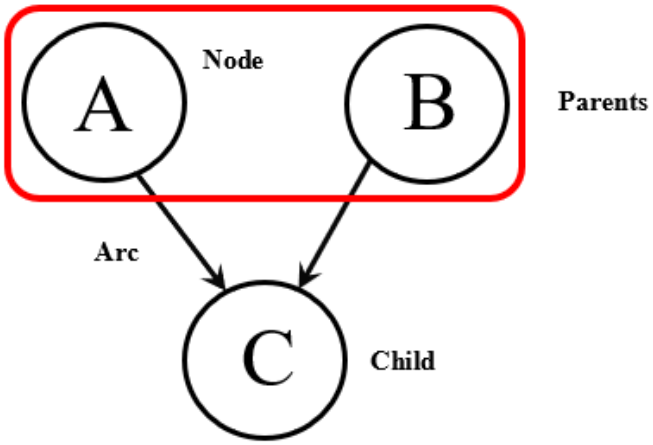

Figure 2: A Bayesian network with three random variables

Each node represents a random variable (qualitative aspect), also called the parent, and the arcs represent the dependency relation between the random variables (quantitative aspect), also called the child, through conditional probabilities. A marginal distribution is specified for each node with no parents, and a conditional distribution is associated with each child node. It can be obtained from data without full dependency relationships between nodes (parent and child), representing the most critical information for models (Hanea et al., 2006). Assuming a set of random variables $(X_1, \cdots, X_n)$ with high dimensional uncertainty encoded with conditional independence statements in the form of a DAG, shown in Figure 2, and probabilistic functions, the factorization of the joint density can be written as shown in Equation (1), according to probability theory.

$$f(x_1, x_2, \cdots, x_n) = f(x_1) \prod_{i=2}^{n} f(x_i | x_1, \cdots, x_{i-1}) \quad \text{(Equation 1)}$$

Equation (1) can be simplified to Equation (2) as a joint probability, each variable with a conditional probability function given $f(X_1 | X_{Pa(i)}, i = 1, \ldots, n$, where $Pa(i)$ represents the parents.

$$f(x_1, x_2, \cdots, x_n) = f(x_1) \prod_{i=2}^{n} f(x_i | x_{Pa(i)}) \quad \text{(Equation 2)}$$

The BN structure defined above can be simplified as $BN = f(D, C)$ where the D represents the parent nodes and directed edges (arcs) as represented in Figure 2 and C is the conditional probability distribution (CPD) of each node and propagation of uncertainty sources. Applying the chain rule to the right side of Equation (1), we can represent the CPD as shown in Equation (3), assuming the parent node random variable. $x_{Pa(i)}$ at any period in time (T) is $i = t_j$ ($\forall_{t_j \in T}$), follows a temporal sequence, and the parent node x_i is the set of prior variables $x_{i-1}, \ldots \ldots, x_1$, as shown in Equation (1) (Pan et al., 2019).

$$f(x_i | x_1, \cdots, x_{i-1}) = \frac{f(x_1, x_2, \cdots, x_n)}{f(x_1, x_2, \cdots, x_{n-1})} \quad \text{(Equation 3)}$$

Copulas

Copulas define the dependence between random variables by simplifying complex relationships into a marginal distribution, which enables the construction of multivariate distributions that satisfy non-parametric measures of dependence and prescribed marginal distributions. No restriction is placed on marginal distributions for multivariate models when copulas are applied. Thus, any bivariate distribution can be constructed by assigning any two assessed marginals subjectively (Clemen and Reilly, 1999; Phoon and Ching, 2018), such as $u = F(x)$ or $v = G(y)$, where $F(x)$ and $G(y)$ are the marginals. If X and Y are random variables with cumulative distribution functions $F_X(x)$ and $F_Y(y)$, respectively, the rank correlation ($r_{X,Y}$) of the random variables, which defines the product-moment correlation,

$$r_{X,Y} = \frac{E((F_X(X)F_X(X)) - E\big(F_X(X)\big)E(F_X(X))}{\sqrt{var\big(F_X(X)\big)var(F_X(X))}} \quad \text{(Equation 4)}$$

Where E is the finite expectation of the random variables (Morales et al., 2008). Thus, bivariate copula C defines the multivariate cumulative distribution function $[0,1]^2$ in which the marginal distribution of the variables is uniform on the interval $[0,1]$. Hence, the random variables, X and Y, can be joined by the copula, as shown below:

$$F_{X,Y}(x, y) = C(F_X(x), F_Y(y)) \quad \text{(Equation 5)}$$

Based on Equation (5), any copula for a continuous joint distribution can be determined. According to Sklar's Theorem (1959) (Clemen and Reilly, 1999; Zhang and Singh, 2019), the bivariate cumulative distribution function (CDF) of two random variables can be written as

$$F_{X,Y}(x,y) = C(F_X(x), F_Y(y)) = C(u_X, u_Y; \theta) \quad \text{(Equation 6)}$$

where, $C(u_X, u_Y; \theta)$, is the bivariate copula function in which θ is a copula measure of dependence between random variables X and Y.

Coupling marginals in a model into a joint distribution requires assigning a distribution function to define model parameters, which can be accomplished by analyzing case histories and subjective opinions from experts through statistical, probabilistic, or conditional quantile approaches. Once suitable marginal distributions have been assigned to fit the data range of the random variables, dependencies of the random variables can be determined. The Pearson product-moment correlation coefficient, δ_{ij}, defines the dependence between variables, quantifying the degree of linearity between them. It is defined as

$$\delta_{ij} = \frac{COV(X_i, X_j)}{\sigma_i \cdot \sigma_j} \quad \text{(Equation 7)}$$

Where COV is the covariance of two standard bivariate normal distributions, X_i and X_j, with standard deviations σ_i and σ_j, respectively. Perfect positive linear correlations have δ_{ij} = 1, negative linear correlations have δ_{ij} = -1, and if there is no correlation δ_{ij} = 0. Several methods can be used to estimate δ_{ij}. Some of the methods include methods of moments, maximum likelihood, and rank correlation methods (Phoon and Ching, 2018). Some popular measures of dependence and association of random variables are Spearman's ρ, a measure of linearity, and Kendall's τ, a measure of concordance.

Fault tree analysis

Fault tree analysis (FTA) is a widely used and accepted method for both qualitative and quantitative risk evaluation in the dam industry. It was initially developed to evaluate reliability and complex (Phoon and Ching, 2018). Fault trees (FTs) are members of the influence diagrams that exclusively express probabilistic relationships among system states without explicit consideration of decisions and values (Henrion et al., 1991). This leads to deducing the conjunction of events leading to the top event. Hence, it is a deductive failure-based approach. FTA relies on a top-down static logical deduction of a critical system event and its causes. As a static risk analysis method, FTA has limitations in dynamic risk analysis associated with

complex systems such as tailings dams. However, these limitations can be alleviated through BNs (Bobbio et al., 2001), as described in the preceding sections above.

The logical application of Boolean algebra to represent the top event allows the deduction of the "failure modes," also known as the minimal cut set, to define how the events cause the top event (Vesely et al., 1981). The cut set defines the basic events in a fault tree that ensure the eventuation of the top event. Hence, a minimum cut set combines the events (system failures) that, by coincidence, cause the top event. The quantitative analysis of FTs has two parts: quantifying the top event's probability and measuring the event's importance to that probability.

Fault trees are mostly tailored to the top event (TE), corresponding to a system failure mode, with the FT only including events that contribute to the TE, meaning the events might not be exhaustive and only cover those events that the expert panels consider as credible events leading to the failure. The structures of the FT are composed of a hierarchical setup of gates where high-placed events in the FT are the outputs of the gates, and the lower events (also called basic events) are the inputs to the gates. In constructing FTs, the basic concepts of fault effects, failure mode and failure mechanisms are important in determining interrelationships between events (Vesely et al., 1981). Thus, failure mechanisms produce failure modes that affect the system operation.

Methodology

Uncertainty analysis is a critical element when analyzing failures for complex structures, such as tailings dams, whether in the design phase to assess the behavior of the structure during the operational phases, or post-failure to determine the inherent parameters and uncertainties that led to failure and how they can be mitigated in future construction, and to learn lessons for future designs. Generally, two sources of uncertainty should be considered: natural or randomness and epistemic uncertainty, which are important in quantitative risk analysis in complex structures, according to Baraldi and Zeo (2008) (Phoon and Ching, 2018).

The applied effort in risk analysis for tailings dams to determine the consequences should be structured to be helpful to the risk control process. A graphical representation of frequencies and consequences is also useful (Hartford and Baecher, 2004). Risk assessment in tailings dams is usually done through the failure modes and effects analysis (FMEA), an inductive analysis method where initiating conditions (basic events) are postulated, and their effects are iterated to get to the top event. It is a method best suited for system failures, where logical frameworks are developed through case histories and expert knowledge to frame risk sources in a system. However, the system has disadvantages in modeling redundancy in dam safety, as dam systems do not behave in a binary manner from functional to non-functional since they exhibit dependencies between failure paths. These issues can be solved by applying

influence diagrams (Bayesian networks), which capture the dependencies between nodes, whether deterministic or probabilistic.

Mapping a fault tree analysis into a Bayesian network

Mapping of a fault tree into a Bayesian network (BN) has been conducted in several studies (Bobbio et al., 2001; George and Renjith, 2021; Khakzad et al., 2011). Most of the studies focus on risk assessment, system dependability, and the capability of BNs to make inferences on the fault tree (FT) and assess the reliability of the top event. This conversion capability from FT to BN enables static information from the FT to be used to examine variables that influence tailings dam failures comprehensively, determine variable dependencies, formulate a model for risk assessment, and conduct inference updating of the prior probability of events on obtaining new information under uncertainty, and application as an accident or predictive analysis for system processes.

Converting an FT into a BN requires converting its binary nature into a marginal probability that can be assigned to each node based on the translation of the basic gate rules. Construction of the BN from an FT is done through an equivalent node transfer from the FT, with parent nodes assigned the marginal probability from the nodes and the arcs assigned the conditional probabilities to indicate the dependencies between nodes. Figure 3 shows a mapping block diagram from FT to BN.

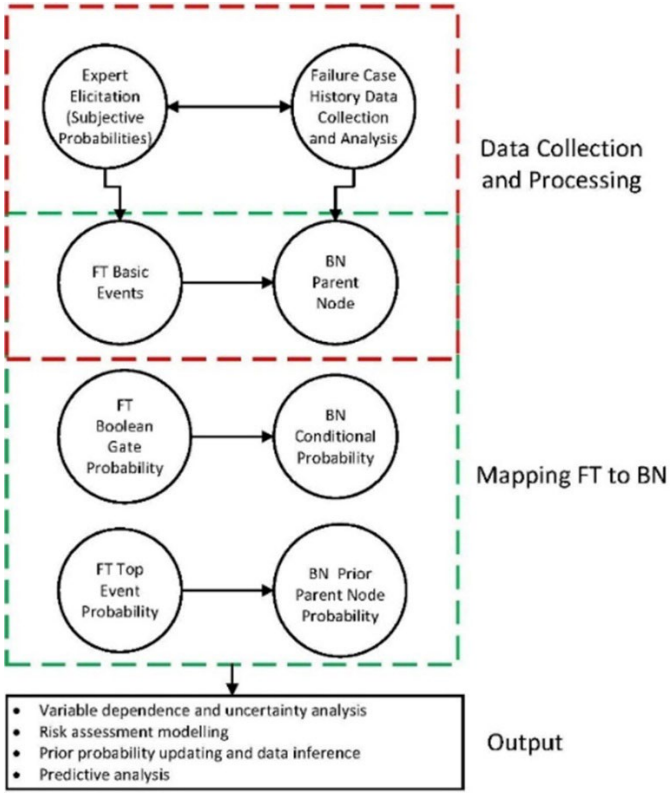

Figure 3: Mapping a fault tree (FT) to a Bayesian network (BN)

The contribution of each event to the top event can be estimated by calculating the probability of the top event and repeating the FT analysis with and without the event, and then transforming the contribution of each event into an improvement index (Khakzad et al., 2011).

Case study – Fundão tailings dam failure

The Fundão tailings dam failure occurred on November 5, 2015. The dam location is Minas Gerais, Brazil. According to the expert panel review report, several people were working on or near the dam at the time of the failure (Morgenstern et al., 2016). An excerpt from the expert panel review report (EPRR) describing the "trigger" events that led to the failure mechanism reads:

"Hence, the failure of the Fundão Tailings Dam by liquefaction flowsliding was the consequence of a chain of events and conditions. A change in design brought about an increase in saturation, which introduced the potential for liquefaction. As a result of various developments, soft slimes encroached into unintended areas on the left abutment of the dam, and the embankment alignment was setback from its originally planned location. As a result of this setback, slimes existed beneath the embankment and were subjected to the loading its raising imposed. This initiated a mechanism of extrusion of the slimes and pulling apart of the sands as the embankment height increased. With only a small additional increment of loading produced by the earthquakes, the triggering of liquefaction was accelerated and the flow slide initiated." – EPRR Executive Summary.

The above excerpt highlights various failure modes and dependencies that could have triggered the flow failure (top event). Expert statements extracted from the EPRR regarding the failure occurrence and timing of events that triggered the flow failure were modeled in the TEFTA software (Reliotec, 2024). Tables 1 to 3 highlight how the probability functions were derived in TEFTA. The respective events used in the model are labeled E1 to E17.

Table 1: Probability functions in the fault tree analysis

Failure probability model	Model	Definition of terms
Constant failure model		The model specifies unavailability and failure frequencies that do not vary with time.
Unrepairable failure model	$q(t) = 1 - (1 - q)e^{-\lambda t}$	Where $q(t)$ is component unavailability, q is component unavailability at $t = 0$, and λ is the component failure rate
Repairable failure model	$q(t) = qe^{-(\lambda+\mu)t} + \frac{\lambda}{\lambda+\mu}(1 - e^{-(\lambda+\mu)t})$	Where $q(t)$ is component unavailability, q is component unavailability at $t = 0$, λ is the component failure rate, and μ is the component repair rate

Failure probability model	Model	Definition of terms
MTBF failure model	$q(t) = \frac{\lambda}{\lambda+\mu}\left(1 - e^{-(\lambda+\mu)t}\right)$ where $\lambda = \frac{1}{MTBF}$ and $\mu = \frac{1}{MTTR}$	Where $q(t)$ is component unavailability, λ is the component failure rate, μ is the component repair rate, $MTBF$ is the mean time between failures, and $MTTR$ is the mean time to repair
MTTF failure model	$q(t) = 1 - e^{-(\lambda+\mu)t}$ where $\lambda = \frac{1}{MTTF}$	Where $q(t)$ is component unavailability, λ is the component failure rate, μ is the component repair rate, and $MTTF$ is the mean time to failure
Weibull failure model	$q(t) = 1 - exp\left[-\left(\frac{t-\gamma}{\eta}\right)^{\beta}\right]$	Where $q(t)$ is component unavailability, η is the component characteristic life, β is the shape, and γ is the location

Table 2: Fundão dam failure fault tree – probability function derivation for modeling

Name	Description	Function	Unit
Bench encroachment	The sand and slimes were no longer physically separated (EPRR Pg. 10) – 2007 – 2012	MTTF(MTTF=5)	Year
Gallery collapse	In July 2010, a vortex appears. Cracking and structural damage were observed during the inspection. In January 2011, a jet grouting program was initiated. July 2012 gallery was unrepairable, and November 2012 repair efforts were abandoned (EPRR Pg. 11)	Unrepairable(q=0, λ=2.333)	Year
Gallery overload	Because of the height of the tailings, the left abutment exceeded the load capacity (EPRR Pg. 11)	Repairable(q=0, λ=0.1666, μ=1)	Year
Blanket drain construction		MTBF(MTBF=1, MTTR=1)	Year
Modified design 826	Concept to raise to El. 920 m in 2011, updated in 2012 (EPRR Pg. 9)	MTBF(MTBF=0.5, MTTR=2)	Year
Starter dam drain failure	Dike 1 starter dam completed in October 2008. On April 13, 2009, large seepage flows occurred (EPRR Pg. 7)	MTBF(MTBF=0.5, MTTR=1.5)	Year
Drain stack concept	Conception between 2004-2007 (EPRR Pg. 4)	MTBF(MTBF=5, MTTR=5)	Year
Static pore pressure increase	Based on blasting and earthquakes	MTTF(MTTF=1)	Day
Excess pore pressure in slimes	Based on blasting and earthquakes	MTTF(MTTF=1)	Day
Solution feature collapse	Based on the gallery collapse	Repairable(q=0, λ=0.1666, μ=1)	Year

Name	Description	Function	Unit
Earthquake	Three small magnitude earthquakes occurred over a period of four minutes, preceding the failure by some 90 minutes (EPRR Pg. 16)	MTTF(MTTF=1.63)	Hour
Saturation of sand	The sand below the dam remained saturated from 2007 to 2012 (EPRR Pg. 10)	MTTF(MTTF=5)	Year
Equipment vibration	On November 15, 2015, most activity was on or near the right abutment where drains were being constructed (EPRR Pg. 16)	Constant(q=0, w=0)	Year
Mine blast	Two blasts occurred at a nearby mine within seconds of each other, three hours before failure (EPRR Pg. 16)	Constant(q=0, w=0)	Year
Without earthquake		Constant(q=0, w=0)	Year

Table 3: Basic event description

Event	Type	Description
E1	Basic	Saturation of sand
E2	Basic	Bench encroachment and slimes deposition
E3	Basic	Secondary gallery collapse (sinkhole)
E4	Basic	Secondary gallery overload
E5	Basic	Blanket drain construction for 940 raise
E6	Basic	Modified design with 826 blanket drain
E7	Basic	Starter dam base drain failure
E8	Basic	“Drained stack design concept”
E9	Basic	Static pore pressure increase
E10	Basic	Excess pore pressure in slimes
E11	Basic	Secondary gallery collapse
E12	Basic	Solution feature collapse
E13	Basic	with earthquake
E14	Basic	without earthquake
E15	Basic	Equipment vibration
E16	Basic	Mine blast
E17	Basic	Seismic event
X1	Intermediate	Static liquefaction
X2	Intermediate	Cyclic liquefaction

Fault tree results analysis

The results from the fault tree analysis in Tables 4 and 5, based on the methodology described above, indicate that the minimal cut set for the flow liquefaction of the Fundão failure was primarily triggered by

the cumulative loading of the three earthquakes, which mobilized dependent events, and static loading through (static) pore pressure increase, causing excess pore pressure build-up in the slimes. However, it is interesting to note that there was also the impact of cyclic liquefaction's contribution to the flow liquefaction mechanism. The results indicated that the seismic event resulting from the earthquake(s) also contributed to the failure mechanism. However, at a lower contribution in comparison to static liquefaction contribution. Based on the above, the probability of flow liquefaction was calculated using Equation 8,
$TE\ (flow\ liquefaction) = X_1 \cup X_2 = 0.9999$.

Table 4: Static liquefaction minimal cut set and contribution to flow liquefaction failure mechanism

Minimal cut set	Probability	Importance index (%)
E13	0.458545874	84.706
E9	0.040810543	7.539
E10	0.040810543	7.539

Table 5: Cyclic liquefaction minimal cut set and contribution to flow liquefaction failure mechanism

Minimal cut set	Probability	Importance index (%)
E17	0.458546	100
E15	0	0
E16	0	0

After processing the fault tree, the data was converted to a Bayesian Network (Bayesnet) using the Uninet Software (Ababei, 2008) as described in the methodology section. The Bayesian network was constructed assuming a uniform marginal distribution for the events and arc directionality as suggested in the EPRR.

The conditional probabilities linking the nodes were obtained by calculating the probability of the top event and repeating the FT analysis with and without the event. For static liquefaction, E1 was 0.569353. The results obtained from this process are shown in Table 6.

Table 6: The probability of each event contributing to the failure

Event	Probability
E1	0.569353
E2	0.999862
E3	0.999618
E4	0.999866
E5	0.99977
E6	0.999428
E7	0.999656
E8	0.999862
E9	0.959074
E10	0.959074
E11	0.999428
E12	0.999866
E13	0.08279
E14	0.999885
E15	0.999885
E16	0.999885
E17	0.08279

A directed acyclic graph (DAG) created from this process is shown in Figure 4. The flow failure was represented as a functional node, which is a union of the static and cyclic liquefaction events ($X_1 \cup X_2$). The Bayesian network could be processed once the DAG and conditional probabilities were assigned to the arcs. Results obtained from this model indicated similar results to those discussed in the previous FT, as shown in Figure 5.

However, in the analytical conditioning of the BN model, the model did not produce similar results as the FT as per the minimal cut set analysis, where E13, E9, and E10 events had the highest importance index in causing the failure. The results indicated a correlation between E1, E2, and E15, leading to X1.

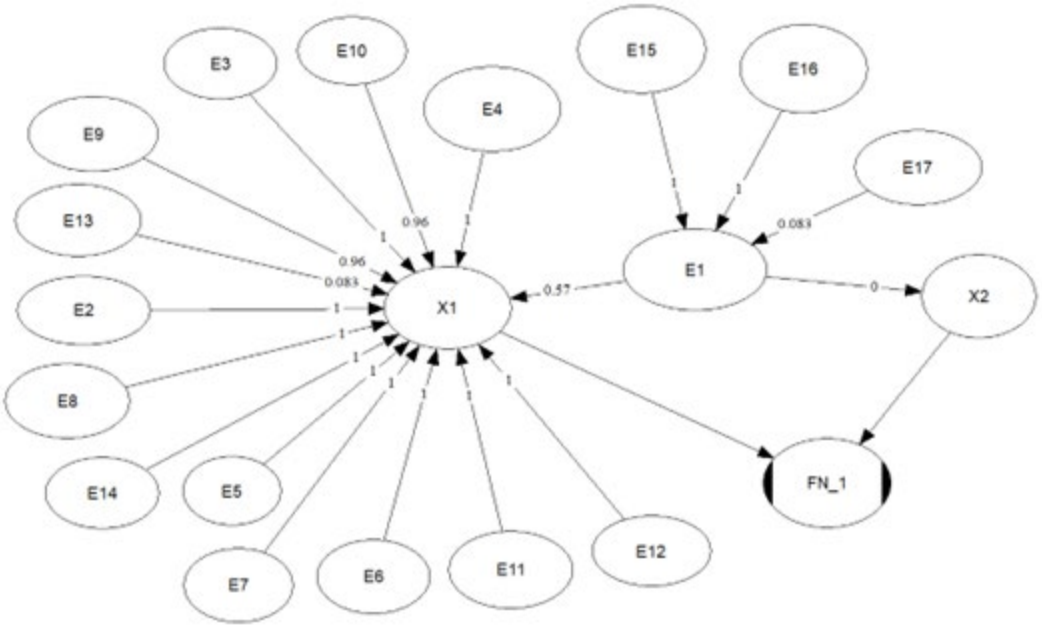

Figure 4: DAG showing nodes and arcs that led to the Fundão failure

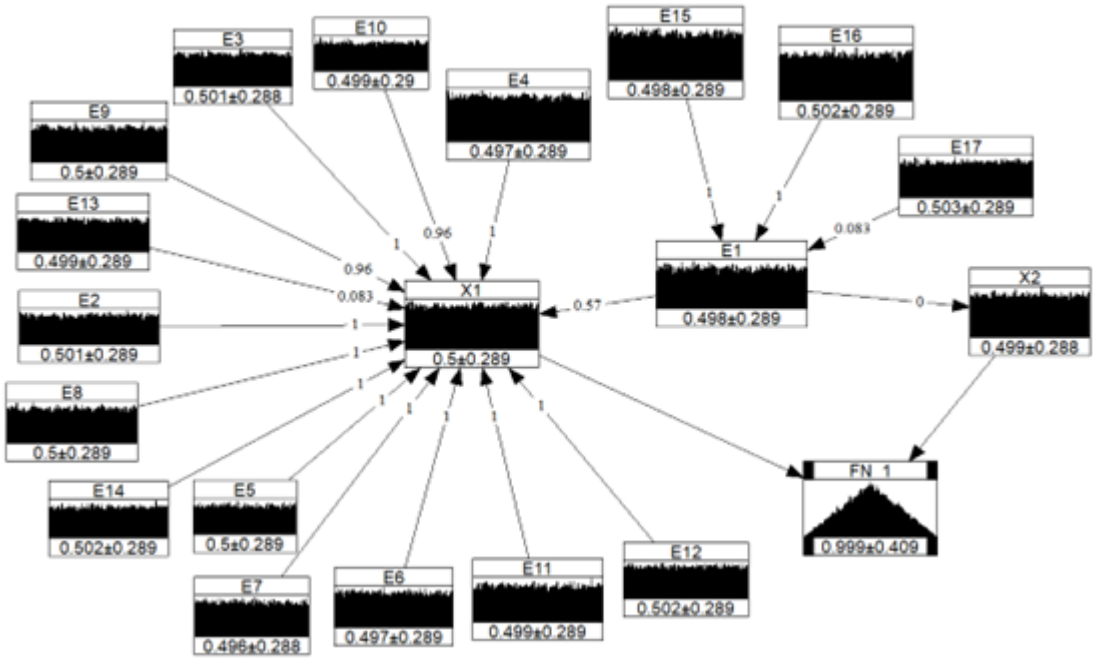

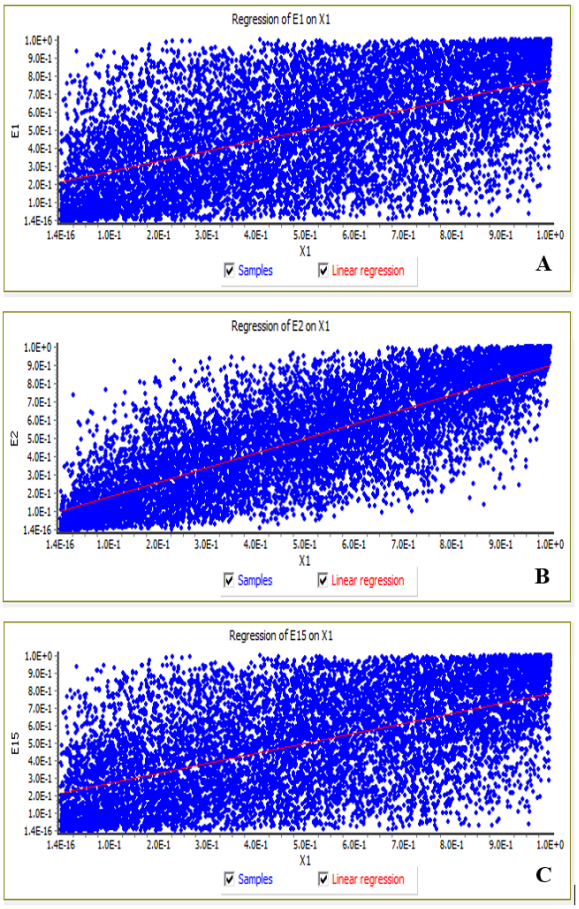

Figure 5: Bayesian network for the Fundão failure

A quantitative analysis of the results highlighted the correlation between the input variables. Quantitative analysis of the Person product moment, Spearman's rank correlation and the regression analysis of the base variables E1, E2 and E15 to predict X1 are shown in Table 7. It can be observed that there is a high correlation between the variables. Another correlation was between E9 and E1, E2, and E15 base variables.

Table 7: Correlation coefficients to predict static liquefaction (X1)

Base variables	E1	E2	E15
Pearson product-moment correlation	0.5698	0.7945	0.5697
Spearman's correlation	0.5696	0.7942	0.5695
Regression coefficient	0.5703	0.7938	0.5702

Conclusion

An alternative approach using Bayesian networks in the analysis of tailings dam risks was addressed in this paper. The shortfalls of the current approach of using static approaches like the fault tree were discussed. An application case study was analyzed, with results indicating that although the BN model had the same result of predicting the flow failure probability, the correlation of the variables to static liquefaction was different to the importance index of the fault tree that had E13, E9, and E10 as the minimal cut set. The BN results indicated that E1, E2, and E15 base variables correlate better with predicting X1 in the case study.

The model could be used to conditionalize the variables by constraining the uncertainty range in the marginal distribution to estimate dependence correlations on other variables. For example, by constraining the probability of the equipment vibration between the interval [0.01,0.03], the dependence effect of this change can be seen on the other variables, such as static liquefaction and overall probability of flow failure, as shown in Figure 7. These results clearly show the advantages of using Bayesian networks over static risk assessment approaches. This inherent capability can be adopted in risk assessments, failure modes analysis, and failure trigger inference for robust tailings dam design and engineering.

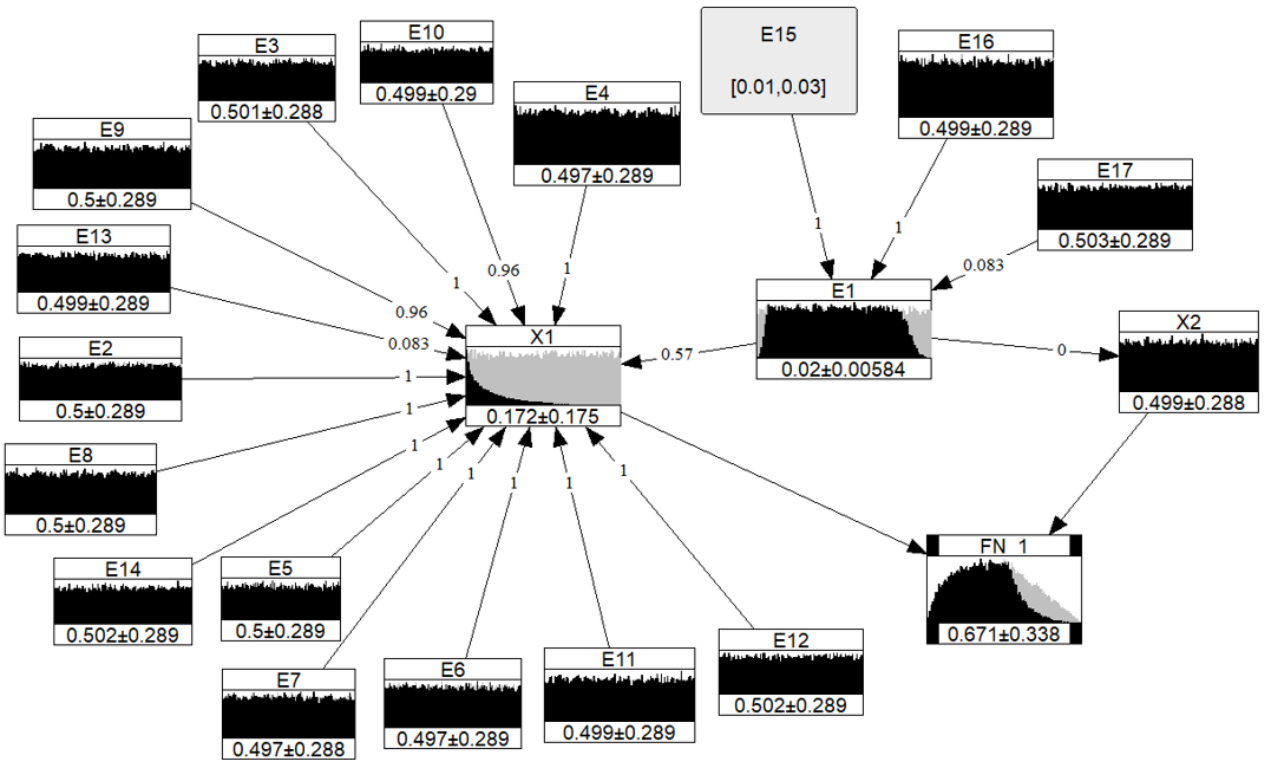

Figure 7: Conditionalizing variable E15 and its dependence relationship with other variables, a function that can be used for inference and predictive analysis

Abstract

Managing fluid fine tailings accumulation in surface mined oil sands is a challenge, and centrifugation is one of the dewatering technologies developed and commercialized by Syncrude Canada at their Mildred Lake surface mined oil sands operation located near Fort McMurray in northern Alberta. Development started with pilot testing in 2007, culminating in the operation of eight Alfa Laval Lynx 1000 centrifuges from 2011 to 2013 in what was known as the centrifuge demonstration plant. From 2013 to 2024, Syncrude's full-scale commercial plant was in operation with 18 Lynx 1000 centrifuges and played a major role in Syncrude's commitment to meeting regulatory requirements for treating fluid fine tailings. The target throughput of 72 tonnes of fines per machine was difficult to consistently achieve because of feed density variations that caused a variety of operational problems including washouts. A study undertaken in 2017 to identify centrifuge plant operational bottlenecks identified a shortcoming in the torque control that is conventionally used to adjust cake discharge rates as feed rate changes. The results of that study lead directly to development of the improved operational approach described in this paper.

The operation of the Syncrude centrifuge plant from 2017 to 2022 relied on controlling the torque on the cake scroll to change the rate at which cake is pushed out of the centrifuge and thereby automatically respond to changes in feed density or flow rate. In practice this is only true if feed properties change slowly. When feed density varies rapidly the torque control cannot respond quickly enough to prevent centrifuge washouts. By examining centrifuge plant data over several years, an equation was developed to determine the ideal scroll speed based on MFT feed density and flow rate. Controlling the centrifuge operation proactively based on feed properties leads to smoother differential speed adjustments and requires less operator intervention. The equation provides a physically motivated first-order relationship between the MFT density, flow rate, and the differential speed, which can be expanded on with a more in-depth analysis

of the data using machine learning. Using a neural net, the optimal differential speed can be predicted based on all the centrifuge parameters, including polymer dosage and bowl speed. In general, the neural net results agree with the equation, but can also account for large changes in centrifuge bowl speed. Currently the operators determine the torque setting to optimize fines capture, and that setting might vary depending upon feed density, clay content, bowl speed, or polymer dosage. Similarly, the equation has a bias term that would be used to account for those parameters that are typically fixed or slowly changing. With either a simple equation or a neural net, adjusting the centrifuge operation in response to changes in the MFT feed measured before it enters the centrifuge will proactively adjust to feed changes before they lead to disruption of the centrifuge operation. Preliminary results of the implementation of these feed forward principles are presented from the Syncrude full-scale centrifuge operation.

Introduction

The centrifuge plant consists of 18 Alfa Laval Lynx-1000 centrifuges split into two trains, which ran from 2017 to 2022. Figure 1 shows a basic diagram of a centrifuge, indicating the operating parameters and important operational details.

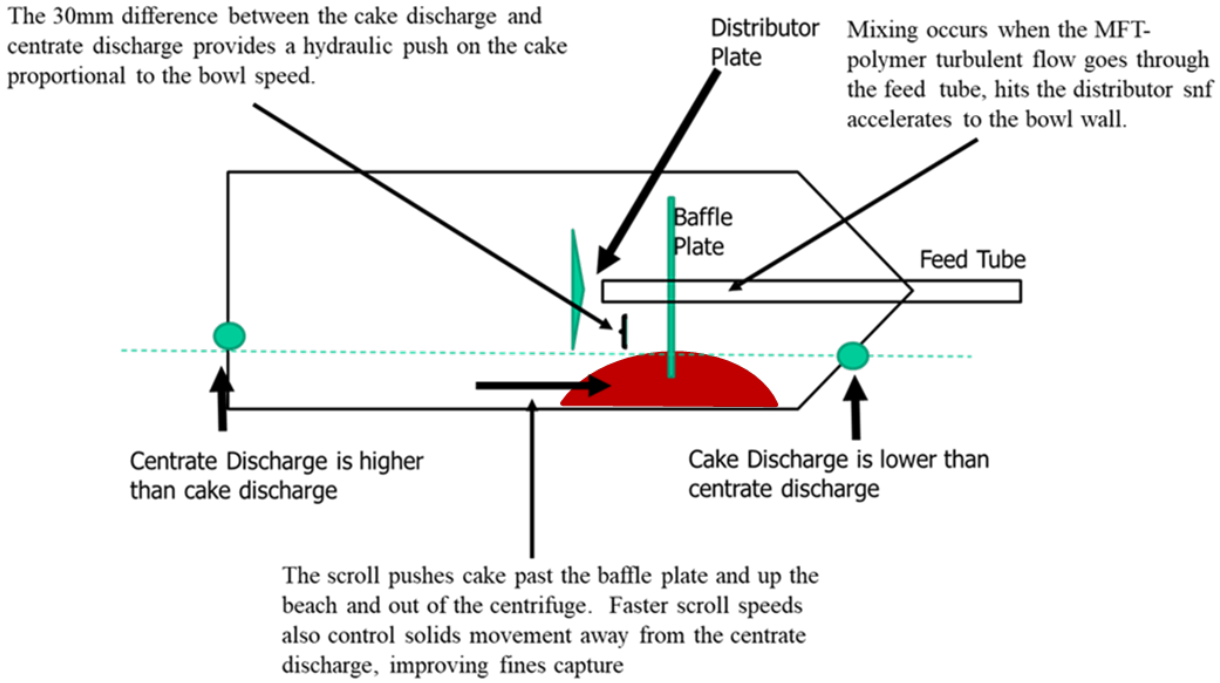

Figure 1: Schematic of the centrifuge with highlights of relevant operating considerations

It is important to note that the centrifuges are designed to operate with a negative pool, which means the centrate discharge is higher than the cake discharge. Operationally, this means that a minimum feed rate and cake formation is required in order to form a cake plug that separates the centrate from the cake

discharge. If the feed rate (MFT density and flow rate) is not high enough this plug can wash out, resulting in significant loss of production.

In order to prevent wash outs and otherwise control the cake discharge rate, torque control is used. The operator sets a scroll discharge torque that the control algorithm attempts to keep constant. The torque on the scroll discharge will be a function of the solids loading, bowl speed, the polymer flocculant mixing and dosage, and the scroll discharge rate itself. With rapidly changing MFT density or flow rate (solids loading) the torque control approach has difficulty responding rapidly enough to prevent cake washouts.

Data from each of the 9 centrifuges in train 1 and 2 (18 total) was taken in 6-hour intervals for three years, from January 2017 to December 2019, and in two-hour intervals from January 2020 to December 2020. Since physical centrate solids and cake solids measurements are taken at three-hour intervals, the increased data sampling frequency for the 2020 data was done to determine if a shorter time interval would change the data quality. It did not. In addition to the date/time of the measurements and the production status of each centrifuge, this study looks at the following key measurements:

1. torque on the cake scroll (kNm)
2. torque setpoint (kNm)
3. differential (cake scroll) speed (rpm)
4. bowl speed (rpm)
5. polymer dosage (g/tonne)
6. polymer flow (m^3/h)
7. MFT flow (m^3/h)
8. MFT density (kg/m^3)
9. cake solids (%weight)
10. centrate solids (%weight).

The first eight of these quantities are indicators of the input into the centrifuge, and the cake solids and centrate solids are indicators of the centrifuge performance. The efficiency of a centrifuge is measured by the solids capture, which is defined as the ratio of solids in the cake to the solids input.

Controlling the torque is not an ideal method for controlling the centrifuges for two reasons. The scroll cake discharge torque is kept constant by adjusting the scroll (differential) speed or cake discharge rate. The algorithm cannot respond quickly enough to maintain torque and the integrity of the cake plug when feed density changes rapidly. Additionally, when the operator recognizes that the torque has changed quickly an intervention is required, which is generally too late to prevent a washout. A feed forward method for controlling the scroll speed in the centrifuges based on MFT density and flow rate before entering the

centrifuge can solve these problems. Since the MFT density gauge is several minutes upstream of the centrifuges, controlling differential speed using that information allows for a more controlled response to potential washouts.

The goal of this analysis is to determine the optimal differential speed for a given MFT density and flow rate, in order to maximize the solids capture and prevent wash outs. Unlike most mineral processing applications, the oilsands tailings MFT density is not controlled in the centrifuge operation. This study uses three years of operational data to determine the relationship between differential speed and MFT flow rate and density for a given bowl speed and polymer dosage that also results in a high (>95%) solids capture. The MFT flow can be controlled somewhat, but should be maximized, if possible, to increase the amount of MFT processed by the centrifuge and help maintain the cake plug.

The polymer is required for the formation of cake, and an optimal value has already been determined in an ADW (accelerated dewatering) process where the mixing has been optimized (Bara, 2020). Increased polymer dose can compensate for imperfect mixing, but overdosing can lead to problems in the cake transport, and in particular with the torque the cake will produce for a given differential speed. Too much polymer can create a slippery cake that is difficult to auger out of the centrifuge. The bowl speed and the MFT flow rate both contribute to the mixing of polymer and MFT. In addition, the bowl speed creates a hydraulic pressure to help transport cake out of the centrifuge (Bara et al., 2011; Mikula et al., 2017; Mikula et al., 2021). In the final analysis, however, the differential speed is the most important factor in transporting the cake out of the centrifuge and therefore in determining the steady state operating conditions for a given MFT flow rate and density.

Results and discussion

Developing an equation for differential speed

The data collected over four years from 2017 to 2020 contains a wide range of operating conditions, far more than could be collected in a sampling program. Unfortunately, this also includes a significant amount of data where centrifuge operation is not optimal. Additionally, since not all the quantities are measured at the same locations or times, there are some cases that lead to unphysical data such as solids captures in excess of 100%. The first step in determining the optimal differential speed for given feed properties is reducing the dataset to only times where centrifuges are running in a steady state and efficiently. The centrifuge can be considered to be running in a steady state if operator intervention is not required, the operator intervenes by changing the torque setpoint, and an algorithm adjusts the differential speed until that torque is reached. If the torque is within 5% of the torque setpoint, it is not likely there has been any recent operator intervention, and the centrifuge is running in a steady state. The efficiency of the centrifuges is measured by the solids capture; a centrifuge is running efficiently with solids capture above 97.5%.

Once the data has been reduced to centrifuges with a high solids capture (above 97.5%) in a steady state (torque within 5% of the torque setpoint), it is then grouped according to feed density by rounding to the nearest 10 kg/m^3. Initially the data is separated into train 1 and train 2, in case there is a significant systematic difference between the trains, but this does not appear to be the case. For a fixed density, we expect a linear relationship between the differential speed and the MFT flow rate, since the differential speed controls the rate at which solids leave the centrifuge, and the MFT flow rate is the rate solids enter the centrifuge. Although there is significant scatter in the data, there is a strong linear relationship between differential speed and MFT flow rate. The slopes and intercepts of these lines for each density grouping are given with their standard errors in Table 1.

Table 1: The slopes and intercepts for the linear fit of differential speed to MFT flow rate, grouped by density range

MFT density	Train 1 slope	Train 1 intercept	Train 2 slope	Train 2 intercept
1,160	0.15 ± 0.012	−2.22 ± 2.15	0.14 ± 0.02	−1.68 ± 2.03
1,170	0.13 ± 0.001	3.05 ± 1.65	0.15 ± 0.01	6.13 ± 1.66
1,180	0.13 ± 0.009	3.60 ± 1.55	0.11 ± 0.01	1.13 ± 1.43
1,190	0.15 ± 0.010	0.97 ± 1.75	0.14 ± 0.01	10.35 ± 1.52
1,200	0.11 ± 0.010	7.46 ± 1.74	0.09 ± 0.01	7.43 ± 1.79
1,210	0.13 ± 0.010	4.84 ± 1.70	0.12 ± 0.01	4.16 ± 1.85
1,220	0.18 ± 0.011	−4.11 ± 1.94	0.14 ± 0.01	6.26 ± 1.74
1,230	0.14 ± 0.011	3.66 ± 1.79	0.13 ± 0.01	8.80 ± 1.89
1,240	0.15 ± 0.011	4.21 ± 1.81	0.18 ± 0.01	−0.47 ± 2.10
1,250	0.12 ± 0.012	8.95 ± 1.90	0.15 ± 0.01	4.79 ± 2.02

The intercepts have large errors, and are near 0, with no strong evidence of a trend as density increases. As a boundary condition, if there is no flow of MFT into the centrifuge, there is no need for the differential to push cake out. It is therefore reasonable to take the intercept to be 0 in all cases and use this to refit the linear equations. The resulting slopes of the new linear fits are given in Table 2. Requiring the y-intercept to be 0 has several advantages. It makes the changes in the slope between density groups more obvious, since the goal is to obtain a value for the differential speed. It also means the slope is simply the ratio between differential speed and MFT flow for a given density group. This will greatly simplify the resulting determination of differential speed.

Table 2: The slopes from the linear fit for differential speed to MFT flow rate, with the y-intercept set to 0

Density	Train 1	Train 2
kg/m³	Estimated slope	Estimated slope
1,140	0.118 ± 0.003	0.126 ± 0.003
1,150	0.133 ± 0.002	0.125 ± 0.002
1,160	0.137 ± 0.002	0.144 ± 0.002
1,170	0.144 ± 0.001	0.142 ± 0.002
1,180	0.147 ± 0.001	0.148 ± 0.001
1,190	0.151 ± 0.001	0.153 ± 0.001
1,200	0.156 ± 0.002	0.162 ± 0.002
1,210	0.160 ± 0.002	0.163 ± 0.002
1,220	0.156 ± 0.002	0.165 ± 0.002
1,230	0.164 ± 0.002	0.171 ± 0.002
1,240	0.172 ± 0.002	0.173 ± 0.002
1,250	0.170 ± 0.002	0.174 ± 0.002

To determine the final equation for differential speed as a function of MFT density and flow rate, the slopes in Table 3 are plotted as a function of the density group, and a linear fit is found to average the data and provide values for any MFT density. Since trains 1 and 2 both give similar results, they can be combined to create a single master equation to determine the differential speed for a given MFT density and flow rate. The combined data is shown in Figure 2.

The equation for the linear fit in Figure 2 is

$$y = 0.4418x - 0.3757 \qquad \text{(Equation 1)}$$

where y is the ratio of differential speed to MFT flow rate and x is the MFT density. This leads to our equation for the differential speed as a function of the MFT density and flow rate:

$$\text{Differential Speed} = (0.4418 * \text{MFT Density} - 0.3757) * \text{MFT FlowRate}. \qquad \text{(Equation 2)}$$

Some differential speed (in rpm) values calculated with this equation are shown in Table 3.

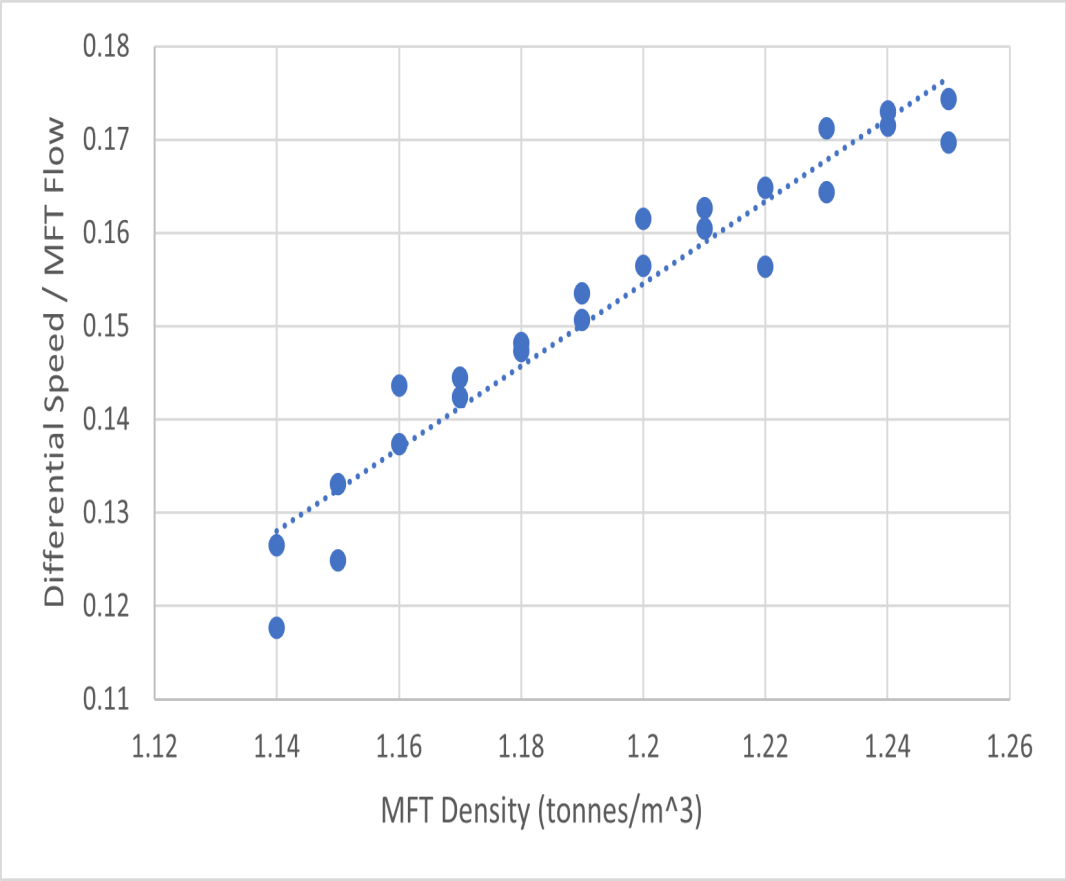

Figure 2: The combined data from Trains 1 and 2

Table 3: The differential speeds (rpm) calculated for some values of MFT density and flow rate

Density (tonnes/m^3)	MFT flow rate (m^3/hour)						
	75	**100**	**125**	**150**	**175**	**200**	**225**
1.14	9.6	12.8	16.0	19.2	22.4	25.6	28.8
1.15	9.9	13.2	16.5	19.9	23.2	26.5	29.8
1.16	10.3	13.7	17.1	20.5	23.9	27.4	30.8
1.17	10.6	14.1	17.7	21.2	24.7	28.2	31.8
1.18	10.9	14.6	18.2	21.8	25.5	29.1	32.8
1.19	11.3	15.0	18.8	22.5	26.3	30.0	33.8
1.20	11.6	15.4	19.3	23.2	27.0	30.9	34.8
1.21	11.9	15.9	19.9	23.8	27.8	31.8	35.7
1.22	12.2	16.3	20.4	24.5	28.6	32.7	36.7
1.23	12.6	16.8	21.0	25.2	29.3	33.5	37.7
1.24	12.9	17.2	21.5	25.8	30.1	34.4	38.7
1.25	13.2	17.7	22.1	26.5	30.9	35.3	39.7

Equation 2 was created using only densities from 1,135 kg/m^3 to 1,255 kg/m^3, grouped by rounding to the nearest 10 kg/m^3. It is possible to consider either a wider range of total densities or a smaller density group size. The main limitation in choosing group size is the amount of data.

Equation 2 assumes an approximate linear relationship between the differential speed and the MFT flow for a given MFT density, and then further assumes a linear relationship between the ratio of differential speed to flow rate and the MFT density. The exact relationships between these quantities may be more complicated, but for many of the applicable values of MFT flow and density, the linear relationship is a good approximation. To account for some of this uncertainty, and to better deal with more extreme values of MFT flow and density, an operator bias can be introduced to the equation to allow for some adjusting of the differential speed.

$$\text{Differential Speed} = \textit{Bias} \times ((0.4418 * \text{MFT Density} - 0.3757) * \text{MFT FlowRate}) \quad \text{(Equation 3)}$$

Deployment of the equation compared to torque control

Centrifuge operation over the four years of operation has been controlled through the torque measured on the scroll. Using the torque to control the differential speed compensates for drift in feed properties. The operator will set the torque value and the control system adjusts the differential speed to maintain that value. The operator will choose the torque setpoint depending on bowl speed, polymer dose, and fines in the MFT in order to maximize the fines capture and maintain high cake solids. As noted earlier the torque control approach has difficulty responding to rapid changes in feed density. The equation that relates feed flow and density to the differential speed is better able to respond to changes in feed density because the density meter is significantly upstream of the centrifuges. The bias factor in the equation is set by the operator to account for bowl speed, polymer dose, and fines content. There was an opportunity on April 13, 2021, to compare the two control systems on nearby centrifuges.

The new control system was commissioned successfully from April 12 to 14, 2021. Preliminary evaluations of an “operator bias” function showed that there is a wide operating window for the system, and that operators could quickly become accustomed to the new system relative to the existing torque control method.

Figure 3 shows data from April 13, when the differential speed of the test centrifuge 1G is shown responding to changes in feed rate. During this five-hour period, the operator bias was adjusted only twice for testing purposes (between .85 to .95). The blue arrows show a lag between the MFT feed rate to 1G and the differential speed response. This response time can be adjusted by appropriate changes to the control system. Figure 4 shows the same time period for centrifuge 1E, using the operator torque setting to define the differential speed. The upper plot of torque setting represents an operator intervention to set the torque, and the lower plot shows the resulting differential speed response. The advantages of the new control system

based on the equation are obvious considering that more than 10 operator changes to the torque setpoint were required during the five-hour test period.

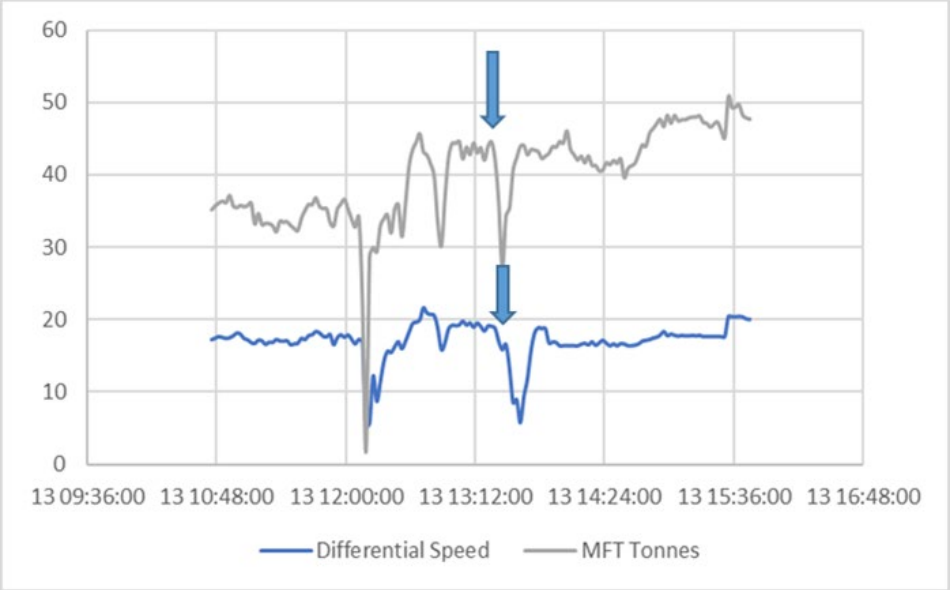

Figure 3: A five-hour test period on April 13, Centrifuge 1G, showing the Equation 3 control of differential based on MFT feed rate shown in tonnes per hour.
During this time period, the operator bias was only changed twice for test purposes

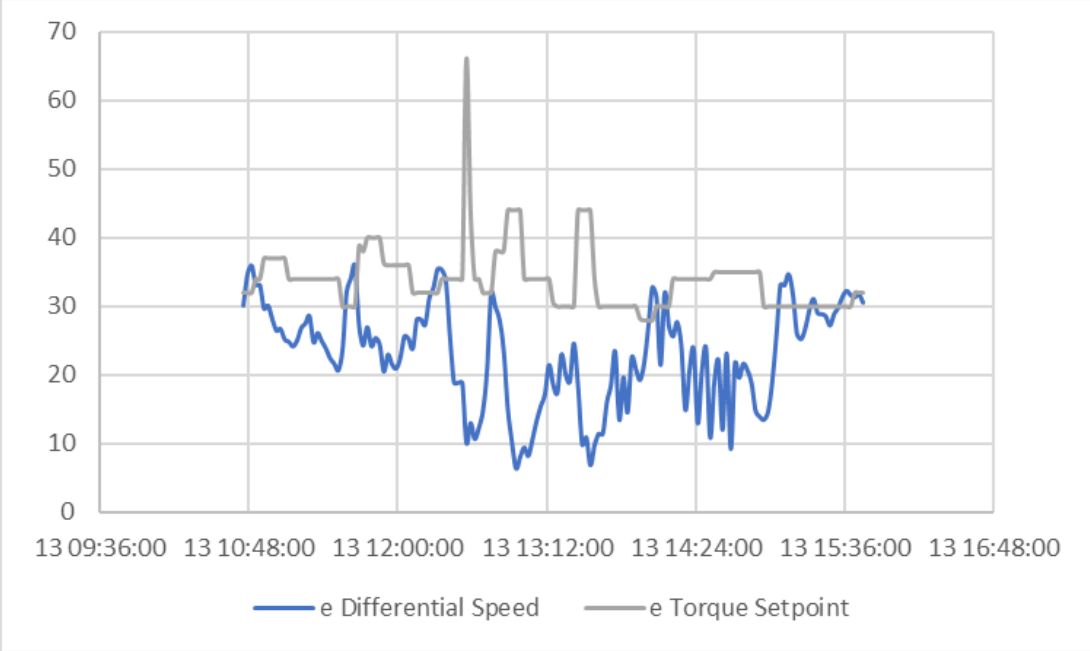

Figure 4: The same five-hour test period as Figure 3, showing centrifuge 1E under the conventional torque control system.
The upper graph shows every time the operator changed the torque setpoint. The lower plot shows the differential response to that change. The indirect control of differential speed (cake removal) by torque settings is clearly inefficient relative to control based on MFT feed rate

In practice the torque control did not lead to a steady differential speed or smooth centrifuge operation. Figure 4 shows how differential speed changes in response to changes in the torque setpoint. Note that in some cases when the torque setpoint is constant, the differential speed oscillates to try to reach a steady torque value.

Machine learning approaches using neural nets

Machine learning can potentially be used as an alternative feed forward approach for controlling differential speed, allowing for the differential speed equation to explicitly take into account bowl speed and polymer dosage, as well as potentially non-linear relationships with the feed properties. Currently those factors are accounted for with the operator choice of bias in the equation.

Neural nets take input variables and pass them through several "hidden layers" of computation to determine an output variable. Each layer consists of a linear combination of the variables in the previous layer. The weights of each combination are determined by minimizing the difference between the predicted output and the actual output from the provided data.

Using the NumPy and Sklearn packages in Python, neural nets are trained on the entire dataset to predict the differential speed based on bowl speed, polymer dose, solids capture, MFT flow rate and MFT density. Figure 5 shows the optimum differential speed predicted from the equation and the neural net for the densities and flow rates.

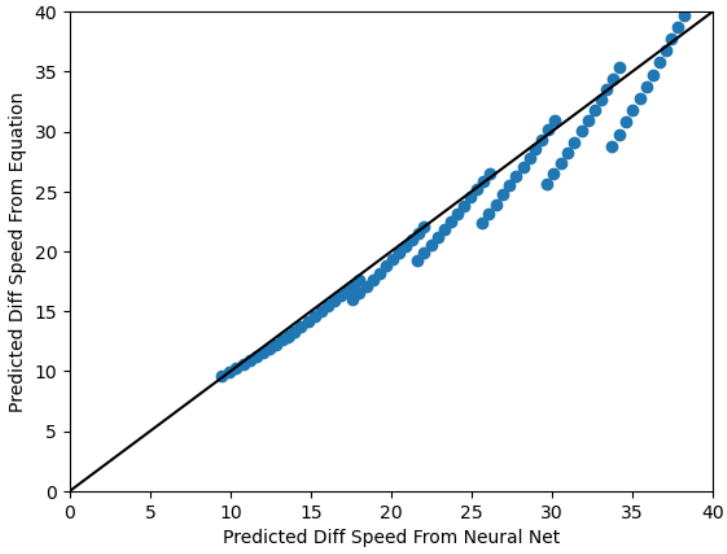

Figure 5: The differential speed from the equation compared with the neural net assuming 1,300 G/tonne polymer dose, 98% solids capture and 1,500 rpm bowl speed for a range of flow rates and densities

Figure 5 assumes a polymer dose of 1,300 g/tonnes, solids capture of 98% and a bowl speed of 1,500 rpm. Figure 6 assumes a polymer dose of 1,300 g/tonnes, solids capture of 98% and a bowl speed of 1,200

rpm. For the higher bowl speed, the neural net predicts higher optimal differential speeds. This is consistent with the physics of the centrifuge: higher bowl speeds create a higher settling rate, allowing for more rapid cake formation and removal without reduced cake solids or risk of washout. With the equation alone, the centrifuge performance differences due to the higher bowl speed need to be accounted for by adjusting the operator bias.

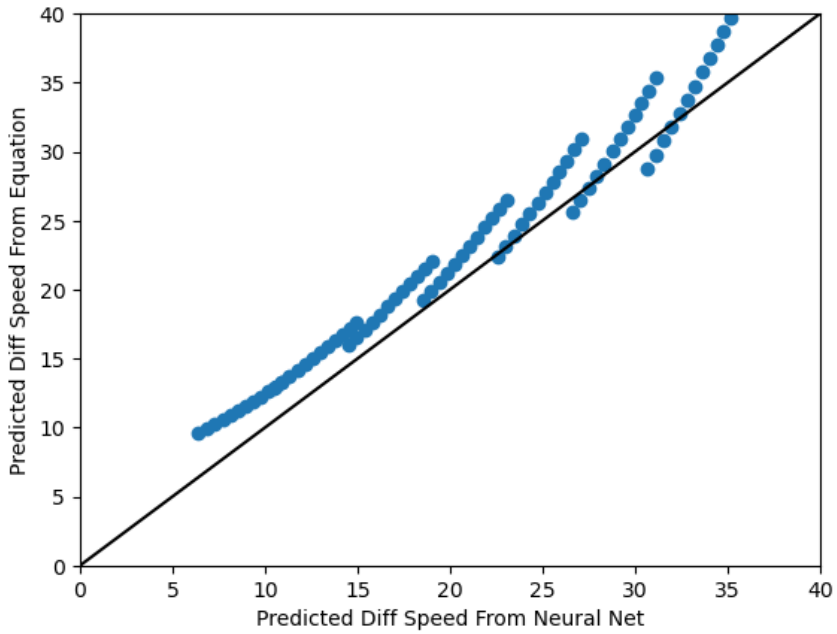

Figure 6: The differential speed from the equation compared with the neural net assuming a 1,300 G/tonne polymer dose, 98% solids capture, and 1,200 rpm bowl speed for a range of flow rates and densities

Conclusion

Operating experience suggests that using the torque to control centrifuge operation is not an optimal approach when feed density varies. With wide swings in feed density the torque control often cannot respond fast enough to prevent washouts. Operator interventions attempting to correct the differential speed by changing the torque setting are also often too little too late. The use of density and flow information from meters ahead of the centrifuges allows the equation determined in this study to adjust the differential speed proactively. This proactive approach will prevent centrifuge washouts when feed density and/or flow rate change rapidly.

This alternative method to the torque control can change differential speed in order to rapidly respond to changes in the MFT feed rate or density. Altering the differential speed in response to changes in the

feed will proactively prevent potential washout problems before they lead to disruption of the centrifuge operation. The equation

$$\text{Differential Speed} = \textit{Bias} \times ((0.4418 * \text{MFT Density} - 0.3757) * \text{MFT FlowRate}) \quad \text{(Equation 4)}$$

includes a bias correction to account for or correct for differences in feed clay content, bowl speed or polymer dosage. This first-order physical approach proved successful in controlling one centrifuge in a limited five-hour test.

Machine learning techniques can more easily consider the other centrifuge operating parameters and could provide control over the differential speed that also takes into account bowl speed and polymer dose. However, since much of the data collected over the four-year period does not reflect optimal centrifuge control, care must be taken in the application of machine learning methods. The results obtained in this study using neural nets to predict the optimal differential speed for given feed conditions agree with the result of the physical approach, but also consider bowl speed and polymer dosage explicitly. While the neural net results may perform better if bowl speed is inconsistent, the main advantage of the equation is that it is easily implemented on any system and requires no additional software. Note also that the bowl speed and polymer dosage are controlled and would not require an automated response.

In most mineral processing systems, the feed properties to a centrifuge or other equipment are carefully controlled. This is not possible with the variability and high-volume throughputs in oil sands tailings operations. The use of upstream data to proactively control equipment could be applied to a wide variety of industrial optimization processes where feed properties can vary considerably. In this case, the use of data mining techniques saved the considerable cost of a sampling campaign and provided a significantly better end product. It is unlikely that even an extensive sampling effort would have seen the wide variety of feed densities that informed this study.

An Often-Overlooked Approach for Slope Stability of Tailings Dams Built Using Centerline and Downstream Construction

Jed D. Greenwood, Barr Engineering Co., USA

Junhong Li, Barr Engineering Co., USA

Abstract

Many tailings dams are founded on overconsolidated clays of stiff to very stiff consistency, which in general tend to provide a relatively suitable foundation for these earthen structures. The authors have found in multiple dam safety reviews that there is a tendency in practice to overlook the nature and impact that the stress changes have on the characteristics of these clays. On the one hand, there are cases in which the stiff clays are solely characterized with drained shear strength because they are seen as "stiff clays" and thus the drained shear strength should govern stability. On the other hand, there are cases in which the possibility of mobilizing the undrained shear strength is acknowledged, but it is assumed that the undrained shear strength ratio initially determined remains constant over time and does not change with increasing effective stresses as the dams are raised. This paper presents lessons learned on the characterization of foundations on clays of stiff to very stiff consistency through several dam safety reviews, as well as practical examples and steps associated with the SHANSEP (Stress History and Normalized Soil Engineering Properties) technique to be utilized in the design of tailings dams using the centerline and downstream construction methods.

Introduction

When tailings dams are founded on overconsolidated clays of stiff to very stiff consistency, these clays tend to provide a relatively suitable foundation for these earthen structures. However, as tailings dams are raised to provide additional storage capacity, the stress history of these foundation clays changes and so does their behavior and undrained shear strength. The authors have found that in practice there is a tendency to overlook the nature and the impact that the stress changes have on the characteristics of these clays. On one hand, there are cases in which the stiff clays are solely characterized with drained shear strength because they are seen as "stiff clays" and thus the drained shear strength should govern stability. This is initially true but upon loading and subsequent consolidation, this behavior changes. On the other hand, there are

cases in which the possibility of mobilizing the undrained shear strength is acknowledged but it is assumed that the undrained shear strength ratio (s_u/σ'_{vc}, or USSR) initially determined on the overconsolidated specimens remains constant over time and does not change with increasing effective stresses as the dams are raised. In reality, the USSR of the clay foundation will change as a function of the stresses imposed by the dam (i.e., overconsolidation ratio, or OCR), which are variable under the dam in terms of stress history, pore pressures, applied loads, and consolidation. This is particularly relevant for centerline and downstream construction, which are becoming more typical in the industry for slurried tailings storage. There is a relatively simple but powerful technique to incorporate these stress history and strength effects in slope stability analyses, which is often overlooked in practice.

The authors have found through multiple dam safety reviews that in practice there is a tendency to overlook the nature and impact that the stress changes have on the characteristics of these clays. This complex impact of stress history on undrained shear strength is best captured by the SHANSEP approach. SHANSEP stands for Stress History and Normalized Soil Engineering Properties. The SHANSEP approach is briefly described subsequently and followed with an applicable example to illustrate its benefits and implications.

SHANSEP concept

SHANSEP is a concept introduced by Ladd and Foott (1974), with follow-up research by Ladd (1991). This approach is based on the experimental observation that the shear strength of many soils can be normalized with respect to the vertical consolidation stress. In other words, the method is based on the concept that, for a given failure mode such as triaxial compression (TC) or direct simple shear (DSS), the undrained stress-strain-strength behavior of most "ordinary" clays is governed by the stress history of the clay. The method assumes that these soils exhibit normalized behavior. Accounting for stress history in the laboratory is done by using mechanical overconsolidation to represent all preconsolidation mechanisms; thus, the procedure explicitly requires the stress history profile for the clay to be evaluated.

The increase in undrained shear strength ratio s_u/σ'_{vc} of clays with increasing OCR can be modeled by the following equation:

$$s_u/\sigma'_{vc} = S(OCR)^m$$

where:

s_u = undrained shear strength

σ'_{vc} = effective vertical consolidation stress

$S = s_u/\sigma'_{vc}$ at OCR = 1

OCR = overconsolidation ratio

m = empirical factor

Obtaining this relationship in the laboratory first involves determining the stress history of the soil in the form of the preconsolidation stress σ'_p , which can be obtained from laboratory consolidation tests or through field methods such as dilatometer or CPT. Specimens are then often isotropically consolidated to 1.5, 2.5, and 4.0 times σ'_p so they can be sheared in the normally consolidated range at OCR = 1, while other specimens are often isotropically consolidated to 2.5 times σ'_p and then unloaded to nominal OCR values of 2, 4, and 6, so they can be sheared in the overconsolidated range (Ladd and DeGroot, 2003). The resulting USSR values can then be plotted against the OCR on a log scale to obtain the empirical factor *m*.

Numerical modeling

A generic, two-dimensional numerical modeling exercise was carried out in FLAC2D to demonstrate the effect of a change in stress history for a "very stiff" foundation clay under staged construction of a downstream tailings dam. The modeling is intended to show that the foundation clay gains undrained shear strength due to material loading and subsequent consolidation during and after each dam raise, but also that the OCR and the corresponding USSR decrease as the dam is raised. The OCR can decrease to the point where the material transitions from a very stiff, dilative clay to a lightly overconsolidated, or even normally consolidated, brittle clay.

Model geometry

The model geometry comprises a downstream tailings dam constructed in six phases on a simple clay foundation, as shown in Figure 1.

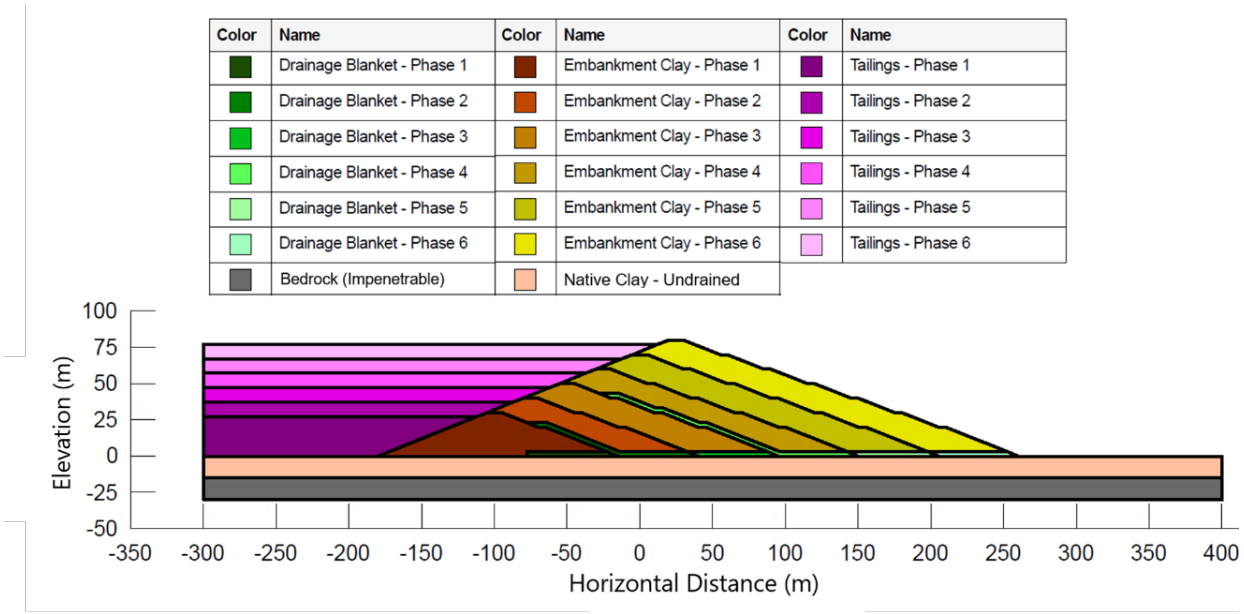

Figure 1: Model geometry of generic downstream tailings dam

The foundation clay is 15 meters thick with a horizontal native ground surface. The clay is underlain by 15-meter-thick bedrock, which is considered to be impenetrable, with a horizontal contact between them.

The embankment comprises a 30-meter-high starter dam called Phase 1, which includes a 3-meter-thick drainage blanket extending 60 meters under the starter dam from the dam toe. The starter dam includes upstream and downstream slopes of 2.5H:1V, with 5-meter-wide benches every 10 meters vertically on the downstream face. Note that the bottom 20 meters on the downstream face do not include a bench. The crest width is 10 meters.

The five additional phases, referred to as Phases 2 through 6, are each 10-meter raises with the same slope and crest geometry as Phase 1. The ultimate dam height is 80 meters with an overall downstream slope of 2.875H:1V.

The drainage blanket is 3 meters thick for Phases 2 through 6 to reduce contrast in zone size and thus reduce model run time. The drainage blanket continuously underlies the embankment, with chimney drains covering the downstream faces of Phases 1 and 3 (extended to the first bench below the crest) to intercept seepage.

The tailings on the upstream side were modeled with a freeboard of 3 meters below the dam crest of each respective phase. The upstream pond is assumed to be at the tailings surface.

Methodology

After the Phase 1 starter dam was placed, the model was run to end-of-primary consolidation such that all excess pore pressures were dissipated. For each phase subsequent raise, the model was run coupled, meaning that mechanical and flow calculations were performed simultaneously to simulate stress increase during embankment filling and consolidation during and after embankment filling. Each phase was gradually raised over a period of one year by ramping up the embankment density in 10 percent increments. After construction was completed for the individual phase, the model was run for an additional two years to allow for consolidation and dissipation of excess porewater pressures. Tailings deposition and the upstream pond were then placed against the upstream face of the dam, with the model brought to end-of-primary conditions. These steps were then repeated for subsequent raises.

Material parameters

The material parameters are shown in Table 1. The undrained shear strength s_u was estimated at the bottom of the clay foundation layer. The pre-consolidation stress was assumed to be about 890 kPa, which corresponds to an OCR of approximately 6 at the bottom of the clay layer, assuming a water table at the native ground surface with hydrostatic pore pressures.

Table 1: Material properties

Property	Bedrock	Native clay	Drainage blanket	Embankment clay	Tailings
Dry Unit Weight, γ_{dry} (kN/m^3)	25.0	17.5	18.0	17.5	14.5
Sat. Unit Weight, γ_{sat} (kN/m^3)	26.0	21.0	21.0	21.0	19.5
Young's Modulus, E (MPa)	100	20	30	20	1
Poisson's Ratio, ν'	0.20	0.30	0.30	0.30	0.25
Horizontal Perm., k_H (m/s)	1.0×10^{-6}	1.0×10^{-8}	2.5×10^{-5}	1.0×10^{-8}	1.0×10^{-6}
Anisotropy, k_H/k_V	1.0	1.0	1.0	1.0	1.0
Cohesion, c' (MPa)	1.5	0	0	0	0
Friction Angle, ϕ' (deg.)	38.0	28.0	35.0	28.0	25.0
USSR[1]	–	$0.22\times OCR^{0.8}$	–	–	0.18

[1] USSR is the yield undrained shear strength ratio; USSR = s_u/σ'_{vc}. Note that some researchers (e.g., Brown and Gillani, 2016) advocate capping the undrained envelope with the drained envelope at low confining stresses because negative porewater pressures can dissipate quickly in the field. This capping was not done in this exercise because the rate at which negative porewater pressures might dissipate, relative to positive porewater pressures, is unknown

Software

The phased construction of the downstream tailings dam presented herein was performed using the FLAC2D (Fast Lagrangian Analysis of Continua) version 8.1 software program developed by Itasca Consulting Group, Inc., which uses the finite difference method to solve nonlinear stress-strain systems. In this method, materials are represented by zones that form a grid to fit the geometry of the cross-section being analyzed. Each element behaves according to the user-prescribed linear or nonlinear stress-strain-strength model (i.e., constitutive model) in response to the applied forces and boundary conditions.

FLAC simulates the consolidation process (i.e., deformation and dissipation of the excess porewater pressures being generated from the embankment fill placement) in a realistic time frame by coupling the mechanical response and the porewater flow regime. As such, the model allows for the analysis of dam stability during construction, when excess porewater pressures are present in the native soils and consolidation is underway.

Results and discussion

During modeling, six monitoring points were established, as shown in Figure 2. Three were set near the bottom of the foundation clay layer, while three were in the middle of the clay layer. The x-coordinates were as follows: -105 m (under Phase 1 dam crest); -25 m (near Phase 1 dam toe); and 25 m (near Phase 2 dam toe, or under the ultimate Phase 6 dam crest).

Figure 3 shows the porewater pressure development during and after construction of Phase 2. The increase in porewater pressure during each 10 percent increment can be seen, with subsequent consolidation

before the next increment is placed. This discretization is a modeling simplification, but the overall general increase in pore pressures throughout the one year of Phase 2 construction can be seen.

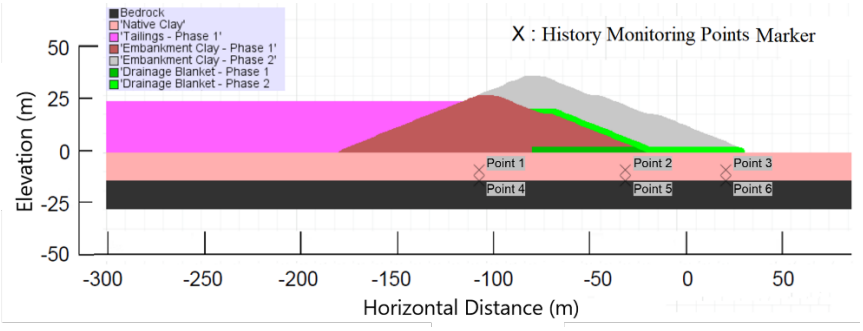

Figure 2: Monitoring point locations (with Phase 2 dam geometry)

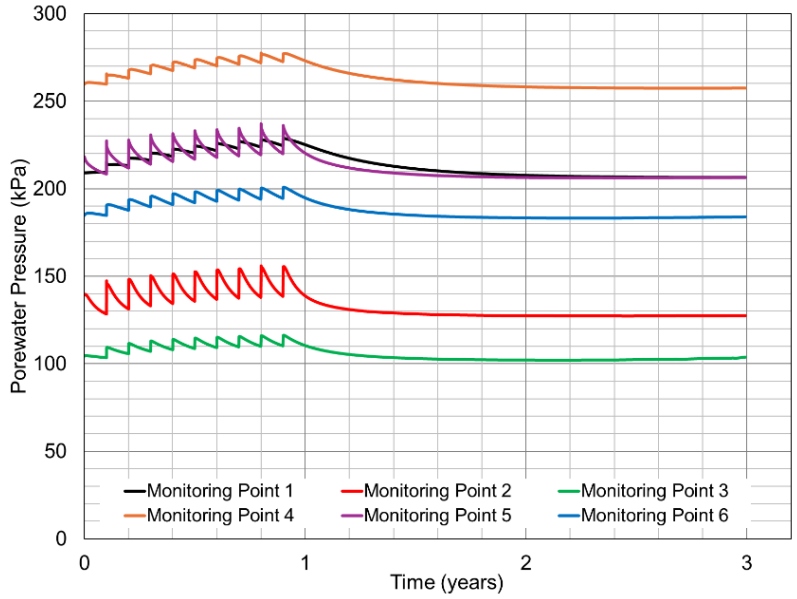

Figure 3: Porewater pressure histories in foundation clay during and after Phase 2 construction

Figure 4 is very similar to Figure 3, but it shows porewater pressure development for Phases 2 through 6. The same discretization can be seen during embankment filling for each phase, along with the two years of consolidation between each raise. It should be noted that an overall increase in porewater pressure can be seen even though end-of-primary conditions are generally reached after each raise. This is because the hydraulic boundary condition is increasing on the upstream face of the dam as the tailings and pond increase with the dam crest. In other words, excess pore pressure dissipation and accompanying effective stress increases are occurring during and after construction of the various raises, even though steady-state pore pressures are increasing throughout the embankment construction as the pond rises.

Figure 5 shows the OCR history at the same six monitoring points for Phases 2 through 6. It can be seen that initial OCR values after Phase 1 range from about 2 to 15. The OCR values of 2 are at Monitoring Points 1 and 4, which are located directly under the crest of the starter dam (Phase 1), such that they have already undergone some loading due to the end-of-primary conditions prior to Phase 2 loading. The OCR values of 15 and 8.5 at Monitoring Points 3 and 6, respectively, are consistent with a "very stiff" clay and represent the foundation clay in its native, pre-construction state. The OCR values then decrease with additional raises until all six fall below 2.0 during Phase 3, and reach 1.0 during Phase 5. During Phase 3, the material likely became contractive at all six monitoring locations and during Phase 5, the material became completely normally consolidated.

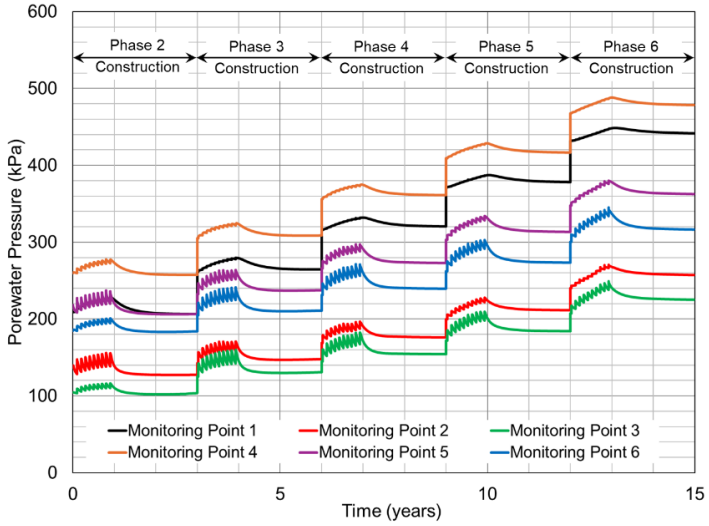

Figure 4: Porewater pressure histories in foundation clay throughout construction (Phases 2 – 6)

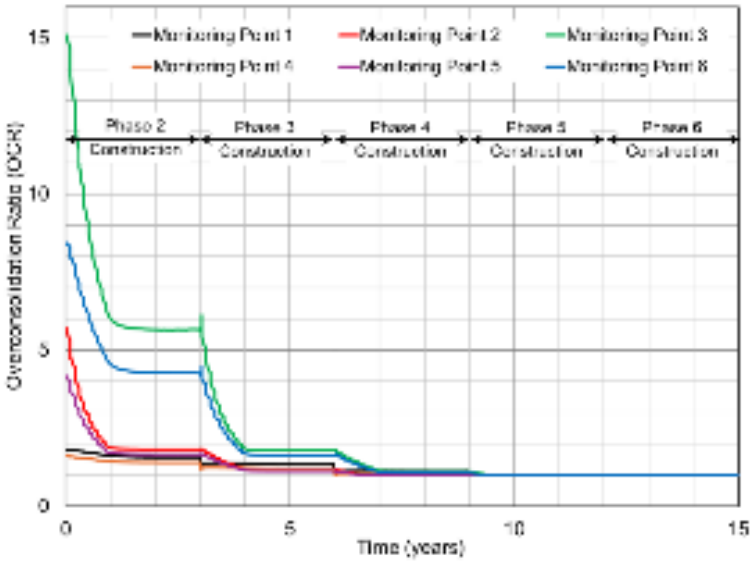

Figure 5: History of OCR at monitoring points throughout the phased construction

Given that the OCR is known throughout the construction process (Phases 2 through 6), the USSR can also be plotted as a function of the SHANSEP relationship, as shown in Figure 6. The initial USSR values at the end of Phase 1 range from about 0.3 to 1.9, with the low USSR values being under the starter dam (Phase 1) crest and the high USSR values being well downstream of the Phase 1 toe. During continued construction, the OCR values then decrease with additional raises until all six monitoring points fall below 0.40 during Phase 3 and reach 0.22 during Phase 5, which is consistent with the USSR of a completely normally consolidated clay.

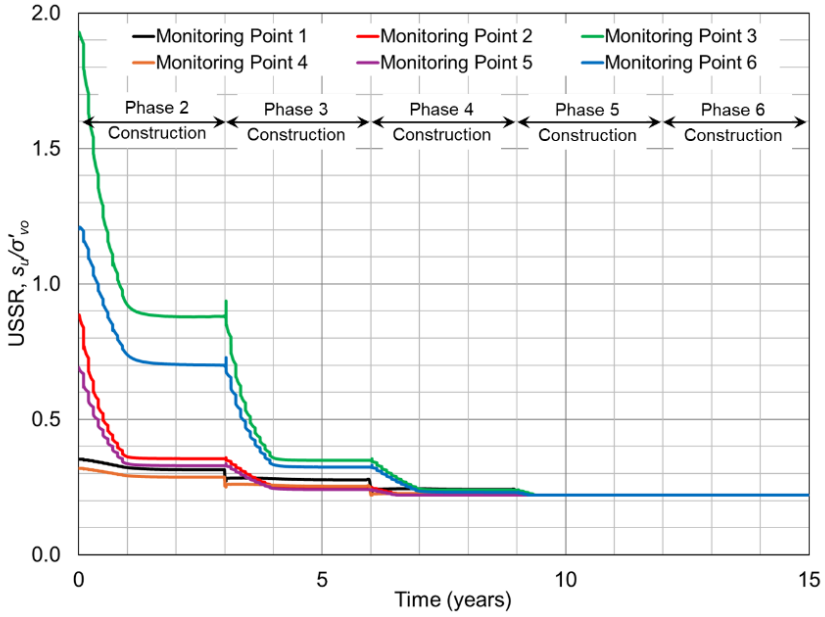

Figure 6: History of USSR at monitoring points throughout the phased construction

Figure 7 shows the evolution of s_u for all six phases of construction. It can be seen that s_u starts at 137 kPa at the bottom of the foundation clay downstream of the starter dam (Phase 1), which classifies the material as "very stiff" according to Terzaghi and Peck (1967). With subsequent raises, the s_u only increases with additional embankment filling and associated consolidation until it reaches about 325 kPa under the upstream portion of the ultimate embankment, with the load from the tailings contributing to this maximum s_u. However, as seen in Figures 5 and 6, the OCR and the normalized undrained shear strength ratio, or USSR, are decreasing, which leads to contractive, brittle behavior in which the undrained shear strength of the clay rather than the drained shear strength will likely be mobilized.

For each phase of construction, the factor of safety was computed for three cases: ESSA, USSA (EOP), and USSA (EOC), as shown in Table 2. ESSA stands for Effective Stress Stability Analysis; USSA stands for Undrained Strength Stability Analysis; EOP stands for End-of-Primary in which excess load-induced porewater pressures from the current raise are dissipated; EOC stands for End-of-Construction, in which

excess load-induced porewater pressures from the current raise are fully engaged. It should be noted that the ESSA factors of safety remain relatively constant throughout all phases of construction, as expected. The USSA cases, on the other hand, show a consistent drop in the computed factor of safety as the USSR in the foundation clay continues to decrease with increasing load from successive embankment filling.

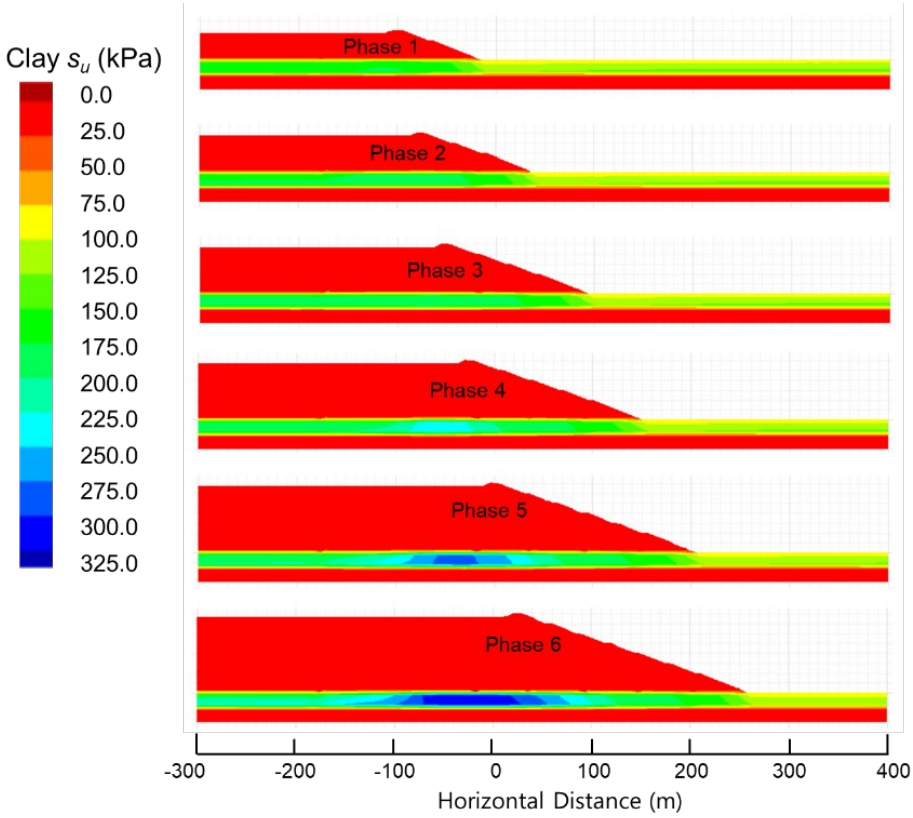

Figure 7: Evolution of s_u in foundation clay throughout the phased construction

Table 2: Factor of safety summary

Phase	ESSA	USSA-EOP	USSA-EOC
Phase 1 (Initial)	1.37	1.58	–
Phase 2	1.36	1.44	1.35
Phase 3	1.37	1.37	1.24
Phase 4	1.37	1.32	1.15
Phase 5	1.37	1.23	1.11
Phase 6	1.36	1.20	1.07

Figure 8 shows the critical slip surface for USSA-EOP conditions at Phase 5, with a computed factor of safety of 1.23. A very large composite, or block, potential failure surface can be seen extending to the

bottom of the foundation clay, indicating that the clay that is becoming normally consolidated at the base of the foundation clay is governing stability.

Figure 9 shows the critical slip surface for USSA-EOC conditions at Phase 6. The computed factor of safety is 1.07, and this represents the most critical undrained case at the ultimate dam height. Obviously, a factor of safety of 1.07 would not be considered acceptable for a tailings dam, especially when a brittle failure mode would be predicted.

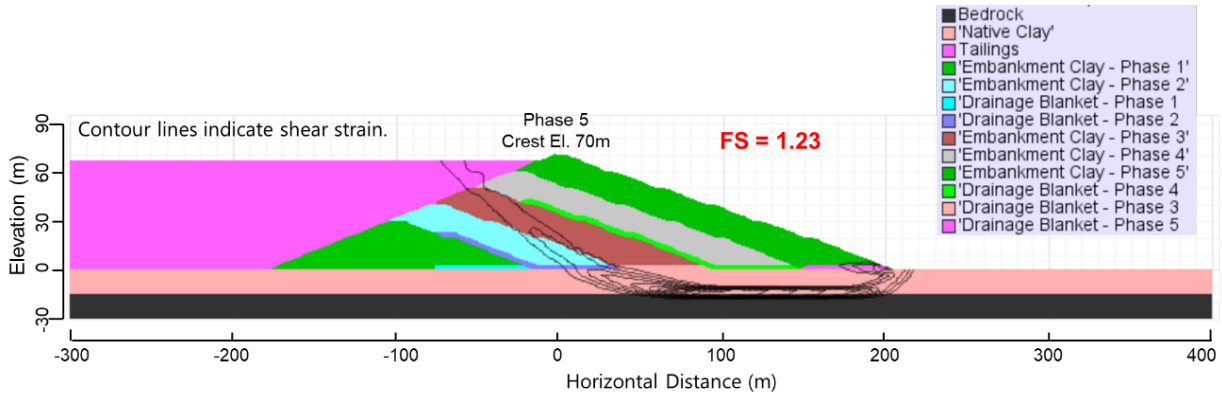

Figure 8: Typical critical slip surface for USSA-EOP conditions (Phase 5 shown)

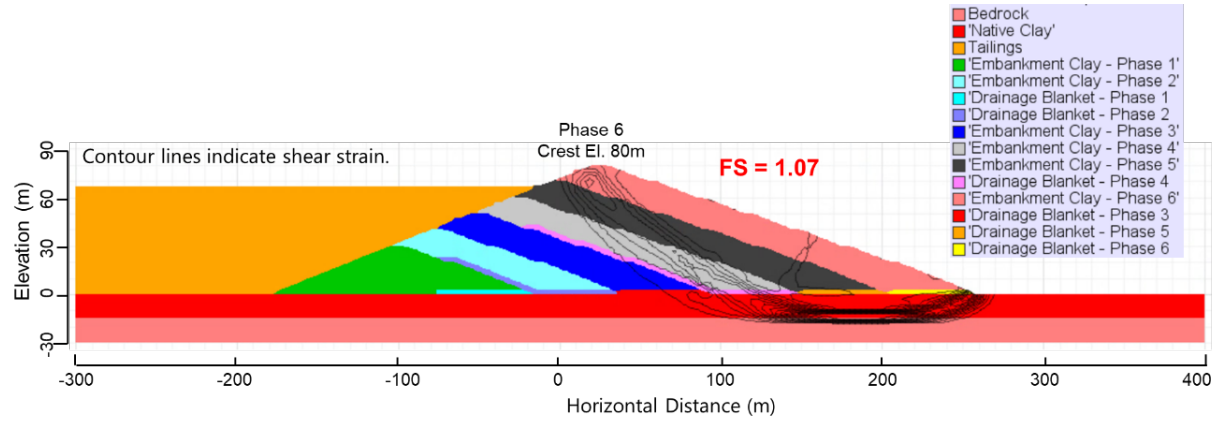

Figure 9: Critical slip surface for USSA-EOC conditions of Phase 6 dam raise

As a point of contrast to the USSA figures related to the SHANSEP phenomenon included above, Figure 10 shows the critical slip surface for the ESSA case at Phase 6, with a computed factor of safety of 1.36. As stated previously, this factor of safety remains relatively constant throughout dam construction, likely due to the shallow potential failure surface at the toe that remains constant throughout construction, in addition to low pore pressures in this area as a result of the drainage blanket. Also, the drained shear strength of the embankment and foundation materials, in the form of the friction angle, remains relatively constant throughout construction, in contrast to the USSR, which decreases as a function of increasing load according to the SHANSEP formulation.

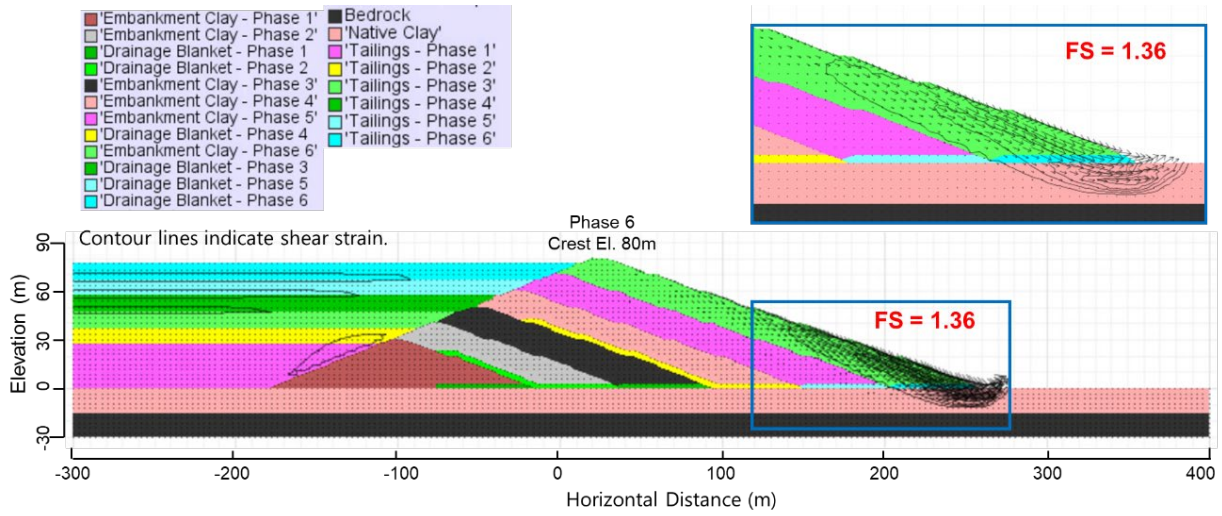

Figure 10: General critical slip surface for ESSA conditions (Phase 6 shown)

Conclusion

The discussion in this paper has led to the following conclusions:

- Overconsolidated clays of stiff to very stiff consistency can provide, in general, a relatively suitable foundation for tailings storage facilities when properly designed, considering the impact of stress history on strength.
- It is found that in practice these foundations are often mischaracterized during design, and this can lead to and has resulted in catastrophic failures.
- In some cases, the stiff clay foundations are solely characterized using the drained shear strength because they are considered “stiff clays” and thus they will mobilize the drained shear strength. While this is initially true, the stress history may change as the effective stress increases and the OCR decreases, resulting in slightly overconsolidated or normally consolidated clays, which tend to mobilize the undrained shear strength.
- In other cases, the possibility of mobilizing the undrained shear strength is acknowledged, but it is assumed that the undrained shear strength ratio initially determined on overconsolidated specimens remains constant over time and does not change with increasing effective stresses as the dams are raised. In reality, the initially high undrained shear strength ratio will tend to decrease with increasing effective stress.
- The SHANSEP procedure represents a practical technique that readily captures the change in undrained shear strength ratio and shear strength based on stress history. An example simulating construction of a downstream tailings dam founded on an overconsolidated clay using SHANSEP has been presented to illustrate its application.

- Figure 5 clearly shows how the OCR at the monitoring points within the foundation clay decreases as the dam crest increases with different construction phases. At Phase 5, the foundation clay becomes normally consolidated with an OCR=1.0.
- Similarly, Figure 6 clearly illustrates how the USSR at the monitoring points within the foundation clay decreases as the dam crest increases with different construction phases. At Phase 5, the foundation clay exhibits an undrained shear strength ratio of 0.22, which is associated with a normally consolidated undrained shear strength.
- In its native, pre-construction state, the bottom of the foundation clay was classified as "very stiff" and exhibited an undrained shear strength of 137 kPa with an OCR of about 8.5. With additional embankment loading, the undrained shear strength increased from 137 to 325 kPa while the OCR decreased from about 8.5 to 1, resulting in the USSR falling from about 1.2 to 0.22.
- Even though the undrained shear strength increased substantially due to embankment filling, the behavior would likely change from dilative, in which the drained shear strength would govern, to contractive in which the undrained shear strength would govern. This change in behavior is significant in that undrained failures of normally consolidated clay foundations can be brittle and sudden.
- The impact of these stress history effects on slope stability is indicated in Table 2, which summarizes the computed factor of safety. Table 2 shows that at Phase 6 the computed factors of safety are lower than the minimum recommended values.

Buttressing of Tailings Storage Facilities

Raquibul Alam, AtkinsRéalis, Canada
Ljiljana Josic, AtkinsRéalis, Canada

Abstract

Tailings dams, which store the tailings (usually in the form of slurry), a byproduct of mining operations, have a global impact. With over 18,000 such dams worldwide (the actual number may be higher), and about 3,500 currently active, the potential for catastrophic failure is not just a concern but a looming threat. The past few decades have seen numerous such failures, each releasing significant quantities of tailings into the natural environment. The resulting damage, including loss of life, environmental degradation, and economic disruption, underscores the urgent need for effective solutions. The instability of many existing tailing dams has become a significant concern in the mining industry. Mining companies are taking different measures in collaboration with engineering consulting companies to address the instability issues of existing tailings dams so as to avoid any casualties. Constructing buttresses at the dam toe is one practical solution, as it can effectively provide a resisting moment against slope failure by providing enough dead load near the toe of the dam. Buttresses are being designed and constructed to stabilize the existing tailings dams worldwide, including in high seismic areas. Adherence to international standards and guidelines is critical to their success and reliability. However, the authors have found that the buttressing of tailings dams has yet to be independently reviewed with an emphasis on fundamentals and design considerations. This paper presents how buttresses reinforce unstable tailings dams. Two case studies have also been summarized and discussed, in which buttresses stabilize the tailings dam by increasing the Factor of Safety (FoS) to safeguard and mitigate dam failures.

Introduction

Tailings are a by-product of the mining operations after extracting and recovering valuable minerals from ore. A tailings dam is typically an earth-fill or rock-fill embankment dam used to create tailings storage facilities (TSF) that store the tailings. The process of transporting these tailings involves using a pipeline to transport the tailings as a slurry to the TSF. This slurry, a mixture of water and soil particles, including medium sand, silt, and clay, is then discharged into the TSF using different techniques, including sub-aerial discharge, sub-aqueous discharge, and thickened discharge (Jewell, 1998). The coarse particles of tailings

(i.e., sand) settle close to discharging points while the fine particles (i.e., silt and clay) move down the beach into the tailings pond (Vick, 1990). Tailings dams are generally constructed by upstream, downstream, or center-line methods (Vick, 1990). Upstream tailings dams often show slope stability problems when the dam raising rate is too fast, generates excess pore water pressure and tailings with low hydraulic conductivity undergo slow consolidation (Zardari, 2011). Slope instability occurs when overturning moments exceed resisting moments, resulting in a slip failure.

On a global scale, the issue of tailings dam failure is not just a concern but a significant and pressing problem. There are more than 18,000 tailings dams, of which about 3,500 are active. Lyu et al. (2019) reported that in the past 100 years, about 1.2% of the total tailings dam failed or breached compared to the 0.01% failure rate of the traditional water storage dam. This alarming statistic, underscoring the global magnitude of the problem, should serve as a wake-up call to the industry. For instance, the 2019 Brumadinho dam disaster in Brazil resulted in the release of 12 million cubic meters of tailings, causing the loss of 270 lives and significant environmental damage. There are numerous causes for tailings dams' failures, including dam slope instability, inadequate foundation support, improper design without following any international guideline or standard, overtopping of tailings, seepage, erosion, earthquake, lack of monitoring and surveillance, etc. (Lyu et al., 2019; Rico et al., 2008). A failure of a tailings dam releases substantial quantities of tailings into the natural environment, causing severe casualties, including loss of life and the deterioration of environmental and cultural values, infrastructure, and economy.

Mining companies are collaborating with engineering consulting companies to address the instability issues of existing tailings dams and prevent potential casualties. This collaborative approach is a testament to the industry's commitment to safety and environmental responsibility. Buttresses, a proven method, are being designed and constructed to stabilize existing tailings dams worldwide, even in high seismic areas. It is important to note that the buttressing of the tailings dam has yet to be independently reviewed with an emphasis on fundamentals and design considerations. This paper aims to fill that gap by presenting how buttresses reinforce unstable tailings dams. Two case studies have also been summarized and discussed, where buttresses have not just increased the Factor of Safety (FoS) but have done so effectively, instilling confidence in their ability to safeguard and mitigate dam failures.

Factors affecting the stability of tailings dam

The literature has extensively cataloged a comprehensive list (e.g., Lyu et al., 2019) of dam failures. These failures, primarily attributed to earthquakes, seepage, foundation failure, and over-topping, are reminders of the critical need for robust design and maintenance of tailings dam construction. The following subsections present an overview of factors affecting dam stabilization.

Seepage/liquefaction

Many historical tailings dams were breached due to the rise in water level. Reasons for the water level (phreatic surface) to rise in the TSF include rains, floods, and the tailings dam's limited drainage capacity. The tailings below the phreatic surface have a slow consolidation process; saturated tailings increase the weight and reduce the shear strength and modulus of deformation, initiating piping effects, and liquefaction of granular materials or strain softening of the cohesive materials and ending up with tailings dam failure. Lyu et al. (2019) reported that about 21.6% of the total dam failures are due to seepage.

Each dam failure has a unique story. For example, the Huangmeishan tailings dam failed in 1986 after continuous rain for several days (Davies et al., 2000). The Omai dam failed in 1994 due to the tailings dam's limited filtration capacity, poor drainage performance, and high phreatic surface (Davies et al., 2000). In Aurul tailings dam, the phreatic line rose in 2000 due to heavy snow and snowmelt, which affected the stability of the tailings dam (Lyu et al., 2019).

Earthquakes

Lyu et al. (2019) reported that a significant portion, about 17.0%, of dam failures can be attributed to the destructive force of earthquakes. The consequences of these failures are stark, as evidenced by the El Cobre copper mine in Chile, which collapsed in 1965 due to earthquake liquefaction, releasing 2.3 Mm^3 of tailings and causing the loss of more than 200 lives (Dobry and Alvarez, 1967). Similarly, the Kayakari dam at the Ohya mine in Japan failed due to liquefaction in 2011, leading to significant damage to the downstream environment, following an earthquake (Lyu et al., 2019).

Foundation failure

Lyu et al. (2019) reported that about 17.3% of dam failures were caused by foundation failure. A notable instance of such a failure is the Mount Polley tailings dam failure in 2014, which released about 25 million m^3 of tailings and tailings water into the downstream lake basin (Petticrew et al., 2015). Lyu et al. (2019) explained that the load from the dam was more than the bearing capacity of the dam foundation material, resulting in shear damage to the dam foundation material. This technical detail is crucial for understanding the root cause of such failures.

Overtopping

Overtopping is one of the major causes of tailings dam failure. Lyu et al. (2019) reported that about 20.6% of dam failures were caused by overtopping. Many tailings ponds are located close to the dam crest. During heavy rainfall events, the water level in the TSF rises quickly. In addition, if the dam's permeability is poor, rainwater is discharged at a prolonged rate, resulting in the overtopping phenomenon, drastically affecting the dam's stability. Lyu et al. (2019) listed the three steps of a dam failure by overtopping: destabilization

under adverse conditions (e.g., flooding), followed by the interaction of tailings sand with water, forming a debris flow with high energy, and ending up with debris flow with high potential energy moving downstream. Merriespruit tailings dam, with less free board and less reservoir area, released 600,000 m^3 of tailings after a few hours of thundershowers in 1994 (Blight, 1997). Zijin tailings pond dam in Guangdong, China, also failed by overtopping after heavy rain, killing 22 people and destroying 6,370 houses (Lyu et al., 2019).

Others

Lyu et al. (2019) reported that about 23.5% of dam failures are caused by other reasons or combinations of two or more causes. One of the most devastating tailings dam failures in recent years happened in Córrego do Feijão Iron Ore Mine ("Dam I"), located 9 km northeast of Brumadinho, in Minas Gerais, Brazil. It suffered a sudden failure, resulting in a catastrophic mudflow that travelled rapidly downstream. The experts found several reasons behind this catastrophe (Peter et al., 2019):

1. a tailings pond closer to the crest resulted in weak tailings near the crest;
2. poor design;
3. insufficient internal drainage resulted in high water levels in the dam, particularly in the toe region;
4. high iron content, that made it susceptible to a brittle to undrained condition; and
5. high and intense regional rainfall reduced the strength of the unsaturated materials above the water level.

Based on the above discussion, it is evident that addressing the instability issues of existing tailings dams is one of the top priorities for mining companies to avoid casualties. The following section has outlined different options for stabilizing tailings dams, providing a roadmap for a safer and more sustainable future.

Stabilization of tailings dam

There are many ways to improve the stabilization of a tailings dam, such as ground improvement and creating unsaturated conditions in tailings to prevent liquefaction and flowability. In the context of tailings dams, unsaturated conditions refer to a state where the voids in the tailings are not entirely filled with water, which can help prevent the tailings from behaving like a liquid. Other methods include treating dam materials to increase their shear strength, using geogrids, constructing a buttress at the toe of a tailings dam, etc.

Several specific methods have been investigated for ground improvement to enhance slope stability and allow an existing dam to rise. For instance, Poulos (1995) found that installing piles on unstable slopes can effectively counteract driving forces and stabilize existing dams, a testament to the success of this method. Samuel and Jordan (2018) presented a case study on the nickel tailings dam in Thompson, Manitoba, where they found that rapid impact compaction of existing dam materials provided a solution by densifying the loose state of the dam material and improving its overall stability. Jet grouting, another ground improvement technique, has also been documented to stabilize the dam slope (e.g., Nikbakhtan et al., 2007), further reinforcing the effectiveness of these methods.

It is well established that the sensitivity of the dam stability depends on the increase in pore water pressure along a potential failure surface. Dewatering, a process of removing water from the tailings, might be an effective way of stabilizing the tailings dam where the phreatic level is high. Fourie and McPhail (1993) have shown that pumping and vertical de-watering wells successfully improved stability by lowering the phreatic surface and decommissioning the tailings dam in the (then) Transvaal province of South Africa. After successful dewatering, Fourie and McPhail (1993) noticed no surface sloughing on the outer slope. Electrokinetic and other dewatering techniques can also be considered for stabilizing tailings dams where excess pore water is an issue for stability (Shang and Xu, 2019).

Chemical treatment can be another solution for tailings dam stabilization by increasing the shear strength of the dam materials. Alsharedah (2023) simulated the treated tailings as construction materials for Sweden's Aitik upstream mine tailings dam. They used emulsified polymer, a cement kiln dust (CKD) mixture and recycled Gypsum (B) as the chemical agents. They concluded that the factor of safety (FoS) with the treated tailings was 20 to 25% higher than that of untreated tailings. Their proposed treatment also reduced the maximum settlement by 40%. Other mixing techniques, such as mixing with biopolymer (Chen et al., 2013), have also been documented to increase dam stability.

The slope stabilization of a tailings dam can also be achieved by using geogrids, due to their high tensile strength and resistance to chemical degradation (Mudenge and Kalumba, 2023). Geogrid reinforcement is a technique where a geogrid, a geosynthetic material with a grid-like structure, is introduced to provide additional strength to the dam structure. This reinforcement introduces a second resisting moment to the conventional moment equilibrium, enhancing the dam's stability. In a study by Mudenge and Kalumba (2023), the geogrid reinforcement system approximately doubled the FoS. However, they pointed out that the efficiency of geogrid reinforcement will vary depending on the geogrid type and other factors, including the tailings' geochemical and geotechnical characteristics and the dam geometry.

Adding a toe buttress is one of the most common and widely used practices in dam retrofitting. A toe buttress is a structure that provides sufficient dead load near the dam's toe and effectively provides a

resisting moment against slope failure. In other words, it counterbalances the driving forces that could cause the dam to fail. Ormann et al. (2013) found that the Aitik tailings dam in northern Sweden was stable up to the eleventh raising if the rockfill buttress was constructed at the downstream toe. Guilherme et al. (2023) concluded that the construction of a reinforcement buttress was needed to stabilize a tailings dam in Brazil. More details on buttressing, including fundamentals, design basis and case studies, are discussed in the following sections.

Fundamentals of stabilizing tailings dams with buttresses

Among the various options, as discussed in the previous section, this paper underscores the effectiveness of stabilizing tailings dams through buttress construction. Adding a buttress at the downstream toe proves to be a robust measure in resisting a tailings dam's slope failure. Figure 1 illustrates a typical circular slope failure, which can be more complex. However, for the sake of clarity, a circular failure surface is considered in this explanation. On a dam slope, two moments typically act on the failure mass: the resisting moment stabilizing the slope and the driving moment destabilizing it. Introducing a buttress at the dam toe significantly reduces the driving moment while simultaneously increasing the resisting moment, effectively stabilizing the dam. The resisting moment and driving moments are defined as follows:

$$\text{Resisting Moment} = T * R \qquad \text{(Equation 1)}$$

$$\text{Driving moment} = W * L \qquad \text{(Equation 2)}$$

Where T = Shear Force; R= Radius (also the moment arm of the shear force); W= weight of the soil (in failure mass), and L= moment arm of the weight

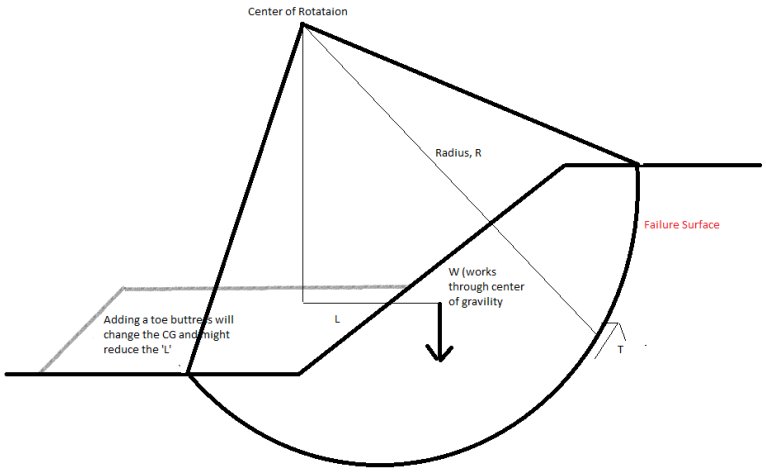

Figure 1: Failure surface on the slope without buttress

Adding a toe buttress modifies the dam's center of gravity. In most cases, it lowers the moment arms, L. As a result, it increases the overall slope stability by reducing the driving moment, as shown in Equation

2. Adding a buttress extends the failure surface through the buttress materials. Shear Force, T, is intricately linked to the soil's cohesion and friction. Therefore, using high-strength buttress materials (with higher cohesion and friction angle) plays a pivotal role in enhancing the resisting moment (Equation 1), thereby bolstering the overall strength and stability of the dam. However, it is crucial to note that optimizing buttress materials is a critical step. While it can increase the weight, W, and the driving moment, as shown in Equation 2, careful planning can prevent these issues. The buttress volume/quantity needs to be optimized to avoid a scenario where the overweight of the rockfill buttress may increase the sliding force and reduce the stability. Optimum design of buttressing ensures slope stability and reduces the construction cost by utilizing the minimum volume of a rockfill, a key consideration in any project.

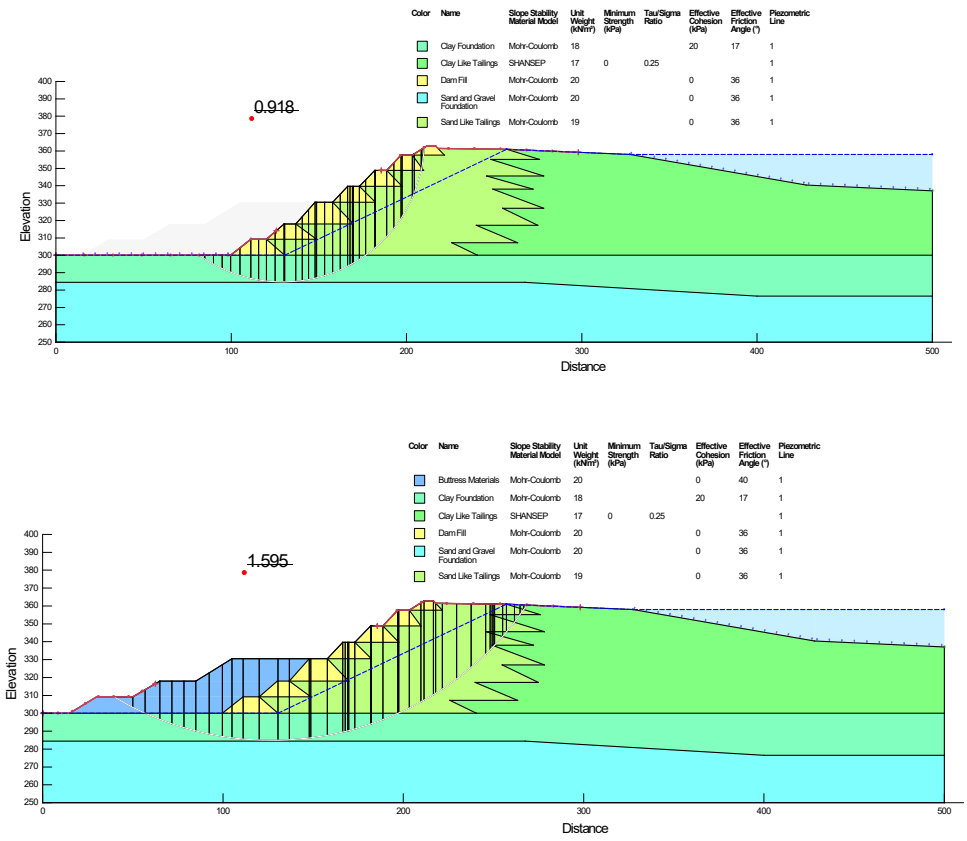

Figure 2: Slope stability analysis results before (upper) and after buttress (lower) construction

The authors have designed a typical tailings storage facility using GeoStudio 2021.4 (Slope/W) for demonstration purposes unrelated to specific projects, which is likely less complicated than an actual tailings storage facility. The strength of the materials used in this design is that they are typical values and are not based on any field or laboratory data. To evaluate the FoS, the authors used the limit equilibrium method (LEM). As seen in Figure 2, the FoS is only 0.918 without the buttress, whereas after adding the buttress, the FoS increases to 1.595. As shown in the illustration, the buttress extends the failure surface

through the buttress materials, which is a typical scenario. However, the failure surface might change based on material properties, geometry, etc. This typical design not only showcases the potential of a buttress to enhance the stability of an existing upstream tailings dam, but also opens up a world of possibilities for further research and innovation in the field.

The design basis of buttressing

There is no universal way of designing tailings dam buttresses, as every dam is unique in terms of tailings properties (such as particle size distribution, density, and chemical composition), mine site conditions (including topography, soil type, and climate), the storage capacity of the dam, and the available construction materials (such as rockfill, or compacted soil). There are national, state, or local governmental statutes, laws, regulations, ordinances, or other government directives for tailings dams and buttresses design, operation, and safety. The Global Industry Standard on Tailings Management (GISTM), a comprehensive framework developed by a coalition of industry leaders, plays a crucial role in providing a safe tailings facility management framework. It sets clear standards when designing dams and buttresses, ensuring that all aspects of design and construction are considered. The Canadian Dam Association (CDA), the Australian National Committee on Large Dams (ANCOLD), and the International Commission on Large Dams (ICOLD) can be used as guidelines. Many mining companies, such as Glencore, have developed standards and guidelines for their mining sites, reflecting each site's unique challenges and conditions.

The initial step in tailings dam or buttress design is the crucial process of dam classification, which involves assessing factors like population at risk and incremental losses. The details of the dam classification, which can be found in references like CDA (2019), ANCOLD (2012), or GISTM (2020), provide a comprehensive understanding of the dam's potential risks and vulnerabilities. The dam classification, determined through a dam break analysis and compared with the guidelines and standards mentioned above, guides the selection of earthquake loading and inflow design flood (IDF) loading conditions for the design analysis.

For example, Table 1 presents the recommended earthquake loading for designing based on dam classification. The authors refer to the CDA (2019) and ANCOLD (2012) for IDF loading, the most severe inflow flood to be considered in the design. Conducting a site-specific seismic hazard assessment is crucial for adapting the peak ground acceleration (PGA) corresponding to the annual exceedance probability (AEP) for liquefaction potential and stability analysis.

Buttressing is a pivotal step in the design process, significantly enhancing the safety of an existing tailings dam. The primary objective is to directly increase the dam's FoS, a critical ratio representing the available shear resistance along the potential failure plane, to the activating shear forces along the same plane. This understanding of FoS is vital in the design process, as it ensures that the dam is strong enough

to withstand potential stress. CDA (2019) and ANCOLD (2012) have recommended that the FoS values be considered under different loading conditions, as presented as examples in Table 2.

Table 1: Recommended design earthquake loading

Dam Category	CDA (2019)	ANCOLD (2012)			GISTM (2020)	
	AEP	OBE	MDE	Post Closure	Operations and Closure (Active care)	Passive-Closure (Passive Care)
Low	1/100 AEP	1:50	1:100	MCE	1/200	1/10,000
Significant	Between 1/100 and 1/1000	1:100	1:1000	MCE	1/1,000	1/10,000
High	1/2475	NA	NA	NA	1/2,475	1/10,000
Very high	Between 1/2475 and 1/10,000 or MCE	NA	NA	NA	1/5,000	1/10,000
Extreme	1/10,000 or MCE	NA	NA	NA	1/10,000	1/10,000
High/Extreme	NA	1:1000	1:10000	MCE		

Note: AEP: Annual Exceedance Probability-Earthquake; OBE: Operational Basis Earthquake; MDE: Maximum Design Earthquake; MCE: Maximum Credible Earthquake NA: Not Applicable

Table 2: Recommended factors of safety

CDA (2019)			ANCOLD (2012)		
Loading Condition	Minimum factor of safety	Slope	Loading Condition	Minimum for Tailings Dams	Shear strength to be used for evaluation
During or at the end of construction	>1.3 Depending on risk assessment during construction	Typically, downstream	Short-term undrained	1.5	Effective Strength
Long-term	1.5	Downstream	Long Term Drained	1.5	Consolidated Undrained Strength
Full or partial rapid drawdown	1.2-1.3	Upstream	Short-term undrained (no potential loss of containment)	1.3	Consolidated Undrained Strength
Pseudo-static	1.0		Post-seismic	1.0 -1.2	Post Seismic Shear Strength
Post-earthquake	1.2				

Stability analysis, a complex process that involves assessing the dam's ability to resist sliding and overturning under various conditions, is a crucial stage in buttress design. The goal is to find a buttress geometry that requires the lowest material volume and simultaneously provides the target FoS under different loading conditions to stabilize the dam. The loading condition will depend on several factors, including liquefaction potential, phase of operation, etc. The input data for slope stability analysis can be adopted from geotechnical investigations, laboratory analysis and instrumentation data. Different

commercial software, such as GeoStudio (geo slope), is available for performing stability analysis. Numerical Analysis (using Flac or Plexis) can also be performed for deformation analysis under earthquake loading to support the design if needed. The Engineer of Record (EoR) should verify the design, and any comments from the Independent Technical Review Board (ITRB) should be incorporated.

Case studies

In the following sub-sections, two case studies have been selected from two different continents, where designing phases show that a buttress at the downstream toe of the dams can effectively solve the stability issue of a tailings dam.

Case study #1

The Aitik tailings dam, primarily constructed using the upstream method, is near Gällivare in northern Sweden. The dam experienced a significant failure in 2000, spanning over 120 m of its length. This event, which underscored the importance of dam stability, prompted numerous subsequent studies on the Aitik tailings dam (e.g., Ormann et al., 2013; Alsharedah, 2023). One such study by Ormann et al. (2013) focused on fortifying the dam's slope by incorporating rockfill berms on the downstream toe. This approach was deemed effective as a substantial volume of rockfill was readily available at a short distance from the TSF. The study also detailed the optimization of the buttress design, with a typical section featuring a rockfill buttress shown in Figure 3.

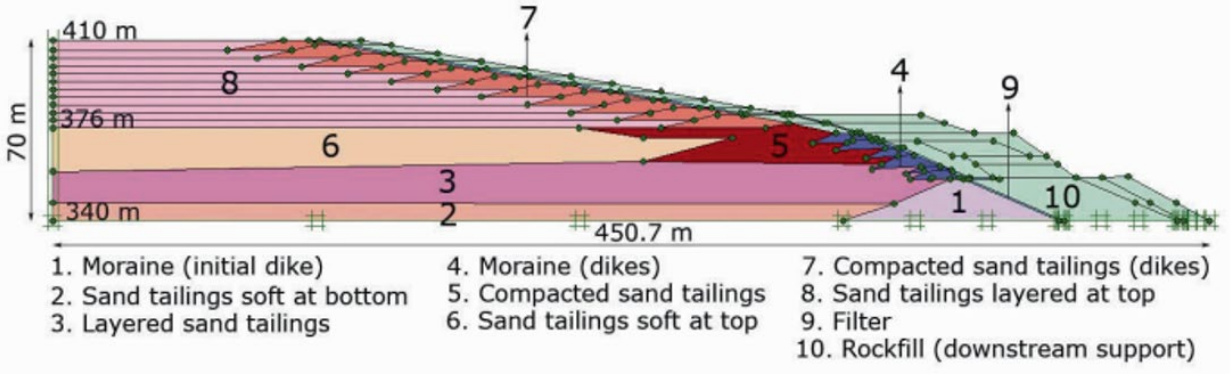

Figure 3: Cross-section of dam E-F (Ormann et al., 2013)

The authors undertook a meticulous finite element analysis using PLAXIS 2D to model the dam's staged construction and optimize the buttress's volume. The model parameters were derived from either laboratory testing or the available literature, ensuring a comprehensive and reliable foundation for the analysis. The phreatic level of the dam was determined using data obtained from piezometers installed at the dam. The dam was assumed to be constructed in eleven stages (from level 376 m to 410 m), with each stage thoroughly accounted for in the analysis.

The consolidation analyses were performed for staged construction to determine strength gain due to the dissipation of excess pore pressures. The Mohr-Coulomb (MC) model was chosen for all the dam's materials (tailings, rockfill and filter), ensuring a comprehensive and accurate representation of the dam's materials. A rockfill buttress was strategically placed on the downstream side, a key factor in improving the slope stability. The volume of the rockfill bank P (Figure 4) was optimized by changing the width and height of the buttress until a FoS of 1.5 was achieved according to the Swedish safety guidelines.

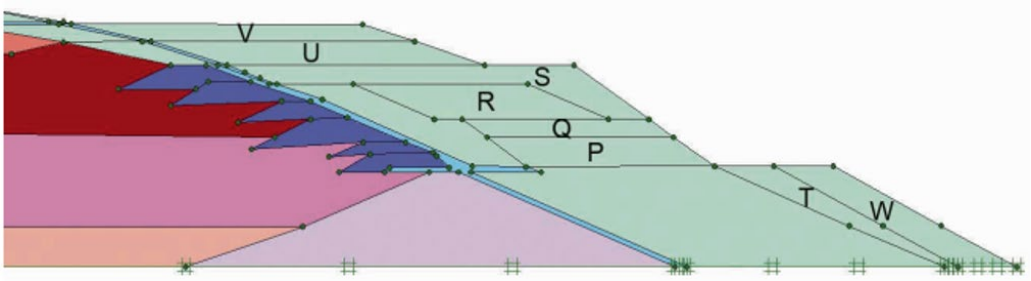

Figure 4: Placement of the rockfill banks on the downstream side to increase slope stability during construction (Ormann et al., 2013)

Following a similar procedure, the rockfill buttress Q, R, S, T, U, V, and W were assessed and designed for the fourth to tenth raisings, respectively (Figure 4). The slope stability was sufficient during the eleventh raising, so no rockfill buttress was added from this raise. This careful study demonstrated that the dam is stable up to the eleventh raising (level 410 m) only if the rockfill buttress was deliberately added to the downstream slope.

Case study #2

Guilherme et al. (2023) presented a study to simulate the stability of a dam in Brazil after reinforcement with a buttress at the downstream toe. The starter dike was designed with a 1H:2V slope. The dam was raised with a 1H:4V slope and constructed with tailings underflow. All the overflow was deposited on the TSF, creating a tailings beach. The structure has a 1 m thick drainage system of sand and gravel. The authors assessed the stability of the dam in two stages.

Firstly, they evaluated the FoS under the dam's current condition, using different failure surfaces, and compared it with CDA and Brazilian regulators' recommendations. Secondly, they assessed the buttress construction at the downstream toe to reinforce the structure, analyzing the excess porewater pressure generated and the deformation in the foundation soil during and after construction. To evaluate the FoS, they used the LEM in the initial condition (without buttress); a coupled analysis was performed using SLOPE/W and SEEP/W. The Morgenstern-Price method was applied. SIGMA/W was used to simulate the buttress construction, considering linear elastic parameters. Figure 5 shows a typical section of the dam and buttress used in the study.

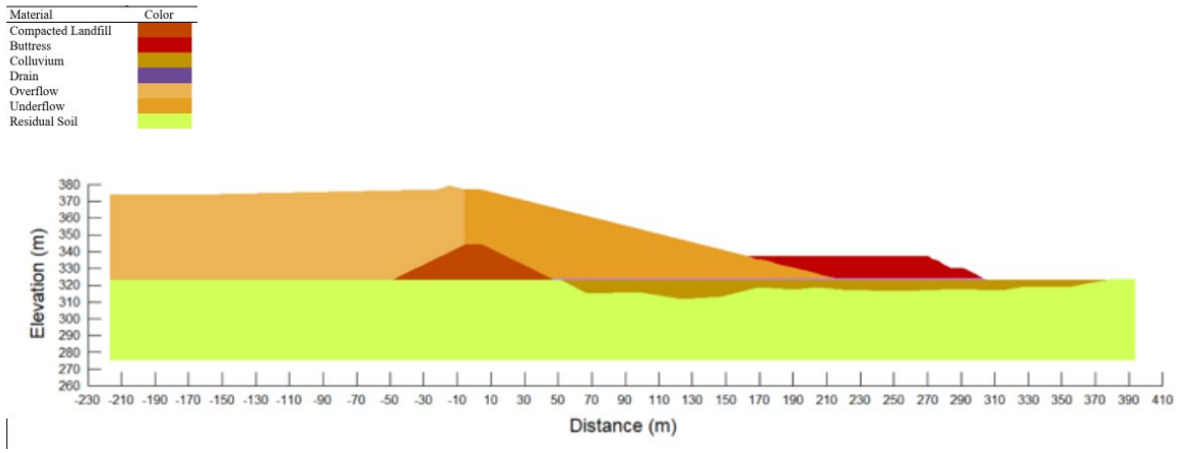

Figure 5: Dam cross-section with the preliminary buttress (in dark red) (Guilherme et al., 2023)

The authors found the structure did not meet the minimum FoS without a buttress at the downstream toe under non-circular, optimized circular, and non-circular surface failure. However, after reinforcing with a buttress, the dam met the requirements of CDA and Brazilian regulators' recommendations (ABNT NBR 13028), achieving an FoS higher than 1.50 as the criterion adopted in their study. The excess pore water pressure generation during and after the construction was evaluated using SIGMA/W. Figure 7 shows the variation of $\overline{B}$ over at a single point, tagged as a "Monitoring point" in the figure. The highest $\overline{B}$ found at the beginning of the buttress construction was 0.67, which decreases over time and becomes zero after approximately 60 days of construction. $\overline{B}$ equals 0, indicating the final dissipation of the generated pore pressure.

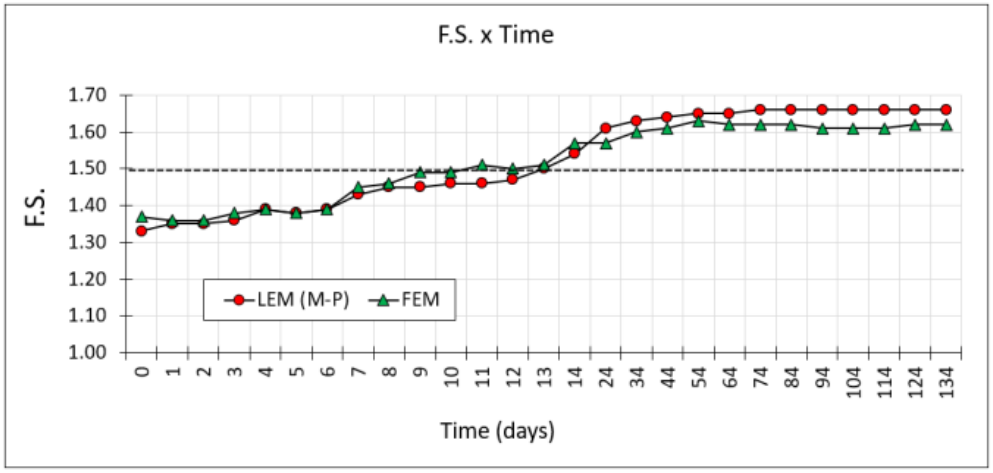

Figure 6: FoS over time (Guilherme et al., 2023)

Figure 6 shows that the calculated FoS (F.S) is lower than 1.50 at the beginning of the construction due to the high generation of porewater pressure. At the end of the construction, on the 14th day, the

porewater pressure dissipates. The calculated FoS (F.S in the figure) becomes higher than 1.50 and reaches the maximum of around 1.65 after 55 days. The study concludes that the construction of a reinforcement buttress was needed to stabilize the dam. However, it might take some time to dissipate the pore water pressure and achieve the target FoS.

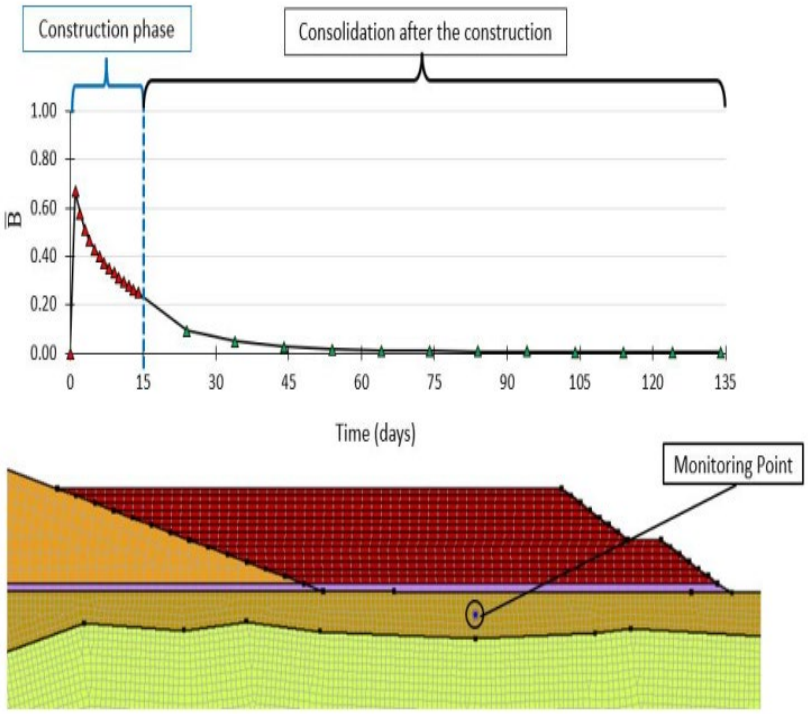

Figure 7 $\bar{B}$ summary over time (Guilherme et al., 2023)

Conclusion

This paper focuses on fundamentals, design basis, and three case studies in which buttressing has been demonstrated as a viable option for stabilizing tailing dams. The following conclusions can be drawn from the discussion:

- A tailings dam can fail for different causes, including but not limited to earthquakes, seepage, foundation failure, and over-topping, underscoring the critical need for robust design and maintenance in dam construction.
- There are many options to stabilize tailings dams, including ground improvement, treating dam materials, buttressing at the downstream toe, dewatering, geogrid application, etc.
- Buttressing is one of the effective solutions for stabilizing tailings dams. The optimum buttress configuration increases the overall slope stability by reducing the driving moment and improving the resisting moment.

- Appropriate guidelines or standard requirements must be followed while designing the buttress, without conflicting with local laws and regulations.
- This paper presents two compelling case studies from open literature. Case study 1 showcases the successful optimization of buttress geometry to stabilize a tailings dam. Case study 2, despite the time it took to achieve the target FoS, illustrates the effectiveness of buttressing in stabilizing a tailings dam once the pore water pressure has disappeared. These successes should instill confidence in the potential of buttressing as a solution.

Transportable Moisture Limit vs. Conveyability Testing

Christopher Olsen, FLSmidth, USA
Kenneth Rahal, FLSmidth, USA
Chris Braun, FLSmidth, USA
Skyler Pinnick, FLSmidth, USA

Abstract

As mining operations move towards adopting dry stack tailings, striking a delicate balance between the costs of dewatering systems and the transportability and stackability of the dewatered tailings becomes paramount. Typically, the expenses linked with dewatering tailings rise proportionally with the volume of water extracted from them. Conversely, the hazards associated with conveying and stacking dewatered tailings decrease significantly with the reduction in water content within the tailings. Achieving an optimal equilibrium between these factors is crucial for ensuring efficient and cost-effective implementation of dry stack tailings systems.

The Flow Moisture Point (FMP) and Transportable Moisture Limit (TML) serve as crucial indicators concerning the moisture content of bulk materials. The FMP signifies the moisture level at which a bulk material initiates flowability issues, transitioning from a cohesive and stagnant state to a free-flowing state. The TML is derived as 90% of the FMP value and represents the maximum allowable moisture content for bulk cargo to be deemed safe for transport. Specifically tied to maritime safety, the TML indicates the moisture content beyond which the material is susceptible to liquefaction.

Similarly, the utilization of a conveyor simulator apparatus for material testing is significant in optimizing operational and economic efficiencies in conveyor design. This level of simulation helps engineers and designers gain valuable insights into how different materials interact with the conveyor components under diverse material conditions. The data acquired from materials tested on the conveyor simulator apparatus serves as input values during the engineering phase of conveyor design, reducing the likelihood of failures and enhancing overall system safety.

As belt conveyor systems for transporting tailings are uncommon, industry standards for tailings conveyor handling are lacking. Consequently, TML testing data has been commonly adopted as a reference for establishing acceptable moisture levels for conveying dewatered tailings via belt conveyors.

This paper will illustrate the comparison of contrasting methods and their respective test data results through a case study focusing on flow table testing for TML and conveyor testing for material conveyability.

Each tailings sample will undergo testing for FMP, TML, conveyability, Proctor compaction, Atterberg limits, and plastic limits. The testing methods will be detailed, with particular attention given to the difference in the energy applied to the sample materials. Subsequently, the paper will analyze and compare the outcomes of these case study tests.

Introduction

The efficient transportation of bulk materials is a cornerstone of industrial operations, necessitating precise engineering and design to ensure both safety and operational effectiveness. The use of a conveyor testing apparatus has emerged as a crucial tool in optimizing these parameters. This apparatus provides engineers and designers with valuable insights into the behavior of different materials, including their varying moisture levels and characteristics, as they are transported along a conveyor belt. The data obtained from these tests are critical during the engineering phase of conveyor design, helping to reduce the likelihood of failures and enhance overall system performance. Notably, while the CEMA (2007) publication "Belt Conveyors for Bulk Materials" offers extensive guidance on conveyor operations and design calculations, it provides limited information on transporting mine tailings. The conveyor tester addresses this gap by simulating conveyor-like energy in the testing sample without the need for a full-size conveyor, allowing laboratory technicians to gather data at any point during the test.

In a parallel context, the Flow Moisture Point (FMP) and Transportable Moisture Limit (TML) are vital indicators of the moisture content in bulk materials, particularly for maritime transport. The FMP signifies the moisture level at which a bulk material begins to encounter flowability issues, shifting from a cohesive and stagnant state to a free-flowing one. This is crucial for managing material flow during loading, unloading, and storage, effectively addressing challenges such as caking and bridging. Conversely, the TML, set at 90% of the FMP, represents the maximum moisture content at which bulk cargo can be safely transported by sea. This limit is specifically tied to maritime safety, indicating the moisture content beyond which the material is susceptible to liquefaction – a phenomenon where solid bulk cargo behaves like a liquid under certain conditions, potentially compromising the ship's stability. In many cases, FMP and TML data from flow table testing have been integrated into material handling via conveyance systems to determine the maximum moisture at which materials, particularly tailings, can be safely transported.

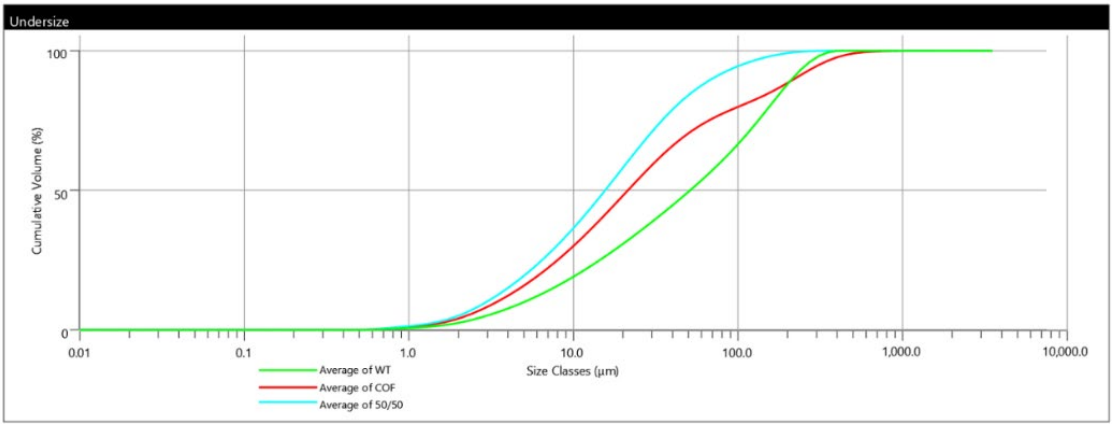
This paper explores the similarities and differences between these two tailings material testing procedures and methods. It compares the intended applications of the test results, material preparation, and energy input into the sample material during testing, and the material data collected from these tests. By examining these aspects, the study aims to provide a comprehensive understanding of how these testing tools contribute to the design of an efficient conveyor system for the transport of bulk materials, addressing gaps found in other conveyor publications.

The tailings samples for the case study

The tailings samples were collected from a pilot study with a focus on evaluating the tailings in various flowsheet dewatering processes. The pilot dewatering equipment included a cyclone, a thickener, and an automatic filterpress (AFP). The three samples collected were from the same tailings stream from the plant.

The Whole Tails (WT) sample bypassed the cyclone separation and was first thickened with the thickener with a XX flocculant, and then pumped to the filter feed tank and then to the AFP, producing a filter cake of 16%/wt moisture[1].

The Cyclone Overflow (COF) sample comes first from the overflow outlet of the cyclone, then is thickened with the thickener with a XX flocculant, and then is pumped to the filter feed tank and then to the AFP, producing a filter cake of 21%/wt moisture.



The 50/50 is a 50% WT and 50% COF sample blended in the filter feed and then pumped to the AFP, producing a filter cake of 18%/wt moisture.

The particle size distribution (PSD) and specific gravity (SG) of the samples are detailed in Table 1 and Table 2, respectively. The SG was measured using a Micromeritics AccuPyc II 1340 v2.01 pycnometer, while the PSD was evaluated with a Malvern Mastersizer v3.50 laser size analyzer. Additionally, an X-ray diffraction (XRD) analyzer was employed to determine the sample material's structure, mineral composition, and physical properties (Table 3).

Table 1: Sample specific gravity and PSD

Sample	SG	PSD		
Units:	g/cm³	P80 passing (µm)	P50 passing (µm)	P10 passing (µm)

Flow moisture point testing

Laboratory testing for the flow moisture point (FMP) involves a systematic procedure to determine the moisture content at which a bulk material changes its flowability characteristics, particularly becoming prone to liquefaction. This testing is crucial for understanding how moisture affects the material's cohesion and flow.

"To prevent the risk of liquefaction, International Maritime Organization (IMO) has specified tests to be carried out as per BC Code to determine upper bound acceptable of moisture content of cargo, which is defined by the Flow Moisture Point (FMP). The Transportable Moisture Limit (TML) is derived from the FMP… The Flow Table test is widely adopted for carrying out the test of FMP and TML" (Pinto et al., 2011).

The testing procedures carried out for this case study are based on the standard for flow table testing and adapted for testing tailings materials. Representative samples are collected to accurately reflect the moisture distribution of the material to be transported. The initial moisture content of the samples is measured to establish a baseline, ensuring that the material is initially in a dry state before controlled moisture is introduced. See Figures 2 through 4 for the before and after images for the flow table testing on the material samples.

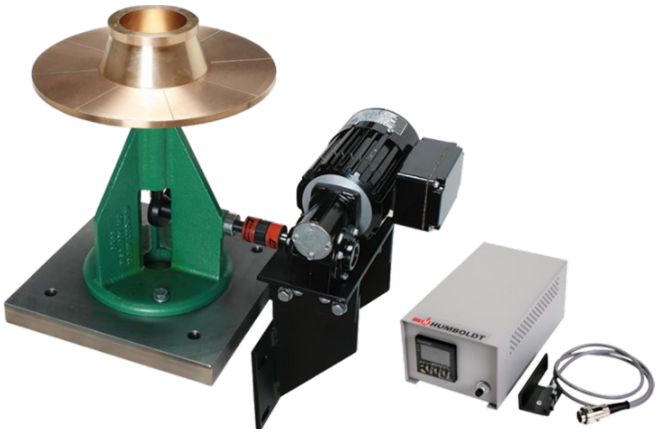

Figure 1: Flow table test unit

The flow table testing apparatus (see Figure 1) agitates the material to mimic handling conditions, assessing its flow characteristics at different moisture contents. The tailings samples were compacted into a truncated cone mold with a base diameter of 100 mm in three compacted levels. The flow table is initiated to apply 25 cycles of 12 mm drops. The testing identifies the moisture level at which the material begins to exhibit fluid-like behavior. Measurements and observations are taken to note changes in cohesion, clumping, and resistance to flow (see Figures 2 through 4).

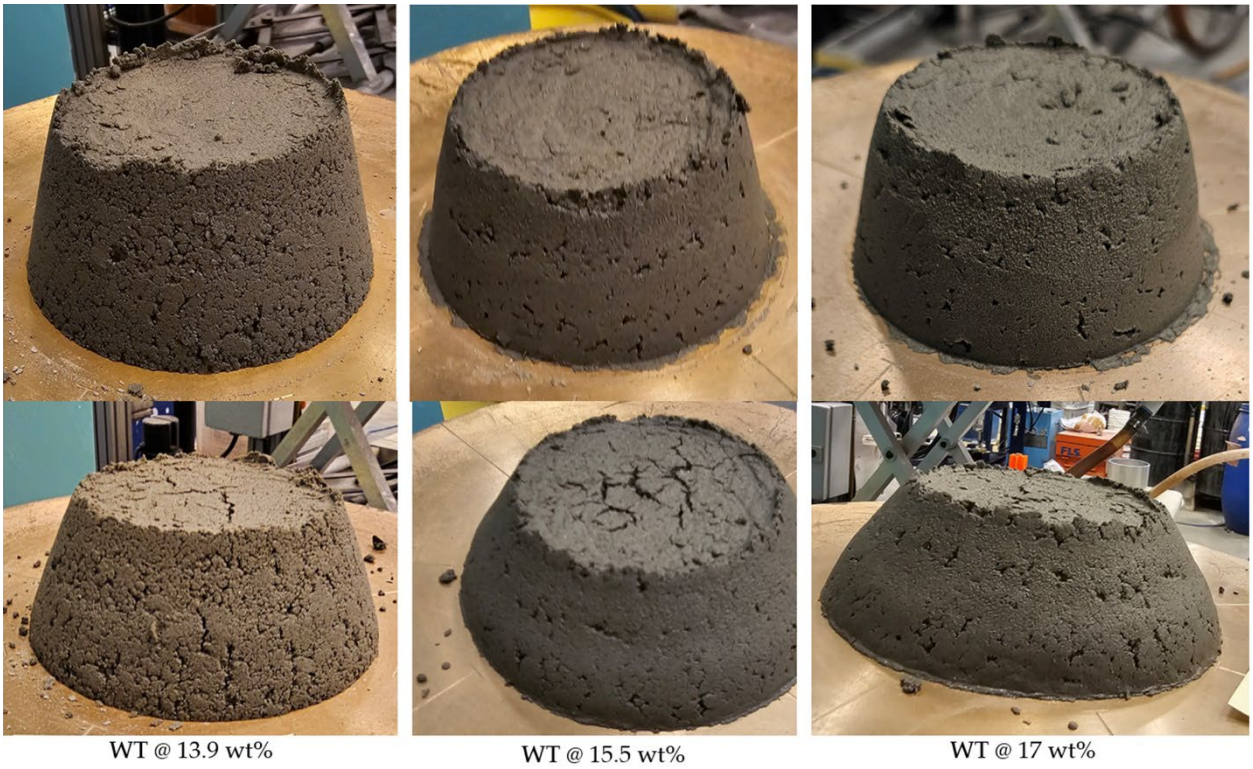

Figure 2: WT samples before and after

The data collected is used to determine the critical moisture content for TML, which is calculated as 90% of the FMP (see Tables 4 through 6). This analysis interprets the material's response to varying moisture levels and identifies the specific point of significant change in flowability.

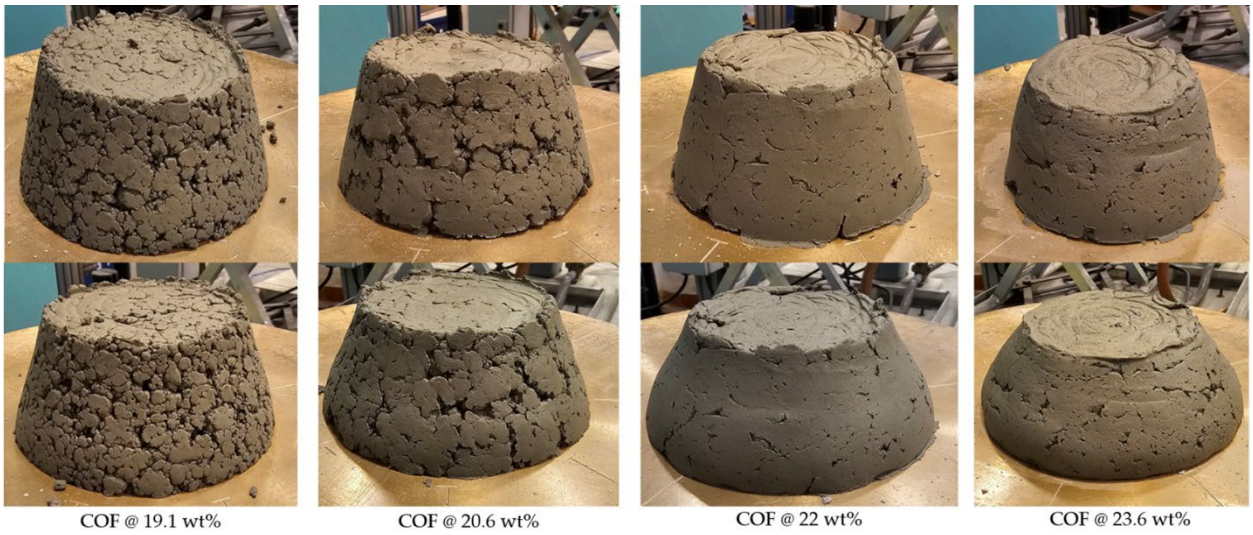

Figure 3: COF samples before and after

Table 6: COF sample flow moisture point

Conveyability testing

The FLS conveyor testing simulators, illustrated in Figure 5, are designed to simulate how bulk materials behave during conveyor transportation. These simulators feature a static belt with revolving idler rollers, whose speed is controlled by a Variable Frequency Drive (VFD). Additionally, the belt's tension is adjustable to match the belt sag parameters established by conveyor sizing calculations. The simulators can also be inclined to represent different conveyor slopes. *"The proper design and operation of the MH portion of the tailing solution requires thorough testing of the conveying properties of the material at the laboratory and pilot scale. This testing will ensure that the material handling system meets the important availability and capacity needs of the mine, even during periods of variability in the upstream processes and mine plan. This testing must include investigation of the impact of moisture content on the MH system"* (Rahal et al., 2018).

Figure 5: Left: conveyor tester 1.0. Right: conveyor tester 2.0

The conveyability testing apparatus simulates real-world conditions to evaluate the behavior of tailings on a conveyor system. Since no standard procedures exist for this unique equipment, FLSmidth has developed specific testing methods. Tests use filter cake samples representing various flowsheet options like whole mill tails, cyclone underflow, and overflow, with different tailings blends, particle sizes, and moisture contents. The goal is to assess the conveyability parameters of these samples.

Each test starts with calibrating the belt speed and tension. Tailings samples, prepared with various blends and moisture levels, are loaded onto the conveyor to simulate realistic conditions. The tests simulate incremental conveyed distances to evaluate material behavior at incremental conveyed distances (see figures 6 through 8). For slope tests, the conveyor runs horizontally for a duration for the material to start to self-compact, then runs for a shorter duration at an incline and then at a decline, observing factors like liquefaction potential, material flow-back, surcharge angle changes (see Table 7), material self-compacting, material loss to belt friction, and deviations from expected behavior. Monitoring these factors helps identify potential issues affecting conveyor system efficiency and design.

Testing comparison

The intent of the results from the material testing

FMP testing establishes a material's moisture content limit, serving as the basis for determining the Transportable Moisture Limit (TML). The TML test identifies the moisture content at which a bulk cargo begins to behave like a liquid. Set 10% below the FMP, the TML represents the maximum moisture content for safely transporting bulk cargo without risking liquefaction, ensuring a safety margin for dynamic conditions during transport.

"A solid bulk cargo consists of three main components: a solid component; a moisture component; and an amount of air (void space) in between. Vibration and the motion of a vessel will cause the cargo stowed in the holds to compact the moisture and small particles contained in the cargo. In certain conditions, a cargo can compact to such an extent that there is no more void space (air) between solid and water particles. When there is more water inside the cargo than there is space between the particles, and the water has nowhere to go, then the water pressure between the particles may rise and press the particles apart. This will either result in a sliding failure or the wet base of the cargo will transition from a solid state to a viscous fluid." (London P&I Club, 2017)

Shipping companies use the TML to comply with international maritime safety regulations, especially those set by the International Maritime Organization (IMO).

"It has been found that moist, loosely deposited fine-grain ore stockpiles can liquify during transportation by barges. This liquefaction occurs when the vibrations caused by the motion of the barges causes the wet ore to densify (compact). The body weight of the ore is transferred to the water existing in the voids between the ore particles and shear resistance is loss. The ore becomes a very dense liquid and this jeopardizes the stability of the vessel." (Gallagher et al., 2005)

These measurement values are crucial for the safe loading and transport of bulk materials by shipping vessels. In some cases, the TML has been adopted as a measurement variable to define the moisture level for tailings transportation on conveyor applications.

The conveyor tester was specifically developed to test materials transported via conveyor belts. "*Both thickened and paste tailings are saturated with water. Filter cake can be saturated or not saturated depending on whether air is used to dewater the cake. Some filters like belt presses and centrifuges cannot blow air through the cake. Saturated and unsaturated filter cake can usually be conveyed but may have a low surcharge angle which is important to understand so the conveyor can be correctly sized. FLSmidth has developed a proprietary test to determine the conveyability of filter tailings… that must be understood to ensure proper conveyor and design."* (Wisdom, 2020). The data collected from the conveyability tests go directly into the engineering design calculations for each conveyor within the system, from plant conveyors to overland conveyors.

Material preparation for the testing apprentices

The preparation of tailings blends and moisture content for both types of testing follow the same procedure. Material blends were sourced from the filter press pilot study, using the three specified sample types. Moisture preparation was carried out according to the specified testing procedures.

In flow table testing, the sample material is compacted into the mold at three levels to fill it completely. This process introduces inconsistencies due to manual compaction. While devices exist to apply consistent pressure, many tests use a spring-loaded tamper for manual compaction. This results in variability between tests and different laboratory technicians. Additionally, this method does not account for the self-compaction of tailings during conveyor agitation, focusing instead on a pre-compacted state before any external energy is applied.

For conveyability testing, the tailings material is dumped into the testing bed, simulating a conveyor-to-conveyor transfer point with realistic drop height, skirtboard boundaries, and cross-sectional fill. The material is in an as-loaded condition, partially compacted with a measurable angle of repose. Ensuring the correct quantity of material is critical for consistency, as under-filled or over-filled conveyor sections can affect the energy input differently than intended by the test procedures.

The energy input into the sample material during testing

In flow table testing, the energy input is associated with the potential energy transferred to the material when the table is raised and subsequently released. This allows the table to fall from a predetermined height, creating a full-impact, inelastic collision. The energy input vector is strictly vertical, meaning the force is directed straight downward. As a result, the tailings material absorbs a significant portion of the collision energy, leading to noticeable effects on the molded sample.

Each time the table falls, the impact causes the molded tailings sample to either bounce and fragment or deform progressively from the base upward. This deformation occurs as the material responds to the force, with the lower layers compacting first and the upper layers following suit. The repeated impacts simulate dynamic impact conditions, providing insights into how the tailings material behaves under stress at varying moisture levels. The vertical impact force not only compacts the material but also causes it to spread radially, mimicking the way tailings would spread when subjected to similar conditions in practical applications.

During the conveyability testing the movement of the tailings material is much more like a wave than a vertical rise and fall inelastic collision. The wave that the tailings material constantly travels on has a low amplitude-to-wavelength ratio, with the wavelength being the points where the conveyor belt contacts the idlers and the amplitude being one-half of the belt sag distance. With the material traveling like a wave, the energy and the force vectors become very different. The tailings material does not absorb nearly the same

amount of energy from the up-and-down movement because it does not experience an inelastic collision. An example comparison between the vertical forces applied in the two test methods is like driving down a bumpy road in a car without any suspension versus the same bumpy road in a car with suspension. See Figure 9 for a side-by-side comparison of the two tests performed on the same samples with the same moisture content. Comparing the highest tested moisture content of the sample types shows the most movement, self-compaction, and deformation from the testing.

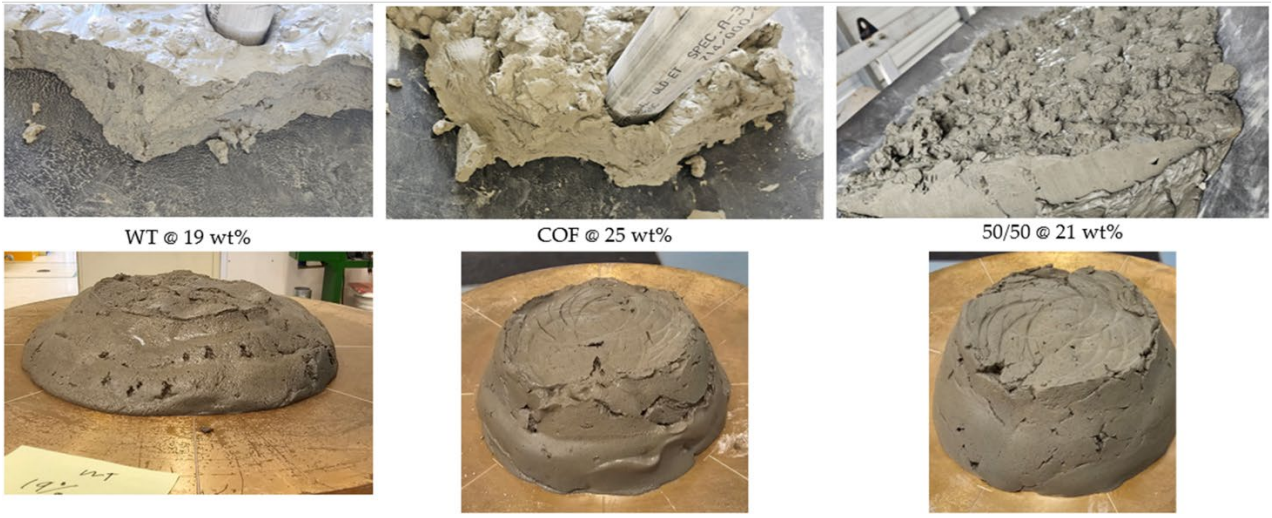

Figure 9: Side-by-side testing comparison of the samples tested at the highest moisture content

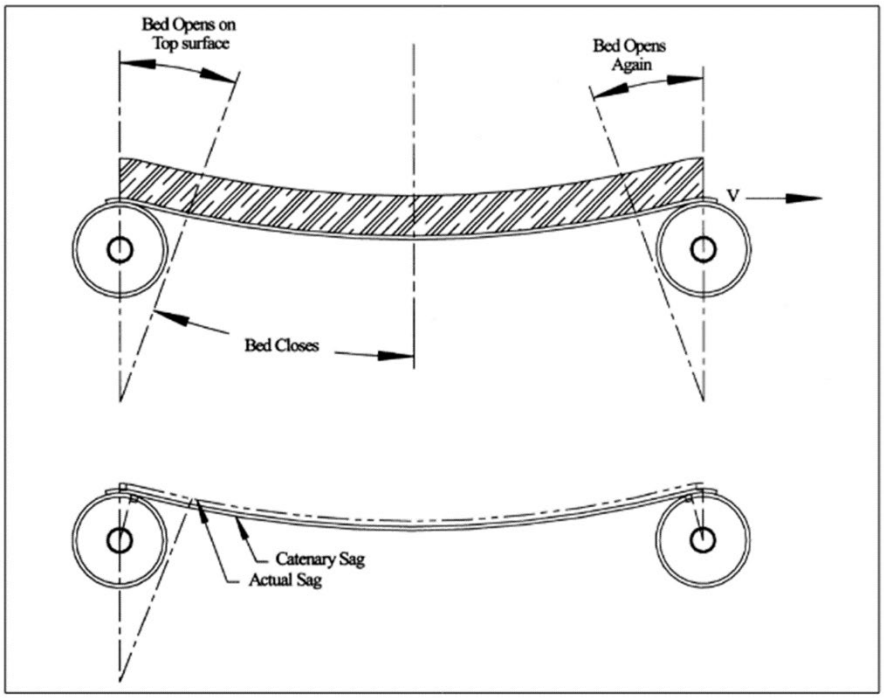

Figure 10: CEMA material deformation caused by belt sag (CEMA, 2007)

The energy input observed with the conveyor tester involves the tailings material continuously undergoing tension and compression forces. The material experiences slight separation as it reaches the apex of the wave amplitude while traveling over the idler, and slight compression at the trough's apex when passing through the belt sag's low point between idlers (see Figure 10). This wave travel energy causes the tailings material to self-compact, promoting internal movement that fills voids and transitions the material bed from its initial angle of repose to the dynamic surcharge angle. This energy transfer from the conveyor belt into the material bed is referred to in CEMA standards as Material Trampling Loss.

"The belt sag causes the individual particles of bulk material to repeatedly move against each other as they progress from one idler to the next, with consequent energy loss due to internal friction. Energy must be added through the material depth to overcome the internal friction forces as the material closes on itself between an idler and the point of maximum sag at the center of the idler spacing. A portion of this energy is recovered as the bed depth opens up again in the section from mid span to the idler. Note that there is no net elevation change and therefore no potential energy change between idlers" (CEMA, 2007).

The CEMA standards outline the calculations for determining material trample loss, which is one of the many factors considered when sizing the power requirements for a conveyor.

The CEMA publications provide a comprehensive list of material and belt factors that contribute to energy loss during conveyor operations. They include the necessary equations to calculate and quantify these losses accurately. The primary purpose of these guidelines is to account for as many energy losses as possible, aiding engineers in correctly determining the energy requirements of a conveyor system.

In the context of conveyor operations, we consider both the energy loss in the conveyor system and the energy gain for the transported material. The material gains energy through material-on-material movement and friction. These interactions, driven by the conveyor's motion, contribute to the material's self-compaction. As the material moves along the conveyor belt, it experiences various forces that cause internal movement, filling voids, and increasing density. If sufficient moisture is present, there may be a fleeting occurrence of material liquefaction. This self-compaction is a critical factor for engineers to consider, as it affects the overall efficiency and design of the conveyor system.

In addition to material trampling in the parallel plane of the conveyor belt, a small amount of material deformation also occurs in a plane perpendicular to the conveyor belt's length. Although not mentioned in CEMA publications, this secondary material trampling is observed during the conveyor tester's testing. It happens when the tension on the conveyor belt causes it to flatten slightly between the idlers and then return to a full trough as the belt moves directly over the carry idler. This "belt flapping" causes the tailings material on the belt to experience tension and compression cycles perpendicular to the belt length.

The compression and tension forces from the belt trampling parallel to the belt and the belt flapping perpendicular to the belt directly oppose each other. When the belt is at the bottom of the sag, trampling is

in compression, and flapping is in tension. Conversely, when the belt is at its peak, directly over the conveyor idler, trampling is in tension, and flapping is in compression.

Figure 11: Top left: the tailings start to "camel hump." Top right: the camel hump continues to form. Bottom: the camel humps at the end of the testing

There have been instances where tailings and other tested materials formed into a "camel hump" on the cross-section of the belt (see Figure 11)[2]. This rare occurrence is considered a combination of belt flapping and material characteristics. In tests performed on this tailings sample, only the sample with lower moisture content exhibited camel humps during testing, indicating that moisture levels might play a role in this phenomenon. Three conveyor tests were conducted, and this anomaly was observed solely in the lowest moisture sample, suggesting that specific conditions are necessary for the camel hump effect to manifest.

Data that is collected from the tests

The flow table test generates highly specific data, focusing on identifying the FMP where material experiences liquefaction under specific energy loading. Understanding the FMP helps industries determine the TML, crucial for implementing preventive measures against material flow issues. These measures include adjusting storage conditions, using moisture control strategies, or selecting suitable handling equipment to maintain optimal material flow. Adhering to TML regulations ensures the moisture content of transported material stays within acceptable limits, vital for international shipping compliance. The primary

[2] Note: the sample referenced in Figure 5 is not among the three test samples from this case study.

goal of using TML for conveyor transport of tailings is to prevent the material from liquefying during conveyance.

Secondary data from the flow table test includes bulk density and visual analysis of material deformation, complementing the primary goal of determining the FMP.

Conveyor testing yields two main data points: the change in the surcharge angle throughout the conveyor's travel length and the maximum slope angle at which material can be conveyed at a tested moisture level. A graph is created based on the tailings sample and its moisture content. For example, if an engineer expects the tailings on the conveyor to have a 16 wt% moisture content and is designing conveyors of 550 m, 2,067 m, and 560 m in length, they can use the graph to determine the appropriate surcharge angle for each conveyor calculation. Additionally, the maximum slope angle data aids in the design and layout of the conveyor system.

Secondary data for the conveyor tests include the initial and ending bulk densities of the tailings material, the initial angle of repose of the material loaded onto the conveyor, and visual observations of the material's behavior during conveyance. These secondary data points provide additional insights into the material's handling characteristics, supporting the optimization of conveyor system design and operation.

Conclusion

The transportation of bulk materials, especially mine tailings, is crucial to industrial operations, requiring precise engineering and design. Specialized testing apparatuses, such as the conveyor tester and FMP testing, provide essential insights into these materials' behavior under various conditions. This paper details the methodologies and outcomes of these tests, highlighting their importance in optimizing conveyor systems and ensuring safe material transport.

The conveyor tester offers a practical solution to the challenges of tailings transportation. By simulating real-world conveyor conditions, it assesses conveyability parameters, including moisture content and material composition. This data directly informs the engineering design of conveyor systems, ensuring they can handle the dynamic nature of bulk materials in mining operations.

FMP testing determines the safe moisture limits for bulk materials during maritime transport. The FMP and derived TML are vital for preventing liquefaction, a hazardous condition where materials behave like liquids under certain conditions. This testing ensures compliance with international maritime safety standards and provides guidelines for managing moisture content in conveyor systems to prevent flowability issues.

Using the TML as a limit for conveyor transport offers only a partial understanding of a broader issue. Conveyor testing of tailings has shown that while these materials can liquefy during transport, they can still be conveyed. Comparing these two testing methodologies highlights their roles in tailings conveyor system

design. FMP testing focuses on moisture-induced flow characteristics, while conveyor testing emphasizes physical handling and dynamics. Both sets of data are useful for determining conveyability, but conveyor testing offers deeper insights and is essential for designing efficient and safe tailings handling systems.

These tests provide comprehensive data supporting the development of robust conveyor systems capable of maintaining operational efficiency and safety. By addressing gaps left by standard conveyor design publications, particularly for mine tailings, these testing methods advance material handling technologies and practices.

Learning from Experience – Let's Get Real

Malcolm Barker, GHD, Australia

Abstract

Having been in the design, safety and risk analysis of dams for nearly fifty years, what have I learned and what does it mean for the younger generation of engineers? Can we learn from other people's experiences or do we just carry on making the same mistakes or errors?

Many of the safety procedures that have been put in place over recent years have significantly reduced the potential for life loss and injury, but these have come at a cost, and have we reduced the risks as low as reasonably practicable in our design and construction for tailings facilities?

In this paper, I will share some of my experiences in the hope that other engineers will learn from my failures and successes.

Introduction

There are good and bad human behaviors that define the way we approach problems of design, construction, operation, maintenance, and finally decommissioning of structures or closure of tailings storage facilities. Life's journey is up and down or round and around, as shown in Figure 1.

Figure 1: Life's journey is up and down or round and about

"Insanity is doing the same thing over and over and expecting a different result." This is a quote often attributed to Albert Einstein, although it is likely he never said this.

"Learning is a matter of gathering knowledge; wisdom is applying that knowledge." Unknown.

So, what about human behavior and how this can lead to failures and successes?

Human behavior

In his article "Dam incidents and failures can fundamentally be attributed to human factors" Irfan (undated) states the following:

"The field of "human factors" considers how and why systems meet or don't meet performance expectations, with an emphasis on understanding and prevention of incidents and failures. The systems considered in human factors work, such as dams, typically include both human and physical aspects, and are sometimes referred to as "sociotechnical" systems. To prevent future dam failures, it is essential that dam safety professionals understand both physical factors and human factors, and how they contribute to failures or safety.

Physical processes deterministically follow physical laws, with no possibility of physical 'mistakes.' Failures are, therefore, fundamentally due to human factors and a story of why a failure happened therefore cannot be complete without reference to contributing human factors."

According to the UK Health and Safety Guidance document "Reducing Error and Influencing Behaviour" (HSG48, 1999), human failures can be categorized as either errors or violations, as shown in Figure 2. In the context of dam safety, "mistakes" are the most common type of human error which contribute to failures. "Violations" generally involve situations in which there is deliberate non-compliance with rules and procedures, usually because the rules or procedures are viewed as unworkable in practice.

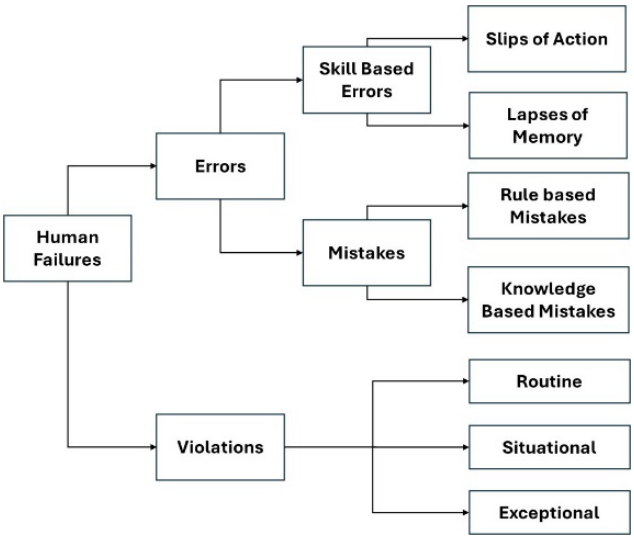

Figure 2: Types of human failure (HSG48, 1999)

Systems such as dams, including the people involved in designing, building, operating, and managing them, tend to conservatively have numerous "barriers" that must be breached for failures to occur. Failures will occur owing to physical and human factors "lining up" in an adverse way that overcomes all barriers. The Swiss cheese model of accident causation, originally proposed by Reason (1997), likens human system

defenses to a series of slices of randomly holed Swiss cheese arranged vertically and parallel to each other with gaps in-between each slice. Figure 3 is a typical Swiss cheese model that shows that engineering is one of the controls for an unwanted event. All of the controls, however, are essentially human-based with the propensity for failures.

What are the barriers in life or organizations that are effective in reducing the risks As Low as Reasonably Practicable (ALARP) when it comes to dam design, construction, operation, and maintenance?

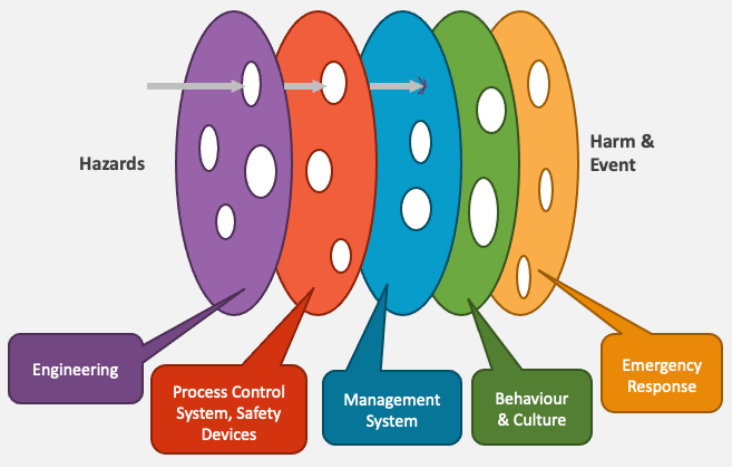

Figure 3: Typical Swiss cheese model of accident causation (https://www.collidu.com/presentation-swiss-cheese-model)

My early learning from other experiences

The following experiences were significant in my early career and provided me with an understanding of how human errors and violations can lead to infrastructure failures, particularly in relation to dams.

St. Francis Dam failure (1928) – Foundation failure (432 fatalities)

Teton dam failure (1976)

The dam failed due to hydraulic fracturing as a result of failure to thoroughly investigate and account for defects in the abutment and foundation (14 casualties).

Source: https://damfailures.org/case-study/teton-dam-idaho-1976/

Table 1 summarizes where things had gone wrong and highlights what human behaviors could have contributed to these failures that I could apply in my dam design career.

Table 1: Human behavior that contributed to failures

Where failures have occurred	Why did the failures occur?	Human behaviors that contributed to these failures
Banqiao Dam	Inadequate spillway capacity in design to cater for the consequence of failure leading to overtopping of dams.	Knowledge based and rules-based mistake in applying flood design parameters
St. Francis Dam	Design and construction flaws that can be made by very experienced people.	Overconfidence knowledge-based mistake – be humble and willing to listen to others
St. Francis Dam Malpasset Dam	Lack of clear understanding of the foundation and failure modes associated with kinematically feasible failure modes – Understand the geological conditions and kinematics of failure modes.	Knowledge based mistake
Malpasset Dam	The importance of understanding foundation uplift and pressure relief or lack of pressure relief in the foundation, even for an arch dam. Precedent is not always good practice.	Knowledge and rules-based mistake
Vaiont Dam	Significance of landslide reservoir rim failures – Look beyond the dam site to understand the historical evidence of slope instability and the effect of impulse-generated waves.	Knowledge based mistake
Vaiont Dam St. Francis Dam	Investigation limitations – we can never have enough, but what is required for a good, robust sustainable design?	Knowledge based mistake and possibly routine violation
Teton Dam	Piping through the embankment core zone into the foundation – lack of filter control and foundation preparation cannot be overlooked or compromised.	Situational violation and knowledge-based mistake
	Lack of communication between design team and the construction team – Ensure regular construction site inspections by the design team and ask for advice.	Systemic routine violation
Teton Dam	Budget constraints – Limited funding cannot be an excuse for not implementing good practice (ALARP).	Situational violation
Tacoma Narrows Bridge	The importance of understanding wind load. For dams, wind causing waves and surge.	Knowledge based mistake

What about my experiences?

I will share some of the experiences from which I learned a great deal, that have relevance to achieving goals and engineering "good practice" and recognizing where human failures occurred, or where opportunities arose that have had a significant bearing on my career pathway.

Zimbabwe

Analysis accuracy

My first job was designing an effluent disposal scheme comprising five maturation ponds with a maximum 2 m depth leading to the outlet works and a canal where two offtakes were used for spray irrigation with pump stations. My manager shared his experience with outlet works design where he did not fully account for the energy dissipation through the outlet works, and because of that the flow through a downstream V

notch weir used for flow measurement on his project was supercritical. All of the discharge measurements were wrong until additional energy dissipation works were installed in the outlet chamber.

This taught me the importance of energy dissipation and tailwater effects for design of outlets, as well as what a lack of knowledge with a very experienced engineer can look like in design. Actually, this scared me into an awareness of how to achieve the levels of accuracy needed for a good operational design.

Safety in design and construction

I was the chief resident engineer for the construction of Mazvikadei Dam, which is a 63.5 m high zoned earthfill embankment dam with a drop inlet spillway. During the construction in 1997, a very experienced contractor was excavating the lower part of the right abutment, which comprised large granite boulders in a soil matrix. The contractor used blasting to break up one very large boulder. During the excavation of the material using benches, which were carefully placed, one of my inspectors was standing on a rock on one of the benches, which collapsed under him and killed him. This was a shocking accident and one which I have lived with for the rest of my career.

This was a result of process control safety, management, and cultural behavior control failures and showed me the importance of safe work methods and understanding the risks associated with construction of something that was meant to be relatively straightforward.

Figure 4: Mazvikadei Dam right abutment core trench excavation (author's photograph)

As shown in Figure 4, the excavation of the cut-off trench clearly revealed the openness and extent of the exfoliation in the granite foundation. Following on from the Teton experience, we were very careful to

seal the downstream joints with mortar and provide a full sand filter against the downstream face as well as foundation slurry and dental concrete to avoid steps and open joints in the cut-off trench.

Compromise in materials for construction:

The diversion works for the Mazvikadei dam comprised construction of a homogeneous highly plastic earthfill embankment coffer dam to divert the river flows through the outlet tunnel. The coffer dam was to allow overtopping to an undefined depth. During the construction, I was trying to optimize use of material and placed less plastic material in some areas. During a large flood, while I was on leave, the coffer dam stood for 14 hours with a depth of flow of about 300 mm over the crest. The assistant resident engineer went to make a call to head office in the night and when he returned after about 10 minutes, the coffer dam had breached, as shown in Figure 5.

Figure 5: Mazvikadei Dam breached coffer dam (author's photograph)

This was a situational violation of the design requirements and taught me not to compromise on material usage in the zones for which it is required, in particular for subsequent construction in the use of properly graded sand filters.

Blast zone

During the construction of the Mazvikadei dam, my office was located in a perfect location on a hill feature between the main dam and the saddle dam about 100 m from the drop inlet spillway entrance channel, as shown in Figure 6. One morning I arrived at my office to find a rock fragment lying on my table that had come through the roof. That could have been a major incident, including potential life loss in the event that a rock had hit anyone around or in the offices.

Clearly this was a knowledge-based mistake related to safe blasting distances, but perhaps also the blasting contractor being overzealous in charging the blast.

Figure 6: Mazvikadei Dam layout and office location

The importance of good testing and alternative use of soil testing equipment

I had the privilege of being assigned to the soils laboratory, where we were using state of the art electronic digital equipment for the triaxial testing, including measurements of pore air pressure. This was seldom done owing to the difficulty of ensuring a good seal with the porous disc measuring the air pressure. Nearly all the tests were done using saturated undrained tests with pore water pressure measurement. I learned the importance of saturation at high pressures to ensure at least 98% saturation to obtain good pore water pressure data, as well as the need for good soils testing equipment, procedures, and well-trained personnel completing the testing.

We were in the process of improving the safety of a buttress dam where we were concrete infilling between the buttresses. I made use of our oedometers to test the various density grades and thicknesses of Polystyrene. This was required to determine which grade would allow construction of the first concrete lift without crushing the Polystyrene, but would then allow crushing on further loading by the buttress dam to ensure that the mass gravity infill concrete load was not reduced.

South Africa

Moving to South Africa – introduction to risk assessment

When I returned to head office after Mazvikadei dam construction in Zimbabwe, I was given the opportunity for promotion above my level of experience of 14 years. I was not confident to take this role.

We moved to South Africa where I was employed in the Department of Water Affairs. I thought I was going to get more design experience in the design branch but I went to work with Dr Chris Oosthuizen in the Dam Safety Sub-Directorate of the design branch. This was one of the most significant changes in my career as I was launched into the world of Dam Safety and Risk Assessment for six wonderful years. This was also an opportunity for moving out of my comfort zone.

Piping along the outlet conduit on first filling owing to lack of filter material

As shown in Figure 7, this was a classic case of piping along the conduit of Zoeknog dam conduit on first filling owing to lack of filter protection around the conduit. The filter zone with geofabric extended to just above the conduit and I was one of the team from Water Affairs to inspect the dam. There was some uncertainty about whether the conduit had structurally deformed allowing the pipe to initiate, as shown by the failed conduit on the right of Figure 7. Following receipt of the photo on the left, it was clear that the conduit had failed owing to the unbalanced load after the piping failure had occurred.

This was a knowledge-based mistake, possibly a situational violation of the design requirements, if the Contractor failed to take the filters to the design level.

Figure 7: Zoeknog Dam piping failure (left: anonymous source; right: author's photograph)

Canada

Risk assessment challenges

While in Canada, I was given the great opportunity to complete a risk analysis for a hydropower concrete gravity dam with vertical lift gates. Given the situation where a load rejection and failure of the gates to operate could occur during a seismic event, resulting in failure of the dam within hours, the challenge was to complete the risk assessment for all failure modes and hazards including seismic, floods, ice, and debris. Following extensive modelling for all of the failure modes, physical model testing for debris loading and a detailed 156-page fault tree analysis for the spillway gate reliability and drainage system failure as well as numerous folders of calculations, we were not able to provide the client with a robust mathematical outcome

for the risk assessment. This resulted in a lot of stress for the team and the client rejecting the risk assessment to complete remedial works to ensure that the gates would open in the event of loss of power to ensure the dam could handle load rejection.

This was a clear result of inadequate knowledge and experience in the field of risk assessment to obtain robust mathematical modeling required for input to probabilistic modeling of the failure modes. Subsequent risk analyses that I have been involved with have placed reliance on judgmental probabilities, aided by modeling of failure modes without the absolute rigor of mathematical analyses to obtain probabilistic input.

Australia

Normalizing site inspection observations and minimizing testing

During routine annual inspections of the embankment at the west side of the tailings storage facility (TSF), I noticed longitudinal cracking. Operators advised that there was an old river channel in this area that was the cause of the cracking and I normalized this as an occurrence without significance as far as embankment safety. After all, the surface of the deposited tailings was firm with no issues for vehicular traffic.

During design for a 4 m upstream raise, we did dynamic cone penetrometer (DCP) testing at 100 m centers around the perimeter to prove the foundation. This raise height was more than the usual 2 to 3 m raise, but we were keen to maximize storage and the client did not want to do closer spacing testing. We were all convinced that the foundation material was relatively uniform with layers of weak material interspersed in the stronger material in a typical manner for tailings. Factors of safety for slope instability were acceptable.

The construction was in progress when I received a call that the embankment was moving. I thought that this was normal for rotational movement but this was translational movement with an opening of about 150 mm. Work was stopped while the design was reviewed and new alignment was used to prevent further failure.

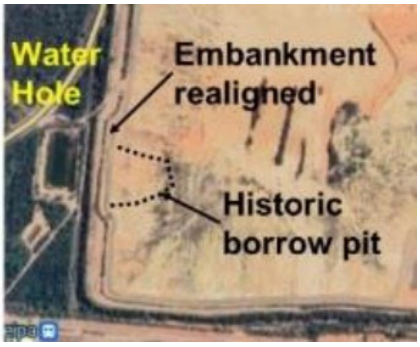

Figure 8: TSF example of normalizing observations and limiting testing for design (Google 2024)

The obvious question "What was the root cause?" was answered by the client design manager, who showed us an obscure figure with the outline of an old borrow area in the area of the failure, as shown in Figure 8. We had not seen this figure before. The first stage of the TSF cell went around this hole to the west and the tailings deposition into the borrow area hole was effectively subaqueous with no drainage owing to the high-water table. Note that water hole on the west of the cell. The investigations found the material had a strength of between 5 to 10 kPa at a depth below 9 m and the translation occurred in this material.

Clearly this was a knowledge-based mistake, as well as a situational violation by assuming the material was similar over the entire foundation area and construction of a larger than normal raise owing to over confidence in the foundation based on visual interpretation.

HSE – steps

This sounds trivial, but three points of contact are always specified when using stairs. However, how many times are the staircases too wide to prevent this happening, or people just don't use the handrail owing to overconfidence? I fell down a flight of nine steps when helping my daughter move as I was carrying my cup of coffee in one hand and my tools in the other. The picture below shows a very narrow step at the corner where I lost my footing and went tumbling down the steps with no way of stopping myself and hit my head on my drill case, which softened the blow.

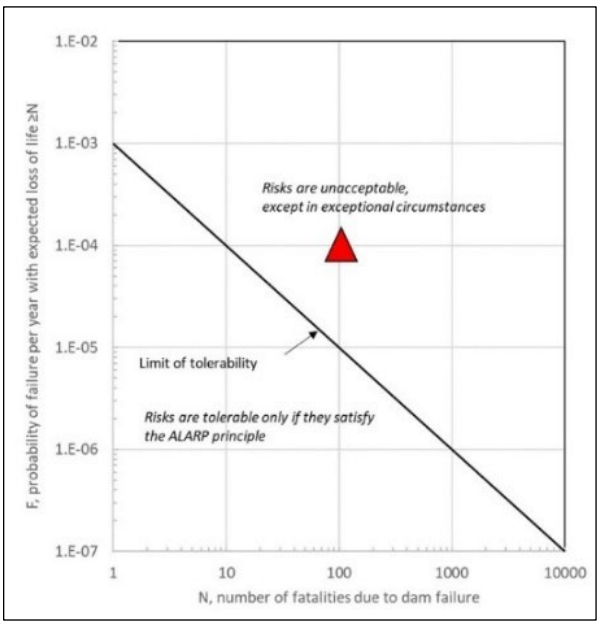

Figure 9: Spiral staircase (author's photograph)

I was all right, but this was clearly a situational violation for not using the handrail, as well as a design problem because there was no landing where the staircase turned the corner rather than narrowing the treads.

Cascade failure and design for fuse plug operation – do's and don'ts of residual risk:

A fuse plug spillway is a collapsible structure installed on spillways, or as a separate section on dams, in

order to increase the dam's flood capacity during remote events. Designing fuse plug spillways can often lead to incremental risk when compared with a flood of the same magnitude, without the rapid change in flow and water level resulting from the fuse plug operation. This is part of the normal operational residual risk, not the dam failure risk. The potential life loss (PLL) associated with some fuse plugs has been estimated to be in the hundreds. With an operational annual probability of 1 in 10,000 and PLL of 100, this would result in the societal risk exceeding the tolerable limit, as shown schematically in Figure 10.

n

Figure 10: ANCOLD societal risk with fuse plug operation example (author's figure)

This figure does not include the other residual flooding risks that would exacerbate the unacceptable risk. In order to achieve an acceptable risk with fuse plug operation at this AEP, the PLL would need to be less than 10 for "normal" operation. Ignoring the residual risks associated with fuse plug normal operation could be a knowledge-based mistake, but once understood becomes a clear situational violation human error.

Biases that affect how we evaluate risk for tailings facilities

We all have biases as a result of our background and engineering experience. In my experience of risk analyses for tailings storage facilities and water dams, some of the more significant biases I have seen are shown in Table 2 (Dwyer, 2018), where I have shown the potential human failure that may result when evaluating data for risk analyses.

Table 2: Biases and human failure

Bias	Description	Resulting human failure
Motivational bias	Having a vested interest in wanting to prove something	Situational Violation
Confirmation bias	Favor ideas that confirm their existing beliefs, ignoring contradictory evidence	Knowledge based mistakes
Optimism bias	When in a good mood, individuals overestimate the likelihood of positive outcomes	Slips of Action
Declinism bias	Favor of the past due to resistance to change	Knowledge based mistakes
Dunning-Kruger Effect	Individuals with low knowledge mistakenly assess their ability as greater than it is, while experts may underestimate their own knowledge	Knowledge based mistakes
Anchoring bias	Relying too heavily on the first piece of information encountered when making decisions	Rule based Mistake
Affect Heuristic	Decisions influenced by emotions or feelings rather than rational analysis	Situational Violation
Outcome bias	Judging decisions based on the outcome rather than the process	Rule based Mistakes
Illusory Superiority	Overestimating one's abilities or qualities relative to others. A belief that your work is correct/accurate	Situational violation
Availability Heuristic	Overestimating the importance of information readily available in memory	Knowledge based mistakes

Being accountable

We all have biases, but we need to be accountable. When dealing with accountability, the triangle of Means, Motivation and Meaning is useful, as shown in Figure 11 and summarized in the following points:

- Means – Make sure that you have the skills and experience for the work. Acknowledge your own fallibility and ask for help where needed.
- Motivation – Are you motivated to do this work and are you curious?
- Meaning – Understand the importance of the work that you are tasked to complete in the project.

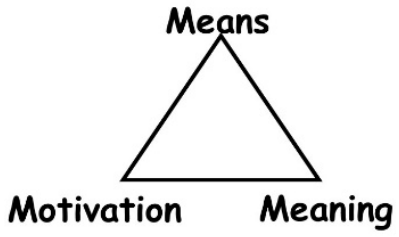

Figure 11: The triangle of Means, Motivation and Meaning (attributed to Trevor Roberts)

When asking people to be accountable, the most important thing is really knowing the people and understanding their limitations and your own limitations for the task in hand.

When dealing with a team, it is important to know the people and understand their limitations, while assisting them to develop their skills. It is also important to communicate on a personal basis whenever possible and to take time to understand what may be causing difficulties in learning and preventing people in the team from applying their experiences, with the aim of preventing mistakes from reoccurring.

Can we as an engineering body ensure that we are accountable and make every effort to get real about what the data is telling us and how to get the ongoing message to professionals as to what failures and experiences are telling us with respect to reducing risks to ALARP?

Let's get real about experiences

In Canada, when becoming a professional engineer you have the privilege (responsibility) of wearing an iron ring as a symbol of professional duty and obligation. The tradition began in 1922. The ring has long been rumored to have been created in response to the collapse of the Quebec Bridge that crosses the Saint Lawrence River. It collapsed twice and claimed 88 lives.

Every major religion in the world has remembrance rituals or celebrations of significant events or experiences. Is there a way for the engineering community to be reminded of historical events that have shaped our engineering design, construction operation, and maintenance? The historical events of interest will differ for water and tailings dams owing to the differing significance of failure modes.

Should international bodies such as ICOLD, ANCOLD, USSD, ASDSO, British Dam Association, and ICMM, to name a few, develop an annual reminder of failures and their significance? This will help to ensure that engineers, technicians, and drafters of all ages and experience are aware of failure modes and how to deal with them in design, construction, operation, and maintenance, in an effort to reduce risk to people and the environment to as low as reasonably practicable (ALARP) in accordance with GISTM requirements.

Conclusion

In the author's opinion, getting real about learning from experiences on a personal level is about understanding why I make mistakes, recognizing my own biases to learning from experiences, and being humble in my approach to all aspects of design, construction, operation and maintenance, risk evaluation and finally closure of tailings facilities.

Southeast Rock Site Tailings Co-disposal Facility

Ben Wickland, WSP Canada Inc., Canada
Don Parsons, Imperial Metals Corporation, Canada
Anthony van Engelen, WSP Canada Inc., Canada
Scott Coombs, NewFields, Canada

Abstract

This paper presents a case study of co-disposal of tailings and waste rock at the Mount Polley Mine, British Columbia, Canada. Approximately 2.2 M m^3 tailings were excavated from Springer Pit over 12 months and stored in the Southeast Rock Disposal Site (SERDS) tailings co-disposal facility. The design concept was to place tailings on the crest of an existing 60 m high rock storage facility. Berms were constructed with rock around to form cells for the tailings and used as haul roads. The berms were raised by the upstream method in 5 m lifts to a total height of 20 m. The design includes overall outer slopes of 2H:1V and a 5 m cover of rock; stores only non-acid generating materials; and has no liners, filters, compaction, instrumentation, or permanent water pond. The facility was operated successfully following standard procedures for rock storage facilities at Mount Polley, with no issues related to instability, liquefaction, seepage, erosion, or water management. The facility provides a case study of tailings co-disposal in a surface facility without a permanent water pond.

Introduction

This paper presents a case study of co-disposal of tailings and rock at the Mount Polley Mine, British Columbia, Canada. Approximately 2.2 M m^3 tailings were excavated from Springer Pit over 12 months and stored in the Southeast Rock Disposal Site (SERDS) tailings co-disposal facility. The site background, facility design, construction, and operation sequence, and a summary of issues and lessons learned, are presented in this paper.

Background

The Mount Polley Mine is a copper and gold mine operated by Mount Polley Mining Corporation (MPMC), a subsidiary of Imperial Metals Corporation. The mine is located on a ridge between Polley Lake and

Bootjack Lake. Major features include the Cariboo and Springer pits, the mill complex, rock disposal sites including the SERDS, and the tailings storage facility (TSF). The mine began production in 1997 and operated until 2001, when operations were suspended for economic reasons. In 2005, the mine restarted and was in operation up to the time of the TSF breach in August 2014. During 2015 and 2016, tailings were discharged as slurry into Springer Pit from the south pit wall (Figures 1 and 2). In June 2016, the mine returned to full operations. Approximately one-third of the tailings were dredged from Springer Pit and pumped as slurry to the TSF between March 2016 and October 2019. Mining operations were suspended again in May 2019 for economic reasons and the site remained in care and maintenance until late 2021. Approximately 2.2 M m^3 of tailings remained in Springer Pit at the end of 2021.

(the TSF is to the south, and is not the subject of this paper)

Source: L. Nikl.

Figure 2: Springer Pit (left), and Cariboo Pit (right) in 2021, looking north

The free water was pumped out of Springer Pit in 2022. The tailings were dewatered from September 2022 to May 2023 by pumping from three wells installed in the tailings from rockfill causeways. Tailings were excavated from May 2023 until May 2024 in 12 m high benches plated with 1 to 2 m of rock (Figure 3). The tailings held near-vertical faces that sometimes toppled during excavation, calving in 1 to 3 m thick slabs, and did not flow or liquefy. No seepage from the bench faces in tailings was observed during excavation.

Figure 3: Excavation of tailings from Cariboo-Springer Pit (top – looking west; bottom – looking southeast)

SERDS tailings co-disposal facility design

The design concept was to place tailings excavated from Springer Pit in cells constructed with rock on the crest of an existing rock disposal site – the SERDS (see Figures 1 and 4). The design concept is shown in Figure 5.

Figure 4: Southeast rock disposal site in 2021 prior to tailings placement (view of crest looking north)

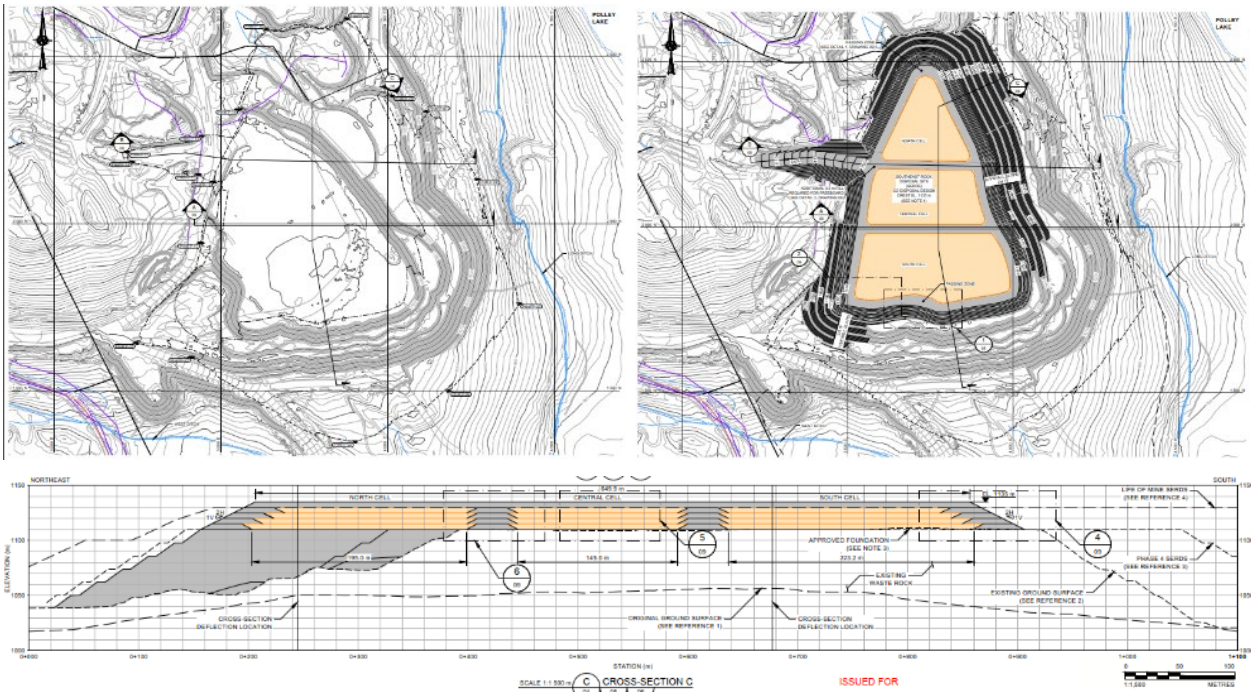

Figure 5: Southeast rock disposal site tailings co-disposal facility design

The design construction sequence considered:

- Widening of the existing crest platform using rock excavated from the Cariboo-Springer Pit.
- Construction of berms on the crest to form cells for tailings storage.
    - Berm construction was staged in 5 m lifts, constructed by the upstream raise method to a total height of 20 m.
    - The rock berms were intended to be used as haul roads to limit traffic over tailings. The design berm crest width was 27 m.
- Storage of tailings and rock excavated from Springer Pit in the cells.
    - The design storage capacity was 3.8 M m^3, which was conservatively overestimated to allow for increase in volume on excavation and for storage of rock with the tailings. The loads reporting to the SERDS could be tailings only, a combination of rock and tailings, and/or rock only. The tailings were anticipated to require surfacing with rock in the pit and in the cells at the SERDS for trafficability and access.
    - Tailings placement by dumping short and pushing into the cells with a bulldozer. The berm alignments limited bulldozer push distance to approximately 100 m.
    - Water management in the cells by collection in sumps and pumping to a downstream surface water management system.
    - Capping the cells after tailings placement with 5 m of rock to control erosion.
- Rock could be placed concurrently in the portions of the SERDS outside the cells and around the toe, which buttresses the outer slopes (not shown in Figure 5).
- Operation follows standard operating procedures for rock disposal sites at Mount Polley.

The facility does not have a permanent water pond, instrumentation, filters, liners or impermeable elements, does not require compaction, and does not rely on the tailings for stability. Rock and tailings placed in the SERDS are non-acid generating (NAG) and are only sourced from Cariboo-Springer pit.

The foundation was characterized by drilling and test pit investigations around the toe of the existing facility. The foundation generally consists of 60 to 70 m of rockfill over up to 20 m of till. No continuous glacial lacustrine units (GLU) were identified in the foundation. The design requires limiting staff presence in the runout zone of the SERDS in case of instability. Little geotechnical information was available on the tailings deposit to inform the design.

Construction and operation

Construction activities generally included:

- Platform construction. The platform of the existing rock storage facility was widened by rock placement.
- Foundation preparation. Crest areas that allowed ponding of water were ripped by bulldozer to promote infiltration. Toe areas were stripped of topsoil to found rockfill on till.
- Berm construction. Rock was hauled by truck, dumped on the berm crests, then pushed and shaped by bulldozer. Typically, end dumps were placed as a first lift, then a ramp was constructed to the 5 m lift height then dump-short and push methods were used to advance the berms over the end dumps. The outer slopes were then trimmed, and safety berms constructed along the crests.
- Cell filling. Tailings and rock were hauled by truck into the cells, end dumped on the floor of the cell, then pushed and shaped by bulldozer. Following covering of the floor of the cell with end dumps, placement was by dump short and push from the berm crests or from causeways constructed across the cells to limit bulldozer push distance. The upper 0.5 m of each 5 m lift was generally rock, to create a trafficable surface for the next lift of end dumps. Tailings placement started in May 2023 and was completed in May 2024.
- Prior to construction of the next lift, the berm crests were ripped to break up traffic surfaces. In some instances, tailings and finer grained materials on the crests were bladed into the cells.

Equipment included a P&H 2300 shovel and Komatsu PC2000 and PC4000 excavators in Cariboo-Springer Pit, CAT 789 & 785 haul trucks and Komatsu 375 bulldozers at the SERDS.

The cell geometry was modified during construction – only two of three cells were constructed to reduce foundation preparation requirements and the quantity of rock required for platform and berm construction. The design carried excess storage capacity, so only two cells were required for the tailings.

Materials included non-acid generating rock used for berm construction, loads of tailings mixed with rock loaded from the tailings benches in Springer Pit, and rock placed in the cells as causeways and running surfaces, summarized in Table 1 as of end of May 2024. The majority of the rockfill cover remained to be placed.

Table 1: Materials placed on the crest of the SERDS based on load counts (source: Mount Polley Mining Corporation – MPMC)

Tailings and rock placed in cells (tonnes)	Rock placed in cells as causeways and surfacing (tonnes)	Rock placed for berm construction (tonnes)
5,129,500	556,200	5,453,500

The tailings consistency varied from sand to silty clay (Figure 6), and placed water contents generally varied between 2% and 30% (Figure 7). The loads of "tailings" reporting to the SERDS generally included 10% to 15% rock. The sandy tailings had 3 to 4% water contents and were immediately trafficable (Figure 8). The wettest tailings slumped after placement, with water expressed at surface that collected in minor ponds then infiltrated within a few days. The tailings did not flow on excavation or placement and did not generate excess water that was required to be managed (Figures 10 and 11). Rock generally consisted of sound, hard, durable rock particles free from organic matter and other unsuitable materials.

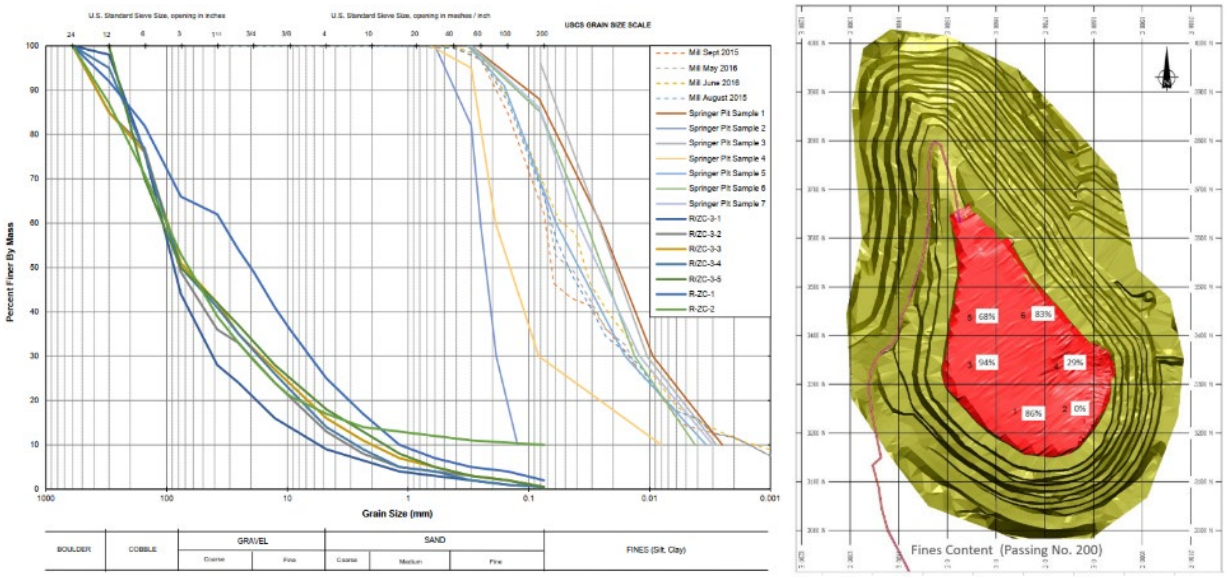

Figure 6: Gradations of tailings from Springer Pit, and historic rock gradations from TSF construction

Figure 9: Finer, wetter tailings

Figure 10: Tailings surface after filling

Figure 11: Tailings In place, capping advancing from north, looking south, 14 May 2024 (source: MPMC)

Conclusion: Challenges and lessons learned

The facility was operated without any geotechnical or water management issues in the first year. No signs of instability or loss of tailings were observed. The primary operational challenge was sequencing berm construction in advance of tailings placement because less rock was available during operation than the design basis mine plan.

The primary area of uncertainty during the design process was the lack of geotechnical information on the tailings deposit in Springer Pit – only six gradations and the specific gravity were available. The design therefore included excess storage capacity, strict requirements to manage water accumulating in the cells, and large perimeter berms. During operation, the tailings performed better than expected and the facility was operated as a dry stack (with robust erosion protection). The tailings did not liquefy on excavation or placement, only two cells were required to store the tailings, and the active management of water envisioned during design was never required because insufficient water accumulated in the cells to require pumping.

Feasibility of Repurposing Wood Processing Waste as an Industrial Liner Material

Robyn Gaebel, Geosyntec Consultants, Canada
Heidi Cossey, Geosyntec Consultants, Canada
Ali Nasseri-Moghaddam, Geosyntec Consultants, Canada
Kristin Salzsauler, Geosyntec Consultants, Canada

Abstract

Owners and operators of tailings storage facilities often have to rely on manufactured liners for their facilities due to the limited availability of clay materials. An alternative and economical option is to use waste by-products, such as wood processing waste, as liner material. This study evaluated the feasibility of repurposing wood processing waste as liner material for tailings storage facilities. Sludge from wood processing facilities has high organic and moisture contents and is expected to behave similar to clay or organic soils. Previous research has shown that pulp and paper sludges have advantageous characteristics, including low hydraulic conductivity, making them suitable for use as hydraulic barriers. As a result, this material has successfully been used in geotechnical applications including landfill cover systems. We propose using wood processing waste as liner material which allows site owners and operators to take advantage of the beneficial properties of this material while addressing the limited availability of natural liner materials.

Sludge samples were received from a Canadian wood processing facility and underwent geotechnical and geochemical testing to i) quantify the process the material would have to undergo to be functional liner material and ii) evaluate the geochemical stability of the waste as liner material. Primary sludge (wood fiber) and raw water treatment plant sludge were included in this testing program. The findings suggest that the wood processing wastes assessed in this study would require handling, specifically compactive effort, but may be suitable for use as a liner material; alternatives to clay and manufactured liners.

Introduction

Availability of suitable liner materials (typically clay) for industrial applications, such as tailings storage facilities (TSFs), is often limited. Consequently, site owners and operators rely on manufactured liners to maintain facility design, which can be cost prohibitive. An alternative economical and readily available

option is the use of waste by-products as liner materials, which is discussed in detail in Gaebel (2019). Wood processing facilities generate residue (wastes) that may be processed into suitable liner materials, given their material properties. Using wood processing waste as liner material is an attractive option because of the abundance of waste available and the proximity of many wood processing facilities to mining projects. This study is one of the first to evaluate the repurposing of wood processing waste as liner material for TSFs. Previous studies on wood processing waste have been conducted but their focus was on use as a cover material rather than a subsurface liner.

The objective of this study is to evaluate the feasibility of repurposing wood processing waste as liner material for TSFs. Two materials from a Canadian wood processing facility were assessed: primary sludge (wood fiber, Material A) and raw water treatment plant sludge (Material B). To assess the suitability of Materials A and B as liner material for TSFs, this study identified a series of geotechnical and geochemical tests. The testing regime was designed to i) quantify the process the materials would have to undergo to be functional liner material; and ii) evaluate the geochemical stability of using repurposed waste as liner material. The testing program evaluated the feasibility of use of these materials by measuring their compactive effort and leachate quality.

Literature review

Beneficial use of wood processing waste

Recent studies have demonstrated successful repurposing of paper recycling and pulp and paper wastes that have characteristics similar to wood processing waste (i.e., sludge with high organic and moisture contents). These materials typically behave similarly to clay or organic soil (Slim et al., 2016). One of the main advantages of repurposing wood processing waste in geotechnical applications is its capabilities as a hydraulic barrier. For example, Van Ham et al. (2009) successfully compacted pulp and paper sludge into a suitable barrier layer in a landfill cover system in British Columbia (BC), Canada. The compacted sludge performed comparably to conventional barrier materials such as geomembranes, compacted clay liners, or geosynthetic clay liners.

Moo-Young and Zimmie (1996) found that paper mill sludge with high water content and compressibility behaved like highly organic soil. The hydraulic conductivity of the sludge was sufficient for use in a landfill cover (10^{-7} cm/s) and could be further decreased with additional consolidation and decomposition of organics (Moo-Young and Zimmie, 1996). Similarly, Alrashed et al. (2016) achieved hydraulic conductivities as low as 6×10^{-8} cm/s using pulp and paper sludge mixed with lime, polymers, or bentonite.

Studies also found that paper sludges may have compressive and shear strengths suitable for use in geotechnical applications, such as retaining walls, after sufficient compaction of the material

(Mavroulidou et al., 2019; Bizjack et al., 2021). Wood processing waste may have other favorable attributes as well, such as the ability to repair itself after being punctured or damaged ("self-healing") and acid-buffering capacity owing to its basic pH (Sylvis Environmental, 2019). Based on previous research and the specific properties of wood processing waste, it is anticipated that this material can be processed into a self-healing, geotechnically sound liner material with potential neutralizing capacity to facilitate the management of acid-generating tailings should any pore water constituents eventually pass through the liner via diffusion or (less likely) advection.

Cost savings are an additional benefit of using wood processing waste as liner material. A pre-feasibility study by Sylvis Environmental (2019) found that material and installation costs for using pulp and paper sludge as liner material would be roughly half that of a geosynthetic clay liner based on the handling requirements. As such, wood processing waste is an attractive option that warrants further evaluation regarding its suitability for use as liner material.

Potential limitations

One of the main concerns with using pulp and paper sludge in landfill cover systems in cold climates is its susceptibility to freeze-thaw cycles, which can increase hydraulic conductivity by one to two orders of magnitude (Moo-Young and Zimmie, 1996). Moo-Young and Zimmie (1996) suggested that increasing the effective stress on the material (thereby increasing consolidation) and protecting the material with a thick layer of overburden may reduce the effects of freeze-thaw on hydraulic conductivity. In the proposed application, using wood processing waste as liner material would better protect the material from freeze-thaw cycles.

The high organic content of pulp and paper waste materials could also be seen as a limitation to repurposing of this material for use in geotechnical applications. However, research has indicated that degradation of organics may improve geotechnical properties of the sludge, such as hydraulic conductivity (Moo-Young and Zimmie, 1996; Zule et al., 2007). Additional testing would be required to determine how biodegradation of organics might impact leachate quality from pulp and paper wastes; for example, decomposition of organics could result in reducing conditions, which could impact the stability of minerals like iron oxyhydroxide. Alternatively, chemical stabilizers, such as hydrated lime, may be added to the sludge to i) prevent biodegradation of organics by hindering the activity of microorganisms; and ii) enhance geotechnical properties and stability of the sludge (Alrashed et al., 2016; Mavroulidou et al., 2019; Slim et al., 2016).

Additionally, there is significant variability in wood processing between different sites. The wastes generated are likely different chemically from site to site, with the waste and sludge streams containing

potential contaminants beyond the metals, anions, and nutrients discussed in this study. This study was conducted at a prefeasibility level with two specific wastes and results could be considered facility specific.

Materials

For this study, two similar wood processing waste sludges were analyzed: primary wood fiber sludge (Material A) and raw water treatment plant sludge (Material B). Both materials are available at volumes that would theoretically be sufficient for construction use. Approximately 100 L of Material A (Figure 1) and 60 L of Material B (Figure 2) were collected from a Canadian wood processing facility in 2024 using an excavator and manual handling for storage and transportation in plastic five-gallon pails.

Figure 1: Material A at sampling

Material A was heterogeneous in terms of particle size (Figure 1) and demonstrated high compressibility with a high void ratio and low density, and a high capacity for water absorption. Material B (Figure 2) was similar to Material A, though it was generally finer grained and had a higher initial moisture content.

Figure 2: Material B in situ

Laboratory analyses

Materials A and B were shipped to ITL Testing in Port Coquitlam, BC, for geotechnical testing and ALS Global in Burnaby, BC, for geochemical testing. Geotechnical testing of the materials is crucial in understanding the compactive effort required to process the waste into suitable liner material, as well as the ease with which this processing could be completed in the field. Geotechnical testing can also indicate physical properties of the materials such as hydraulic conductivity and moisture attributes.

Materials A and B are considered non-hazardous and generally contain fine organics and inorganics, as well as food-grade polymer residual (J. Fowler, personal communication, July 10, 2024). However, geochemical assessment of the chemical properties was deemed critical in understanding the feasibility of use, specifically for any impacts to the environment and interaction with tailings or other waste material.

Geotechnical analyses included modified and standard Proctor tests (ASTM D1557, 2021a; ASTM D698, 2021b). Method C (150 mm diameter mold) was used for the standard Proctor test of Material A because the material was not homogenized before the, test and thus a larger mold was needed to accommodate the larger particle sizes. Method A (100 mm diameter mold) was used for the other Proctor tests. Four-point Proctor curves were generated for each set of Proctor tests. Samples were dried in the open air rather than in an oven, as placing the materials in an oven resulted in material deterioration, even at low temperatures. During the moisture content material conditioning, the samples were left for a longer amount of time than would have been used for clay materials to improve water absorption. The Proctor test points were developed from the saturated side, utilizing higher than optimum moisture content and then moving to points on the drier than optimum side due to the high-water absorbency expected and demonstrated by the material.

Material A needed processing prior to performing geotechnical testing to create a homogenous material for analyses. It underwent material conditioning (homogenization) using a hand blender to create smaller sized particles for better homogeneity of water content for the modified Proctor analyses. The homogenized Material A sample is presented in Figure 3.

Figure 3: Homogenized sample of Material A

This additional processing would have altered the initial particle size distribution of this material, equating to a need for additional handling or processing requirements for use in the field. Material B was more homogenized and had a smaller particle size than Material A. As such, Material B did not require material conditioning (homogenization) prior to geotechnical testing. Material B was also provided at a higher moisture content.

Geochemical testing involved analyzing the leachate quality of both Materials A and B. Leachate quality was evaluated by measuring pH, alkalinity, and concentrations of nitrogen, phosphorous, sulfate, and metals in shake flask extraction tests of Materials A and B (3:1 ratio with deionized water). The analyses performed followed modified versions of the methods outlined in MEND (2009), US EPA (1997, 2014), and APHA, AWWA, and WEF (2023).

Results and discussion

Results of the Proctor tests for Materials A and B are presented in Table 1. Material A underwent both modified (Method A) and standard (Method C) Proctor tests, whereas Material B was analyzed using the standard Proctor test (Method A). The initial moisture content for Material A was 120%, whereas the initial moisture content for Material B was over three times higher, at 400%. The optimum moisture content for each of the three tests was similar to or lower than the initial moisture content. This indicates that both materials would need to be dried prior to compaction in the field.

Material A underwent both standard and modified Proctor testing for comparison in processing and to identify the effect that processing could have. Because the method used for each of the Proctor tests varied, the compactive energy of each test was calculated using Equation 1 (Das, 2013). Given the higher compactive effort (larger hammer weight, higher drop height, and increased number of lifts) associated with the modified test (2,696 kN-m/m^3 for Method A), this test resulted in a higher maximum dry density (577 kg/m^3) and lower optimum moisture content (68%) for Material A relative to the standard test, which used a lower compactive energy (588 kN-m/m^3) and resulted in a maximum dry density of 412 kg/m^3 and an optimum moisture content of 121 wt%.

$$Compactive\ energy = \frac{(number\ of\ blows\ per\ layer)\ x\ (number\ of\ layers)\ x\ (weight\ of\ hammer)\ x\ (height\ of\ drop)}{volume\ of\ mold} \quad (1)$$

Table 1: Geotechnical Proctor results for Materials A and B

Sample Material	Proctor Test	Initial Moisture Content (%)*	Optimum Moisture Content (%)	Maximum Dry Density (kg/m³)	Compactive Energy (kN-m/m³)
Material A: Primary Sludge	Modified Proctor Method A (ASTM D1557, 2021a)	120	68	588	2696
Material A: Primary Sludge	Standard Proctor Method C (ASTM D698, 2021b)	120	121	412	588
Material B: Raw Water Treatment Plant Sludge	Standard Proctor Method A (ASTM D698, 2021b)	400	45	981	591

* Values are estimates rather than exact measurements

Material B had a higher maximum dry density (981 kg/m^3) and lower optimum moisture content (45%) than Material A when similar or lower compactive energy was used. This indicates that Material B would require less compactive effort in the field to be processed into a liner. Material B also required less physical conditioning to create a homogenous material to work with, and Material B bound together between subsequent lifts whereas Material A did not, as shown in Figure 4. This may be because Material A is more fibrous and has a larger particle size than Material B. Material A was also observed to have a lower water absorption capacity than Material B.

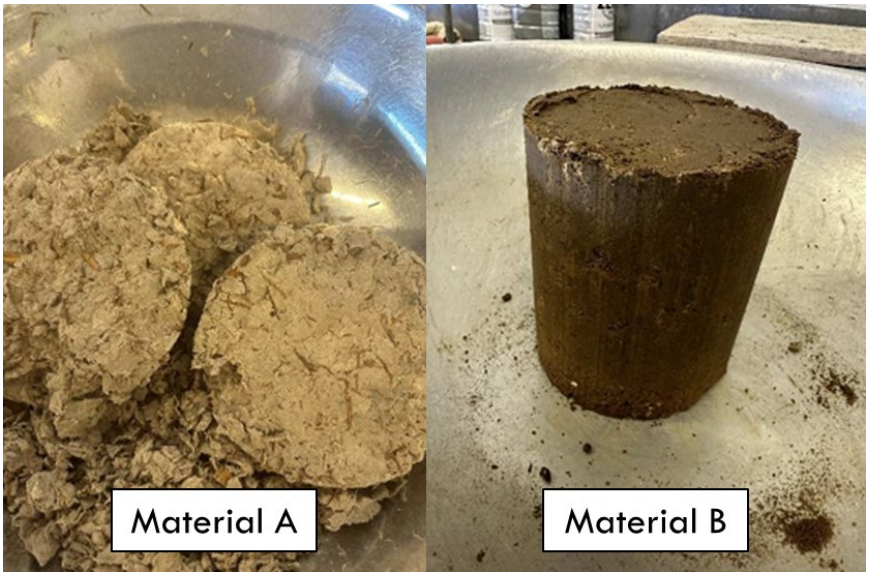

Figure 4: Materials A and B after Proctor testing

Particle size distribution tests were excluded from this study due to the nature of the materials and budget limitations. Estimates of the particle size were conducted as part of the material handling for the Proctor testing and indicated that Material A was similar to a well graded gravel before processing while Material B was a homogenous clay. It was noted once Material B was dried, the material handled identically to clay with a dry density of more than twice Material A.

Results of duplicate shake flask extraction tests for Materials A and B are presented in Table 2 (see next page). Shake flask extractions evaluate the soluble constituents that are most readily leached from material. Evaluating soluble constituents in the wood processing waste sludges is an important component of this study, as the soluble constituents could eventually be leached to the surrounding environment if the materials were repurposed for liner application.

The leachate from Material A was basic, with an average pH of 10.1. The average alkalinity was 379 mg/L as $CaCO_3$, which suggests that the material has a high buffering capacity. The leachate hardness was high for Material A, with an average of 208 mg/L, which can be attributed to relatively high concentrations of leachable magnesium. Concentrations of leachable nutrients and metals were generally low or below detection for Material A. Material B leachate had a circumneutral pH of 7.5 and a lower alkalinity (29.3 mg/L as $CaCO_3$) than Material A. This suggests that Material B could have a lower acid-buffering capacity compared to Material A. Leachable metals in Material B were generally similar to those of Material A, though select metals (aluminum, manganese, and strontium) had higher leachable concentrations in Material B. Compared to Material A, the nutrients ammonia and nitrate were elevated in Material B leachate, with average concentrations of 1.78 and 6.28 mg/L as N, respectively. Concentrations of other parameters were generally similar between the two materials, though Material A had higher concentrations of leachable salt (sodium, 170 mg/L) than Material B.

Taken together, these results suggest that leachate generated from Materials A and B would generally be of acceptable quality and leachate from Material A would have acid-buffering capacity. However, the shake flask extractions were performed using deionized water as the leaching solution, with a 3:1 solid to liquid ratio, and 24-hour residence time. In the field, the leachate quality of these materials may be different due to the chemistry of the water, the ratio of solids to liquids, and the contact time (MEND, 2009).

While concentrations of metals were generally low or below detection in the leachate for Materials A and B, as noted, wastes from other facilities may differ. Because of the variability in wood processing wastes, results are limited to the material that was assessed. Most of the literature evaluating geotechnical applications of pulp and paper wastes did not evaluate the geochemical characteristics of the waste, though Van Ham et al. (2009) found that pulp and paper sludge in a landfill barrier system had low levels of nutrients but elevated concentrations of salt. Additional studies of these types of materials should include geochemical testing as part of evaluating their suitability for repurposing in geotechnical applications.

Table 2: Geochemistry shake flask extraction results for Materials A and B. Results presented as average ± standard deviation

Analyte	Units	Material A	Material B
Alkalinity, total (as $CaCO_3$)	mg/L	379 ± 16	29.3 ± 1.3
Aluminum	µg/L	28.9 ± 19.7	120 ± 6

Zinc	mg/L	< 0.010	< 0.010

Conclusion

The availability of suitable natural liner materials for industrial applications such as TSFs is often limited, leading to reliance on manufactured liners, which can be cost prohibitive. This study explored an alternative solution by evaluating the potential use of wood processing waste as liner material. Given the abundance of wood processing residues and their proximity to many mining projects, this option is both economical and practical, though effort and handling may be required.

Through geotechnical and geochemical testing of primary wood fiber sludge (Material A) and raw water treatment plant sludge (Material B) from a Canadian wood processing facility, this study confirms that these materials could be repurposed. The performance of the materials, specifically Material B, was promising as these waste products were able to be processed and compacted using standard practices to produce results similar to geotechnical materials. As noted, Material B specifically exhibited properties similar to homogeneous clay, preliminarily indicating it would be a suitable hydraulic barrier and act as a liner material. Optionality also would exist to mix materials to offset the dry aggregate nature of Material A with the clay-like properties of Material B for a better performing material. Further, geochemical testing indicated that leachate generated from Materials A and B would generally be of acceptable quality.

The testing program was designed to better understand the processes required to transform these materials into functional liners and to evaluate their geochemical stability. The findings of this research indicate a promising potential for using wood processing waste as an effective and sustainable liner material for TSFs. This approach not only addresses the issue of limited natural liner materials but also offers an environmentally friendly method of waste management for wood processing facilities.

Future studies and further testing are recommended to optimize the processing techniques and fully understand the long-term performance of these repurposed materials. To confirm the behavior of the materials is consistent, the laboratory analyses discussed here, as well as other laboratory analyses including particle size distribution and hydraulic conductivity, should be conducted. Microcosm studies could also be conducted to better understand how organics degradation might impact both geotechnical and geochemical performance.

As this study provides a proof-of-concept, next steps are envisioned to include the laboratory investigations detailed above, as well as desktop studies identifying the available and required volumes of material needed for a liner. At the field scale, next steps include benchtop or field level development of cells which would allow for i) bench scale validation of concept and ii) an evaluation of the constructability and long-term geotechnical and geochemical performance of these materials.

Acknowledgements

The authors would like to thank the Canadian wood processing facility for their support and for providing materials for with this study. The authors acknowledge the support and assistance received from ITL Testing and ALS in completing the analytical portion of this study. The authors are also thankful for financial support provided by Geosyntec's Canadian Operations Research and Development (CORD) Committee in conducting this research.

Abstract

The process of stacking filtered tailings has several stages that are directly correlated and therefore interdependent. This process is divided into operational and geotechnical control stages, which are: the granulometric control stage of the tailings produced at the plant, the tailings transportation stage using trucks, the tailings disposal stage in the areas, the tailings spreading stage, the treatment stage using harrow tractors to reduce moisture, the testing stage to determine the moisture of the material for compaction, the topographic survey stage to determine the thickness of the layers, the area leveling and compaction stage, and the void ratio testing stage to approve the layer. In specific cases during rainy periods, additional stages of disposal in areas for moisture reduction and moisture testing may be necessary.

The operational capacity of the stack is directly related to area and to the amount of equipment available, including bulldozers, tractors with plow harrows, graders, compaction rollers, trucks, and the area available for disposing the material, since due to the difference between the moisture at which the tailings leave the plant and the moisture at which they must be compacted in order to guarantee the control parameters determined in the project, there is an average of four days of work on the spread material.

The entire process is controlled by systems that determine in which areas the material should be disposed of, showing how long the material has been undergoing treatment to reduce moisture, with a demonstration of working time and the results of moisture tests carried out for control reasons. In this same system, the entire topographic process, and the final release of the area with the void ratio is launched, speeding up the flow of information and ensuring safety in stacking operations.

Finally, control of the design geometries is essential for the structural stability of the operational stages. All this control is carried out by a topographical team, accompanied by a team of designers and registration engineers (EoR), following all the geometric assumptions necessary for the minimum safety factors, complemented by analysis of the controls and treatment of the results of the instrumentation in the operational phase.

Introduction

In the iron ore concentration process, physical-chemical processes are used to concentrate the ore and reach the levels necessary to meet the commercial specifications of the product. In this separation, the gangue minerals are separated from the minerals of interest and are generated: the concentrated product with the highest content of the mineral of interest; and the tailings with the lowest content of the mineral of interest and the highest content of gangue minerals (Wills and Finch, 2015). This tailing, as it is not of economic interest, is discarded, being historically disposed of in structures such as dams.

After the tragedies that occurred with tailings dams in Mariana and Brumadinho, the Brazilian mineral industry began to look for alternative ways of disposing of tailings. For this purpose, stacking of filtered tailings has been developed simultaneously by several mining companies, being an operationally viable form of disposal and with associated potential damage lower than that of a hydraulic tailings dam (Cacciuttolo and Atencio, 2023).

In iron mining, the most common concentration process is wet flotation, generating a concentrate pulp and a tailings pulp (Houot, 1983). To make these tailings manageable, it is necessary to dewater them, which can be achieved efficiently through filtration. After filtering, the tailings can be loaded and transported using traditional mining loading and transport equipment.

Finally, this material arrives at the disposal site and must go through the stacking process, which includes a series of unit operations such as spreading, leveling, topographic checking, homogenization, moisture treatment, compaction, and geotechnical tests that must guarantee project specifications. necessary for the safety of the stack (Guimarães, 2011).

In 2019, the Itabiruçu Dam in the Itabira mining complex was shut down. This dam was where most of the hydraulic tailings generated in the concentration plants were directed. In the short term, these tailings were provisionally disposed of in unexhausted pits. However, the volume available in these pits was restricted, giving rise to the challenge of quickly implementing the innovative processes of filtering and dry stacking tailings to mitigate impacts on ore production.

The filtration at the Conceição I plant began operating in 2020, but its capacity was insufficient to accommodate 100% of the tailings generated at the plants. Between 2020 and 2021, experimental landfills were carried out that subsidized the Itabira stacking filtered tailings projects. In 2022, the operation of the

Conceição II filtration began, which was built with capacity to serve the two concentration plants of the Conceição mine. In the same year, the dry stacking of filtered tailings began at the waste and tailings disposal stack (WTDS or PDER in Portuguese), Ipoema Borrachudo (Figure 1). And at the end of 2023, the Cauê filtration plant was started up, completing the construction of filtration plants to serve all of Itabira's tailings with a total capacity of 42 Mt per year. This is one of Itabira's biggest challenges – compacting approximately 115,000 tons per day.

The objective of this paper is to carry out a case study of filtered tailing piling in Itabira, describe its operational processes, and discuss improvements and difficulties associated with it.

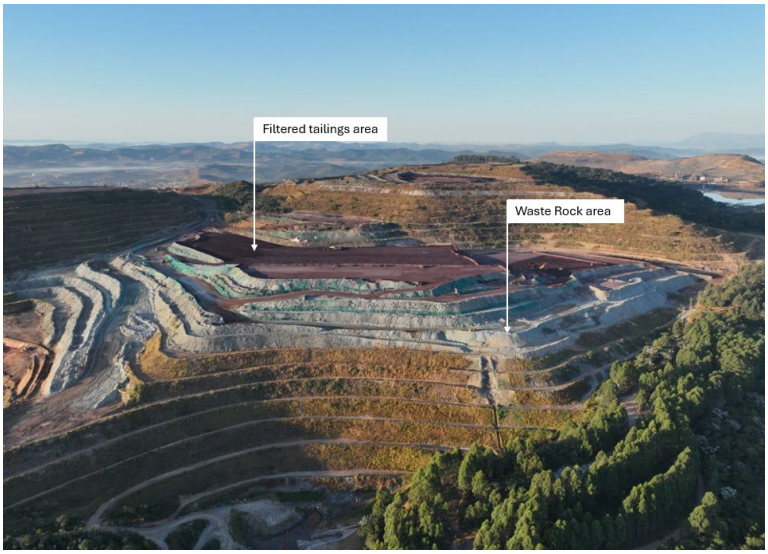

Figure 1: Filtered tailings and tailing rock pile – Ipoema Borrachudo

Methodology

The activity of compacting landfills in conventional civil works was operationally consolidated and rigorously studied throughout the 20th century, with large projects of dams, bridges, airports and roads that were a necessity for human development at the time (Lokkas et al., 2021). From all this demand came the peak of the development of soil mechanics, with significant publications such as *Soil Mechanics in Engineering Practice* by Karl Terzaghi and Ralph B. Peck, to support the development and implementation of large projects around the world. The work carried out by the entire global engineering body was focused on effective controls on soil compaction. At that time, the compaction of filtered tailings was not necessary in Brazil nor around the world, given the availability of dams for the disposal of hydraulic tailings and the high cost of operation (Cacciuttolo and Atencio, 2023).

The first step in operationalizing the filtered tailing disposal project in Itabira was to seek to adequately understand all the characteristics of the filtered tailing, based on characterization studies and

experimental landfills to evaluate the material's response to the compaction process. The main basis for starting operations was associated with compaction practices already applied to soils, but always observing and understanding the divergences arising from the difference between soils and tailing, making adaptations to the process to enable the compaction of the large volume of filtered tailing in a single day.

The second step in operationalization was to understand all the criteria listed in the structure's operating manual and associate them with the necessary resources to be able to execute all the steps, fulfilling the operating rate necessary to compact the entire mass of tailing produced in the period. Based on this assessment, we were able to divide the process into large teams: Production and destination; Stacking operation; Auxiliary teams; and Quality control.

The production and disposal group is associated with the tailing filtration plant, where we need to guarantee the physical and chemical characteristics of the material, which informs decisions as to which destination will be given to the tailing, depending on the filtration output moisture. The compaction operation group has all the equipment for transporting, loading, spreading, homogenizing, treating and compacting the filtered tailing. Auxiliary teams play a fundamental role in the entire operation cycle and are home to all the topography and laboratory personnel. The quality control team is responsible for construction inspection; their main objective is to ensure compliance with the structure's operating manual and to approve the layers.

This was the first stage of structuring the process. From there, the quantity of equipment and people in the operation of the structure was developed, in addition to the structuring of the operational cycle and management systems.

Results and discussion

This section will be subdivided into the macroprocesses that make up the filtered tailings disposal chain: filtration, loading and hauling, and dry stacking.

Filtration

In Brazil, the traditional process of concentrating itabiritic iron ores involves the stages of crushing, sieving, grinding, desliming, classification, flotation, and filtering of the product, in addition to auxiliary stages such as belt transport or pumping (Araujo and Peres, 2006). Tailings filtration is a new operation within processing plants, and seeks to transform the waste arising from desliming and flotation, which is in a pulp condition, with a low percentage of solids, into a material with relatively low moisture that can be handled by loading and hauling equipment.

In Itabira, separate buildings were built for filtration. The hydraulic waste from the concentration plants is pumped to these buildings, reaching an agitator tank where the filtration plant process begins, as

seen in Figure 2. Since the tailings have a significant percentage of fines (between 10 and 20% of materials passing through the 10 μm sieve), after leaving the agitator tank, it passes through a battery of cyclones that separate the finer material that will undergo thickening from the coarser material that will go directly to the tanks that feed the filters.

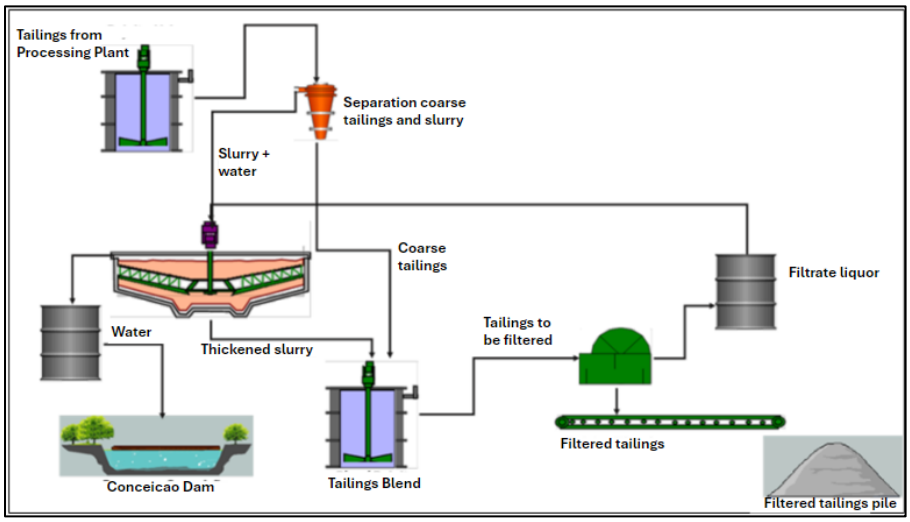

Figure 2: Simplified flowchart of a tailings filtration plant

The thickener densifies the finer portion of the material, recovering water, and optimizing the performance of the filters to allow filtration to achieve a lower final moisture content of the material than if the tailings went straight into the filters. After thickening, the fines exit through the thickener underflow and go to the tank that will feed the filters. The water obtained from the thickener is directed to a dam that no longer receives tailings, only water that is reused in the concentration plant.

The filters at the Itabira filtration plants are vertical filters, which use a technology that achieves an adequate reduction of material moisture. Less maintenance is required for them. Consequently, they have greater physical availability than flat filters or press filters (Dahlstron and Silverblatt, 1977). The filtrate liquor that leaves the filters returns to the thickener, to keep the solids in the circuit and send only clean water to the dam. The filtered tailings fall onto belt conveyors, which take them to the buffer pile where the material will be loaded and transported.

On the belt conveyor, through an automatic sampler, aliquots are collected every 15 minutes, to make up a sample that is collected and sent every hour for physical-chemical laboratory tests. These tests assess moisture, chemical composition ,and grain size distribution of the material, which serves as a basis for evaluating the quality of the material.

There are limits specified in the project for the grain size distribution of the material that can be stacked, as seen in Figure 3. If there is any disturbance in the process that generates material that falls

outside these limits, it will be rejected. It cannot be stacked and has to be discarded in another disposal location.

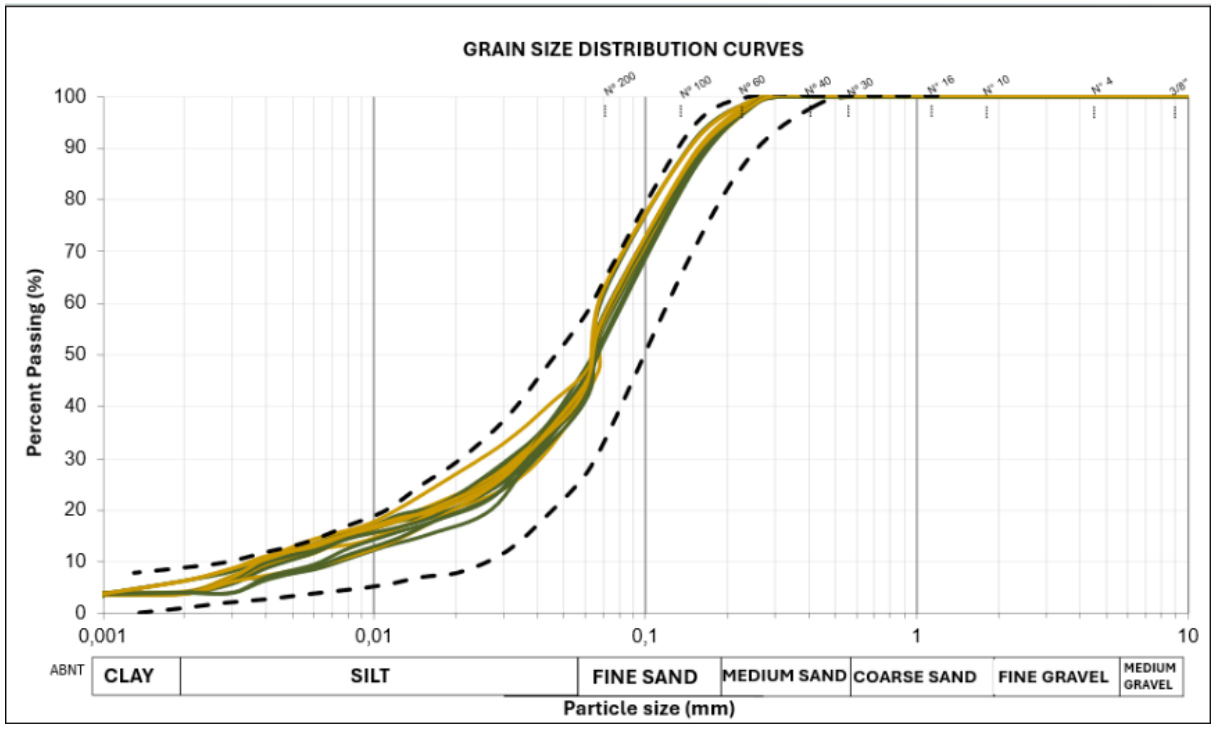

Figure 3: Grain size curves of the filtered tailings

Moisture, on the other hand, does not disqualify the material. However, if it exceeds a certain limit, it will lengthen the time for treatment and final drying of the waste in the stacking area, reducing the productivity of the available area. In this case, the material is sent to storage areas for drying, but will later be recovered and dry stacked. On the other hand, when the material is within the particle size and humidity limits, it is sent directly to the stacking area.

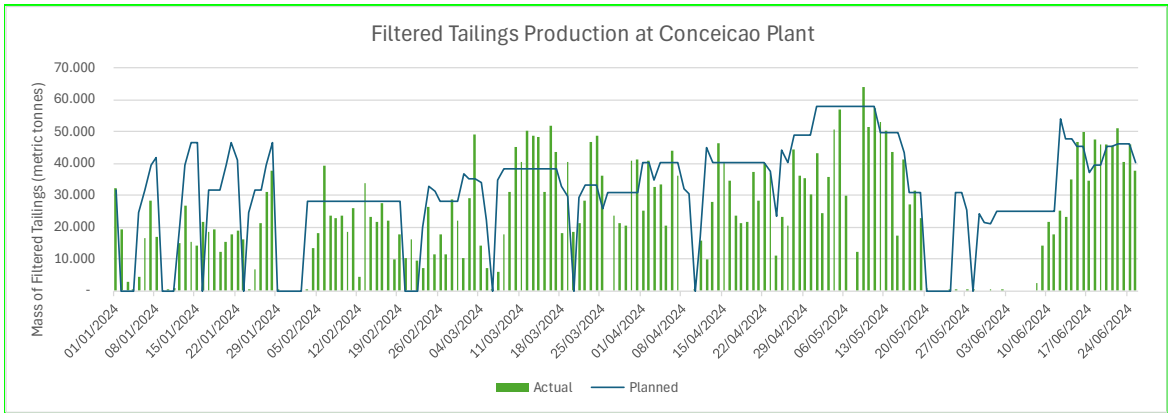

Figure 4: Daily production of the filtered tailings

Loading and hauling

After filtering, belt conveyors take the already filtered waste to a mobile boom that will form the tailing buffer pile for loading. This spear rotates with a constant radius, forming a pile with a circular arc shape, with a geometry similar to a "bean." For this reason, this stack is called the bean stack.

In this area the boom rotates, controlled by automatic systems, forming a pile on one side only, to guarantee the safety of the loading operation. In other words, while the pile on the right side is being formed, material is not falling into the pile on the left side. This allows the loading machine to operate without the risk of material falling onto itself. In addition to the safety of the equipment, this division into two piles facilitates control of the quality of the material. As soon as a pile completes its formation, the laboratory results of the analyses of the samples collected on the belt is recorded, and the control room checks the quality of the material in terms of particle size and humidity, to define the destination of the material.

With a defined destination, the material is loaded by LeTourneau L-2350 large loading equipment (as shown in Figure 5) and transported by CAT 793F off-road trucks. The same equipment is used to load ore and waste, bringing flexibility to mine operations in the use of resources.

Figure 5: Loading and hauling of filtered tailings at the "bean" stock pile

Dry stacking

PDER Ipoema Borrachudo was designed to carry out the controlled disposal of filtered tailings and rock waste, originating from the process of processing iron ore from the Conceição Mine and Minas do Meio

mine. The characteristics of the materials to be stacked are low iron content and low moisture content.

PDER Ipoema Borrachudo is subdivided into smaller sections, in order to facilitate the control of activities and the technological control of stacking. These zones are called banks, sections and lanes, which evolve vertically in layers.

- Bank: elevated subdivisions of PDER, with names that are related to their quota (e.g. 1010, 1020, 1030, 1040). It is made up of a set of bays, which rise in layers and joint heights.
- Sections: superficial subdivisions of the bank, named after variations of the phonetic alphabet (e.g. Alfa, Bravo, Charlie, and others). This is made up of a set of 2 or 3 tracks.
- Lanes: the lowest degree of superficial subdivision of the section, its name is the composition of the section name and number (e.g. Alpha F1, Alpha F2, Alpha F3). The area and volume are pre-defined, usually 2,300 tons of filtered tailing per lane. Note: the operating manual limits the volume of lanes to 1,000 m³. Therefore, for filtered tailing with a density of 2.3 t/m³, the capacity is 2,300 t.
- Layer: the vertical subdivision of the bench, with a thickness that can vary from 35 to 55 cm.

Visual identification of the subdivisions of the tracks is carried out using white spikes, which are seen only when in the field. All spatial and geographic control of the stack is supported by a bay management system and other geolocation technologies (terrain, grid control, and others).

Figure 6: Spatial subdivisions of the stacking area as seen in the operational control software

The filtered tailing stacking operation is cyclical, with the PDER bands evolving sequentially in layers of defined thickness. All cycles are standardized, with pre-defined steps and objective criteria for quality

approval. The operational team must conduct activities so that the tracks evolve quickly, but at all times must also guarantee compliance with geotechnical quality criteria and safety rules and good practices.

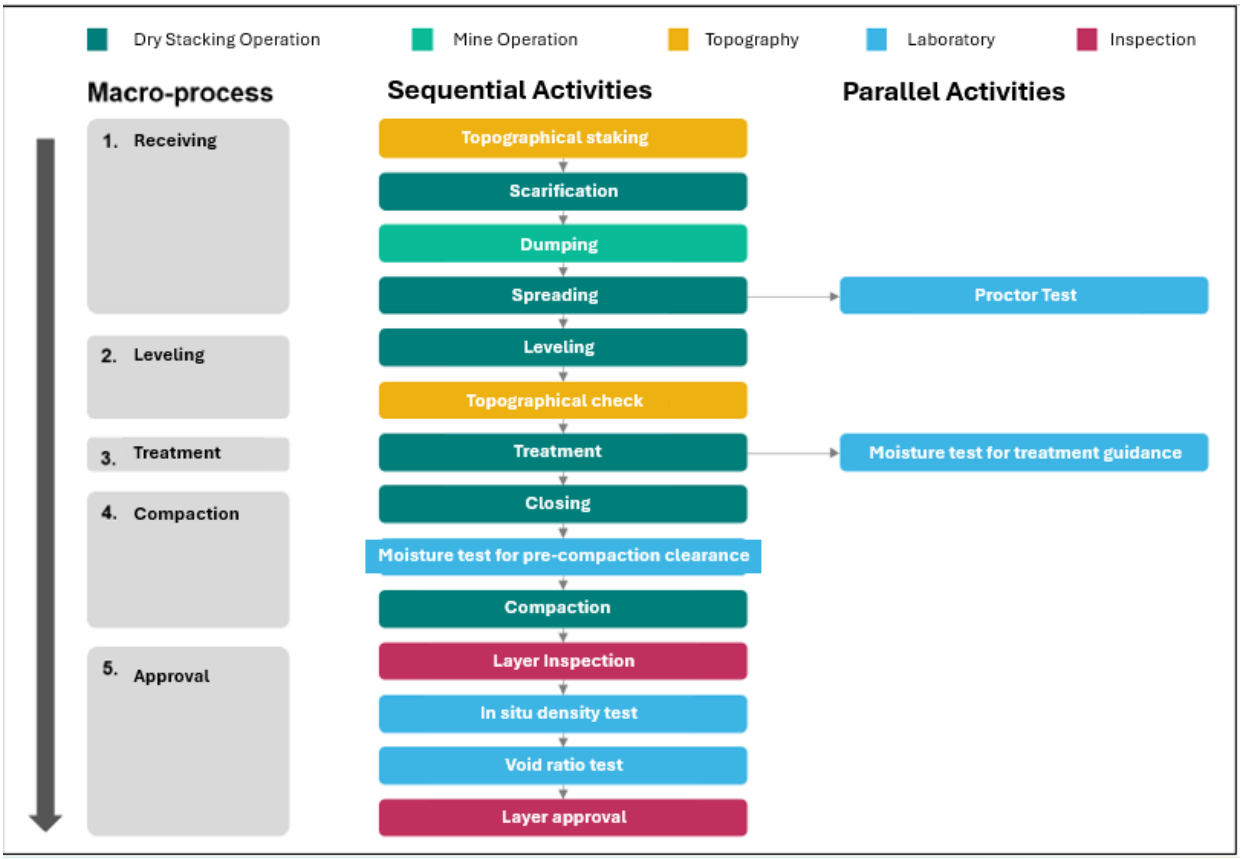

Figure 7: Operational cycle of the tailings dry stacking in Itabira

Receiving macroprocess

The receiving macroprocess consists of topographic marking, scarification, tipping, and spreading.

The topographic marking process is carried out by the topography team. The objective is to provide visual references of the limits of the bands to be received and the layer thickness for technicians and operators, facilitating spatial navigation in the field. The operation technician is responsible for understanding which markings are necessary and requesting them from the topography team.

Before receiving material for a new layer, the surface of the previous layer must be scratched via the scarification process, increasing adhesion between layers. To do this, operators can use the plow harrow or the motor grader's scarifier. The scarification must not be greater than 5 cm, and in periods of rain, exposing scarified strips to rain must be avoided, as this can generate a preferential flow of water, increasing the risk of puddles or ravines in approved layers. Therefore, in periods of rain, only strips that will receive material in the following hours should be scarified.

Once prepared, the strips can receive approved filtered tailing, delivered with off-road trucks that tip material into the PDER. The receiving strategy will be defined by the receiving technician, maximizing productivity, but respecting all safety rules for equipment operation. The origin of the material can be directly from the bean pile (after the quality of the pile has been approved in the design criteria) or from the material stock in the PRUs.

To avoid contamination, off-road truck operators must check the weighbridge in a suitable location before loading, especially for trucks whose last trip was for ore or waste. If there is any material in the weighbridge, cleaning must be requested. The presence of contamination can damage piling equipment and impact the results of geotechnical tests.

Tilting should preferably be carried out in advance, in the longitudinal direction of the seat. Off-road trucks must always travel under the loose, recently spread layers, respecting the maximum speed of 20 km/hour. The transit of these under approved layers must be avoided. However, if necessary, it must be carried out under supervision and at reduced speed. The objective is to avoid damage to previous layers.

The piles of material tipped by off-road trucks are broken using medium- and large-tracked tractors (for example, CAT D8 or D10), in the spreading stage. The crawler tractors are equipped with Terrain software, and must spread the layer, respecting the layer thickness. At this point, it is not necessary to meet the thickness specification with an accuracy of 5 cm, as there is a subsequent leveling step, but care must be taken to avoid the need for excessive cuts or fills.

As soon as the bay region is received and the area is safe for people to enter (i.e., no large equipment is moving), a sample must be collected per bay to perform the Proctor test. This test provides the optimal humidity and target density of the material, which can be compared with humidity and density tests carried out in the field in subsequent stages.

Figure 8: Receiving process

Leveling macro process

The leveling step consists of shaping the layer thickness so that it meets the established criteria (+-5 cm error from the defined layer thickness). The receiving technician must guide the motor grader operator within the limits of the lane to be leveled and in the direction of leveling, preferably in a longitudinal direction.

The process is carried out with motor graders equipped with high-precision technology called Terrain, to identify whether there are cuts or fills in relation to the topographic project. The receiving technician must check the terrain accuracy at least once every four work shifts, with the help of GPS. It is important to pay special attention when there are discrepancies in relation to other equipment and at night, when the occurrence of ionospheric scintillation is greater, or in case of doubts or discrepancies in the software findings.

Treatment macroprocess

The treatment stage consists of preparing the material disposed in the field for the compaction process. The two main issues to be resolved at this point are the regulation of humidity and the reduction of material heterogeneity.

The material sent to PDER Ipoema Borrachudo usually has an optimum moisture ranging from 9% to 13%, with small exceptions, with the physical and chemical characteristics of the material determining the variation within this range.

Once the layer is leveled and the thickness is checked, the next stage is the treatment stage, which begins with a tactile-visual assessment of the layer.

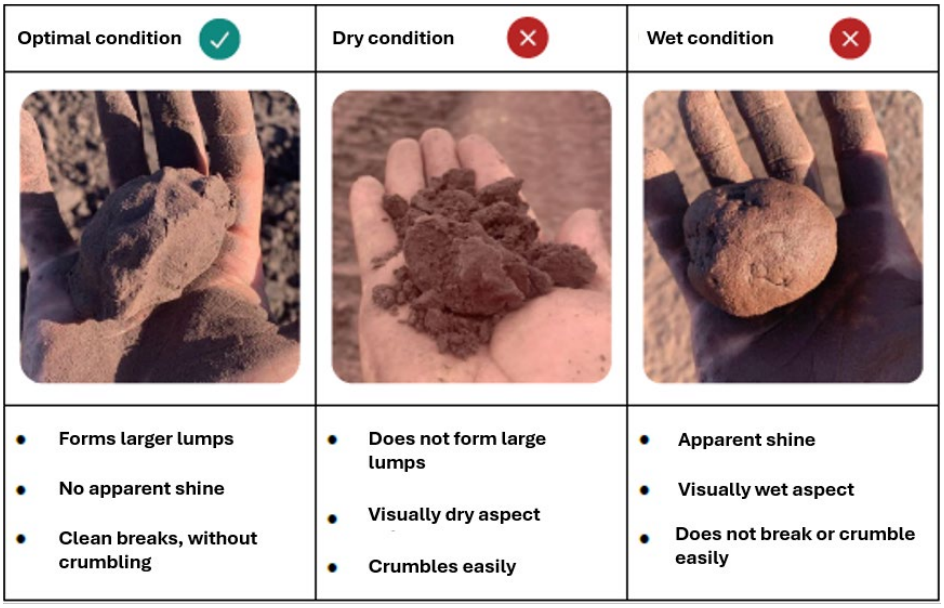

Figure 9: Visual and tactile inspection done by the treatment technician

This assessment is important to decide on appropriate treatment for the material. This method consists of using touch and vision, aligned with the maturity and experience of the treatment technician, to classify the material. There are some characteristics to evaluate during this investigation. A test that can be carried out consists of removing the soil in field conditions with bare hands, and squeezing it well until it forms a "cake." Once formed, the soil can be shaken in the hands to evaluate characteristics such as color, shine, consistency, and formation of clods.

Based on this assessment, the treatment technician can identify cases that require immediate treatment: when the layer has moisture far above the ideal level or far below it. If the layer has humidity close to ideal, it is only necessary to carry out homogenization with two passes with a plowing harrow, and then the technician will ask the laboratory to collect three sample points per lane to validate that the moisture is within the specified range for compression.

When the technician assesses that the material is damp, and/or presents a deviation greater than 1 p.p. for wet branch, drying must be carried out in the field. The drying process consists of opening the layer and exposing it to the daytime sun, homogenizing from time to time. It is estimated that the tailing filtered in PDER loses between 1 and 2 p.p. on average sunny days, with an open layer, between 06:00 and 20:00.

When the material is visually dry, and/or has a moisture deviation greater than 2 p.p. for the dry branch, the treatment is to add water. This operation is carried out by opening the layer with a plow and adding water with a water truck. This must be gradual to avoid flooding the strip. During the operation of the water truck, priority should be given to using the "shower" implement, which applies water in smaller quantities, and mitigates the risk of black flies appearing. Homogenizing the material after adding water is important to ensure successful compaction.

Figure 10: Treatment process

Compaction macroprocess

After treatment, whether it was homogenization, addition of water or drying in the sun, the layer will be open and disturbed. Therefore, it must first be closed again using a motor grader, ensuring that the thickness returns to the specified range.

Next, moisture test samples will be collected to validate that it is indeed within the specified range, which must meet two criteria: the geotechnical moisture must be within the range of 9% to 13% (design criteria), and the operational recommendation is that the moisture deviation (obtained by subtracting the field moisture from the optimal moisture of the material obtained in the Proctor test) must be within the range of -3 to +1.0 p.p.

Moisture levels drier than -3 tend to not be able to adequately densify the material, and so cannot achieve good compaction. On the other hand, deviations wetter than +1 tend to generate excess water between the voids in the material and the compaction energy of the roller cannot completely densify the material due to the excess water, generating a "rubbery" quality.

Once there is adequate moisture and the layer is closed, the next step is to compact the lane, which is carried out by the compaction roller. The treatment technician must request the passage of the compaction roller and clarify the boundaries of the strip that will be compacted and the number of passes. Two passes (two back and forth) of the compaction roller are used to carry out complete compaction. The compaction roller must always follow the same direction in which the layer is closed with the motor grader, which is normally longitudinal.

By default, compression is performed at high amplitude and low frequency. Other parameters can be used in exceptional cases (e.g., additional energy in the band). The ideal speed of the equipment is 4.5 to 5.0 km/h (similar to a person walking) – any discrepancy could harm the compaction result. The roller must pass (30 to 50 cm) between compaction lanes, avoiding spaces without receiving energy.

Approval macroprocess

After compaction, in order for it to be approved, the layer must be inspected by the operations, topography and inspection team. This inspection may find features such as rubberiness; lack of compaction in any section, with material still loose; inadequate thickness; or any occurrence that visually indicates that the compaction of the lane was not successful. If any non-compliance is identified, the lane must be reworked in the non-conforming section until it is in good condition.

Once the material passes inspection, the laboratory will collect a sample for density and void index tests. The approval criterion is only the void index; however, the field density is a good operational indication that the densification was successful. The result of the void index test using the vacuum pump method to obtain the real density of the grains takes around 14 hours. To speed up the process, the operation

can use the density as a reference to decide whether the compaction of the layer needs to be redone, or if it can proceed to the final test.

The history of the material worked shows that when the field density reaches values above 2,150 g/cm³, the probability of passing the void index is high, above 95%. On the other hand, below 2,000 g/cm³, the approval rate is low, below 10%. If the density is in the intermediate range, between 2,000 and 2,150 g/cm³, the field technician will use the target density value obtained in the Proctor test for reference.

If it is above the reference of 2,150 g/cm³, or if it is between 2,000 and 2,150, it presents a density greater than the target density obtained in Proctor, and the lane sample must await the void index test. If the density does not reach these references, the layer must be reworked, whether this is just additional compaction or a new moisture treatment. This decision will be made by the field technician who will evaluate the conditions of the track at the time and choose the most appropriate approach.

Having passed inspection, with good density, the void index test is awaited, with a criterion of a maximum of 0.6. If the void index is above 0.6, the layer must be reworked until the established criteria are reached. Once within the limit, the layer will be approved and the cycle starts again.

Geotechnical process control

Geotechnical control of the structure takes place throughout the entire operation, monitored by a team dedicated to supervising the tailing piling stages. Layer release tests are carried out systematically by the laboratory team. In addition to this control, undisturbed samples are collected every 8 layers of compacted tailing. From these collections, tests are carried out to confirm the mechanical behavior of the material.

Figure 11: Collection of undisturbed samples

Figure 12: Collection of in-situ compacted soil cylinder sample

Conclusion

The filtered tailings disposal process is a major challenge due to the difficulty in achieving synergy of the various unit operations associated with the compaction process, which until now was not part of the operational stages in a mine. The particularities of each tailing will encourage variations in the stacking process, but the compaction dynamics remain the same as in soil embankment processes. Much of the disposal strategy is associated with the area available for compaction and the availability of equipment for compacting large volumes. The control of activities involves equipment automation and systematization based on the development of control software, fleet management, and production stages.

Performance Assessment of a Filtered Tailings Storage Facility Partially Built with Uncompacted Tailings

Edwin Sanchez, Anddes, Peru
Denys Parra, Anddes, Peru

Abstract

The common practice of dry stacking for filtered tailings disposal includes stacking, spreading, aeration to reduce moisture provided by the filtration plant, and compaction with smooth vibratory rollers. All of this is done to create a material with dilative behavior, adequate strength, and very low liquefaction potential, contributing to the stability of the facility without the need for large retention dams. These processes involve significant operating costs for the disposal of filtered tailings, which is one of the main restrictions for the use of this technology. This work has focused on analyzing the static behavior of a filtered tailings storage facility, which will be built by dividing the facility into two zones: 1) a structural zone made up of compacted tailings to ensure the overall stability of the facility; and 2) a non-structural zone made up of filtered tailings disposed as received, that is, without compaction. The inherent risk of this solution is that the relatively low initial degree of saturation of the uncompacted tailings in loose conditions may be increased by the static loads of the tailings disposal up to the saturation, making it susceptible to static or seismic liquefaction. The geotechnical parameters of the foundation soils and the filtered tailings were estimated based on field, literature, and laboratory geotechnical investigations. The tailings disposal operation was simulated through numerical modelling using Sigma/W, in which the uncompacted filtered tailings were analyzed by the NorSand model. The simulation results indicated that it is possible to place uncompacted filtered tailings, thereby reducing operating costs, but this requires reducing the moisture content of these materials to at least the optimum to prevent liquefaction and ensure the overall stability of the facility.

Introduction

Currently, not much research is conducted on filtered tailings. Additionally, in recent years, the number of tailings dams built using this technology has been increasing due to its safety advantages compared to more traditional tailings disposal procedures (Copeland et al., 2023; Cacciuttolo and Pérez Campomanes, 2022; Pizarro and Olivares, 2018; Davies and Rice, 2001; Hambley and Verbeek, 2020).

Filtered tailings are usually placed in the storage facility and spread to promote moisture loss until reaching the optimum moisture content, after which they are compacted to increase their strength and generate a self-supporting structure. This process requires a high operating cost, which is one of the main restrictions on the use of this technology. Therefore, with the aim of reducing costs, the following questions arise: is it necessary to reduce the moisture of the filtered tailings below the values obtained in the filtration plant? Is it possible to place the filtered tailings, or at least part of them, uncompacted without compromising the structural integrity of the facility? This research aims to answer these questions.

Filtered tailings basic characteristics

The filtered tailings are classified as non-plastic sandy silt, ML; the fines content varies from 63 to 71%; the liquid limit is between 17 and 19; and the plasticity is very low to non-plastic. The uncompacted filtered tailings have a hydraulic conductivity of 1.3×10^{-6} to 7.3×10^{-7} cm/s.

Initial configuration of the FTSF

Structural and non-structural zones

To guarantee the correct stability condition of the projected filtered tailings storage facility (FTSF), a shell or structural zone needs to be built consisting of structural fill, that is, filtered tailings compacted to 95% of its maximum dry density according to the Standard Proctor Test, in layers of up to 50 cm. Behind this shell, uncompacted tailings will be placed by dumping with trucks. A limit equilibrium analysis was performed with the objective of an initial determination of the structural zone extension.

Stability analysis of the initial configuration

Stability assessments were carried out through limit equilibrium analyses of the section (shown in Figure 1), using the Slope/W module from Geostudio software (2023), using Spencer's procedure (1967) alongside the cuckoo search algorithm by Yang and Deb (2010). These analyses were carried out by modifying the extension of the structural zone (Tailings C) and considering the most critical behavior of the uncompacted tailings (Tailings NC), that is, an undrained response, static or seismic liquefaction of these materials and their characterization through their residual strength. Pore water pressure was not considered in this preliminary analysis. Based on triaxial testing results, Tailings C material was modeled with a density of 20 kN/m^3, zero cohesion and an angle of friction of 35 degrees, while Tailings NC was modeled with a density of 14 kN/m^3 and undrained residual strength ratio of S_{ur}/σ'_0=0.11 obtained conservatively from a monotonic simple shear test after liquefaction by cyclic loading. The required post-liquefaction factor of safety (FoS) for this analysis mut be equal to or greater than 1.2, which is considered acceptable for a post-liquefaction condition according to the Canadian Dam Association (CDA, 2019).

Figure 1 shows the most critical failure surface based on the limit equilibrium analysis. It was concluded that the extension of the structural zone (Tailings C) must be at least 250 meters to guarantee the stability of the FTSF for a critical condition represented by the liquefaction of the uncompacted tailings.

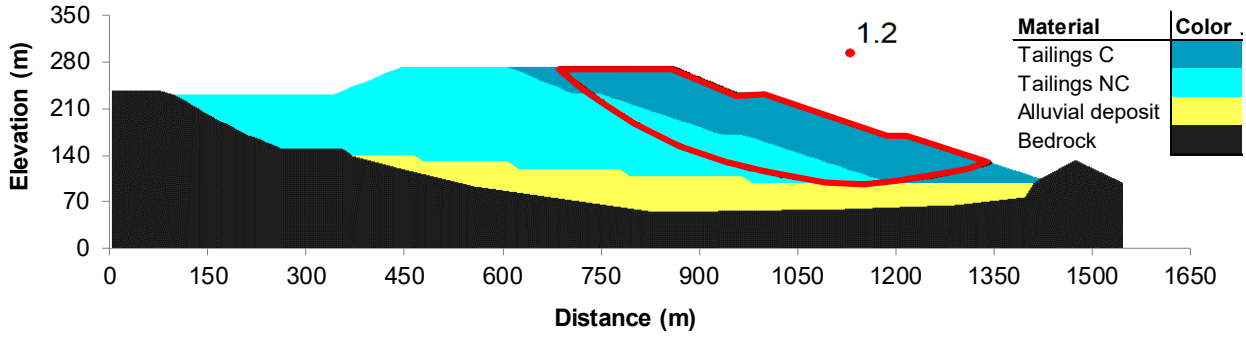

Figure 1: Section analyzed for definition of the structural zone

Cases analyzed

Two cases were analyzed. In both of them the moisture content of Tailings C material was reduced from 20% (as received from the filtration plant) to the optimum, which is 16%, achieved after in-situ drying by aerating, and compacted at 95% of their maximum dry density of 17.3 kN/m³ based on the Standard Proctor Test, to try to produce a material with essentially dilative behavior. Uncompacted filtered tailings NC were disposed of by stacking, exhibiting contractive behavior. The foundation consists of a sand alluvial deposit classified as SM overlying an andesite bedrock (see Figure 1).

Oedometer test results

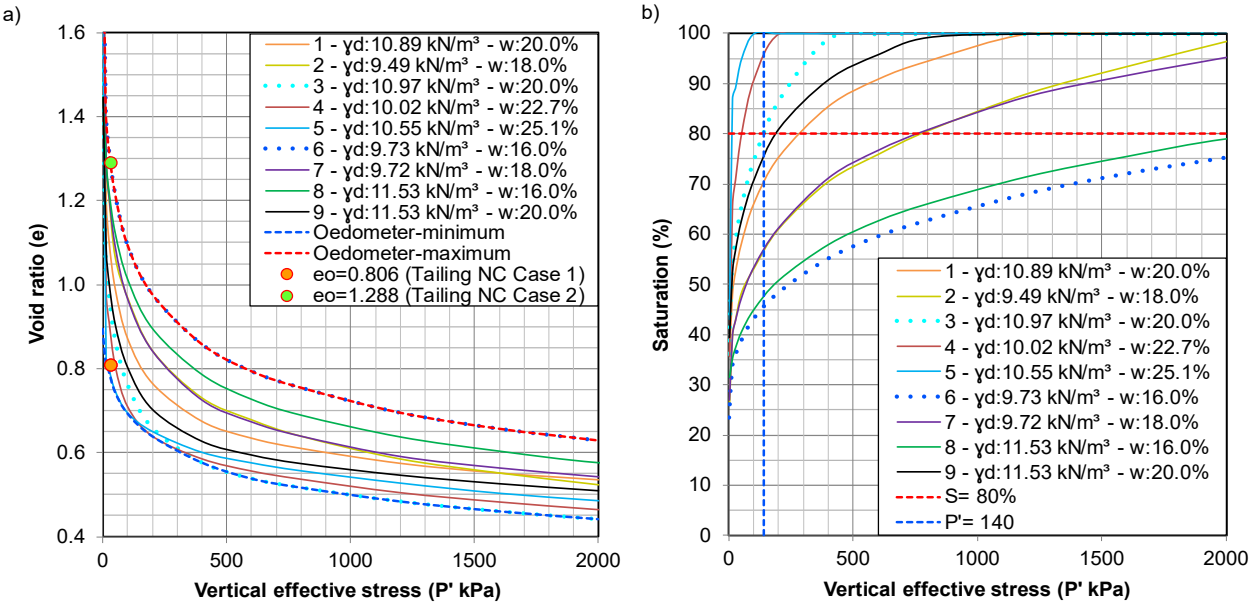

Figure 2: Oedometer curves of a) vertical stress vs. void ratio and b) vertical stress vs. saturation

Figure 2 shows the results of an oedometer test conducted on Tailings NC, where a variability in void ratios and degree of saturation was observed, primarily influenced by their density and initial moisture content. Based on the oedometer testing, the maximum and minimum envelopes were evaluated to establish the initial void ratio for each lift of the Tailings NC, assuming an average lift of 5 meters thick that provides a vertical stress of 70 kPa, and considering that the control nodes are located in the middle of each lift.

According to Aghazamani et al. (2021), soils with equal to or greater than 80% saturation and with a contractive behavior, are prone to liquefaction; thus, an undrained behavior was chosen for such conditions.

Case 1

This represents the conditions of the uncompacted filtered tailings with an average moisture content of 20% obtained from the filtration plant. The initial void ratio was assumed to represent the lower envelope of the oedometer curves (see Figure 2a), corresponding to tailings filtered at a vertical stress of 35 kPa (half a lift), resulting in an initial void ratio of 0.806 and a corresponding degree of saturation of 60% (Figure 2b), which is a relatively high initial value. According to Figure 2b, 80% saturation (threshold value below which conditions are essentially drained,) is reached with a vertical stress of 140 kPa, which corresponds to loads transmitted by two lifts (Tailings NC-D1 in Figure 3). Layers from the bottom to the top generate greater stresses, and therefore, saturation degrees greater than 80%, so Tailings NC-U in Figure 3 were analyzed in an undrained condition.

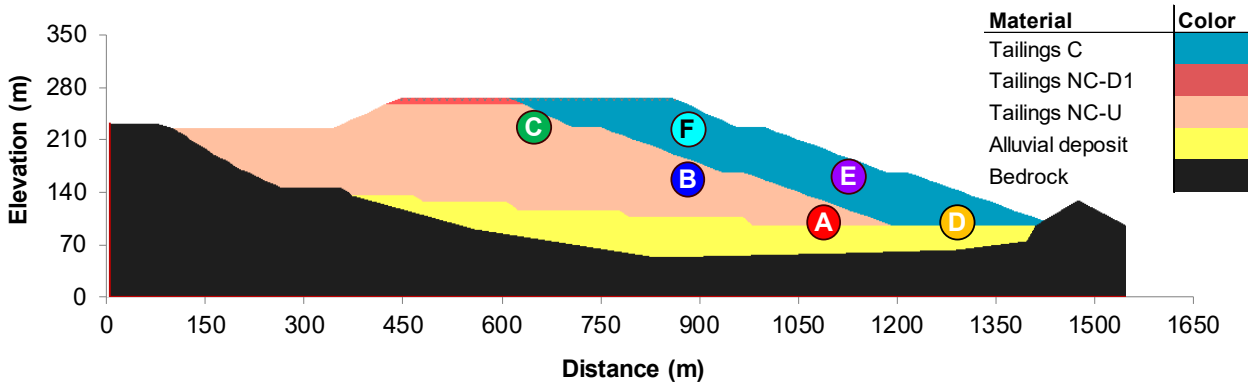

Figure 3: Section analyzed for Case 1

Case 2

This represents the conditions of uncompacted filtered tailings with the optimum moisture content of 16%, which is achieved in the same way as Tailings C, i.e., it is spread in small layers and undergoes in-situ drying by aerating, which increases the operating cost of the FTSF. Based on the oedometer test curves, the upper boundary representing the behavior of uncompacted filtered tailings with 16% moisture content and a vertical stress of 35 kPa, corresponds to an initial void ratio of 1.288 (Figure 2a); the corresponding degree of saturation is 37% (Figure 2b). As can be seen in Figure 2b, the degree of saturation of the selected curve

is less than 80% up to 2,000 kPa of vertical stress, i.e., it is higher than the maximum height of the FTSF. Therefore, Tailings NC-D2 in Figure 4 were analyzed considering drained behavior.

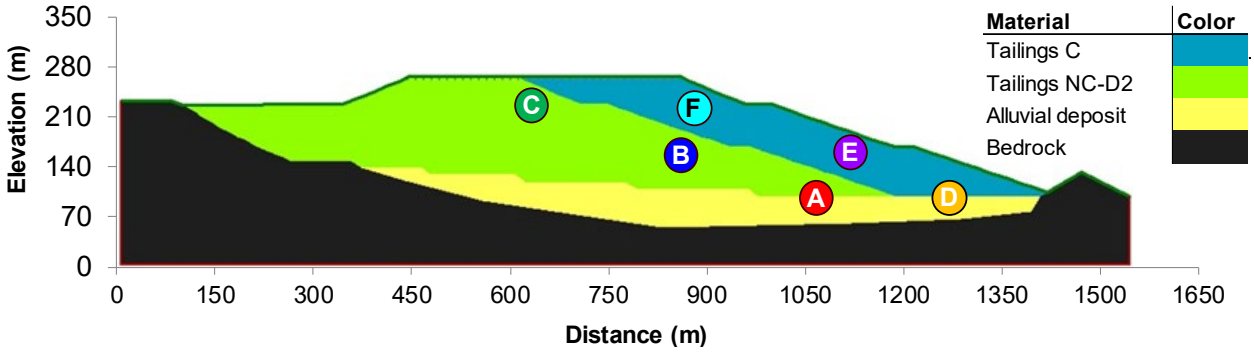

Figure 4: Section analyzed for Case 2

It is important to note that the initial condition (void ratio) for the Tailings C in Case 1 and Case 2, was obtained at the maximum dry density of the Standard Proctor, with a dry density of 17.3 kN/m³, and a moisture content of 16%. Six representative control points from the initial, intermediate, and final stages of the Tailings NC (A, B and C) and Tailings C (D, E and F) shown in Figures 3 and 4, were considered to compare the contractive and dilative behavior of the filtered tailings.

Performance assessment of FTSF

Constitutive models

In geotechnical numerical modeling, selecting the right constitutive models is crucial for accurate simulations. The NorSand (NS) model, introduced by Jefferies and Been (2016), is based on critical state soil mechanics, and is adept at simulating static liquefaction and dilatancy in granular materials. Its parameters allow for modeling of complex behavior in tailings, demonstrating its effectiveness in predicting the responses of different tailing types under stress, and was used for modeling the uncompacted filtered tailings. The Hardening Soil (HS) model, developed by Schanz et al. in 1999, is advanced and non-linear, designed for detailed soil behavior simulation. It incorporates stress limit states with confinement-dependent strength and stiffness parameters, which is essential for realistic soil behavior modeling under high loads, such as in tailings storage facilities. This model was used for the compacted filtered tailings and the alluvial foundation soil. The generalized Hoek-Brown (GHB) model, an evolution of the original Hoek-Brown failure criterion, is widely used for modeling rock masses in geotechnical engineering (Hoek et al., 2002) and was used for bedrock modeling. These models, each with distinct advantages, are integral to geotechnical engineering, especially in numerical modeling, for a comprehensive analysis of soil and rock behavior under various conditions.

Numerical modeling

To assess the serviceability of the structure based on deformation, a finite element numerical modeling was conducted for Case 1 and Case 2. A plastic analysis was performed, considering lifts of 5 meters, using the Sigma/W module of the Geostudio software (2022). These analyses were performed to identify liquefaction zones of the Tailings NC (Case 1), magnitude of displacements in the whole structure, and stress path in the control points within the FTSF, among other factors. In Case 1, the criteria for conducting this analysis was based on the drained behavior of the Tailings NC for the first 10 meters raise (2 lifts), followed by an undrained behavior of this material for deeper layers. In contrast, for Case 2, all layers were modeled with drained behavior, as determined from oedometer tests.

For this study, a field investigation and laboratory testing program were conducted for the characterization of the foundation soil, including drillholes, test pits, and geophysical surveying. The geotechnical characterization of the filtered tailings was performed based on laboratory testing including oedometer and drained and undrained isotropically consolidated triaxial tests to characterize material strength. Also,

information from the literature (Robertson et al., 2017), and from Anddes' project database was used to characterize the geotechnical properties of the foundation and tailings. For the finite element method (FEM), the Norsand constitutive model was calibrated according to Jefferies and Been (2016), while Hardening Soil and Generalized Hoek-Brown models were calibrated based on Geostudio (2022) (see Tables 1 and 2). Figure 5 shows the calibration for the uncompacted tailings with the triaxial tests performed.

Finite element analysis

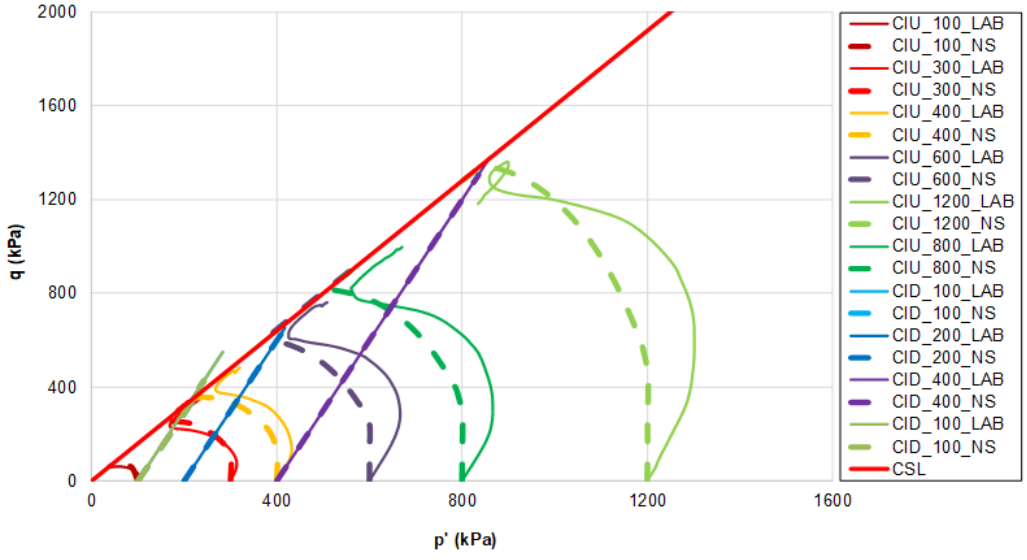

Figure 5: Model calibration based on triaxial tests. p'-q diagram

Figure 6 shows the finite element mesh of the numerical analysis of Case 1 with the discretization for each material; similar mesh was prepared for the analysis of Case 2. For both cases, the FTSF raise was simulated by 34 lifts of 5 meters thickness. For Case 1 where the conditions are undrained, the dissipation of pore water pressure generated during disposal has not been considered, due to the very low permeability of the filtered tailings, even when not compacted, which significantly reduces the water flow.

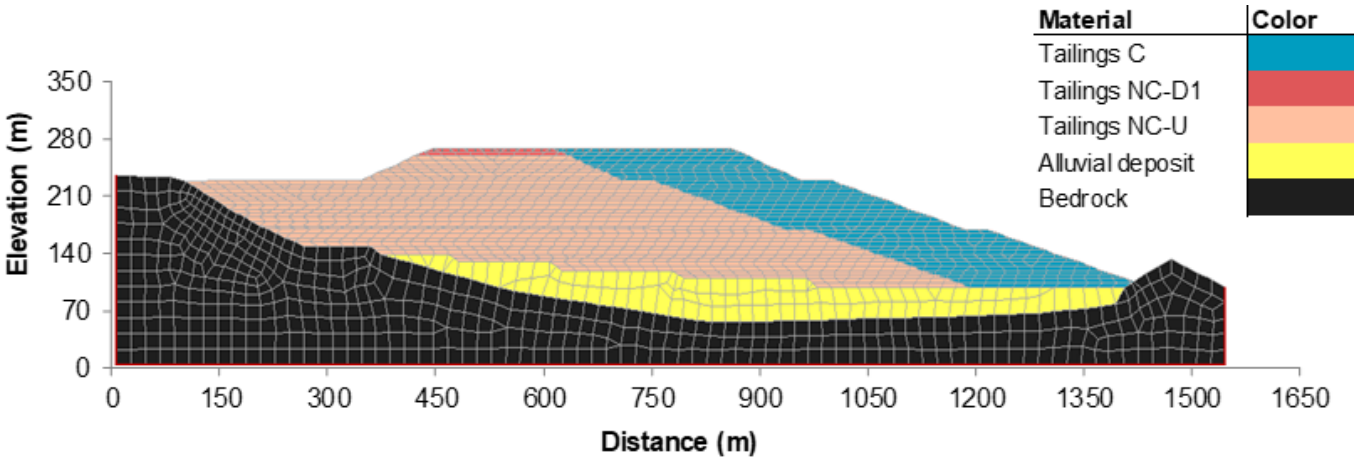

Figure 6: Finite element mesh for analysis of Case 1

Figures 7a and 7b show the p' vs. q and p' vs. void ratio (e) graphs during the filtered tailings disposal. In Figure 7a, for Case 1 and Case 2, where M is the critical state stress ratio defined based on drained and undrained triaxial tests performed to determine the critical state line (CSL), and IL is the instability line defined as the maximum q value after which the critical state is reached. As can be seen in Figure 7a, the stress paths of control points A, B and C (Tailings NC-U) for Case 1 show a clear contractive trend, reaching the instability line at $\eta=q/p'=0.74$, and then liquefaction at the critical state, while points D, E, and F (Tailings C) show a dilative behavior.

For Case 2, the stress paths in all cases do not show a contractive trend or decrease in effective stress. That is because the saturation degree is less than 80% with no generation of excess pore pressures. Figure 7b shows that points A, B, and C for Case 1, reach the CSL and static liquefaction occurs, while points D, E, and F are far from the CSL. The same analysis was performed for the entire finite element model.

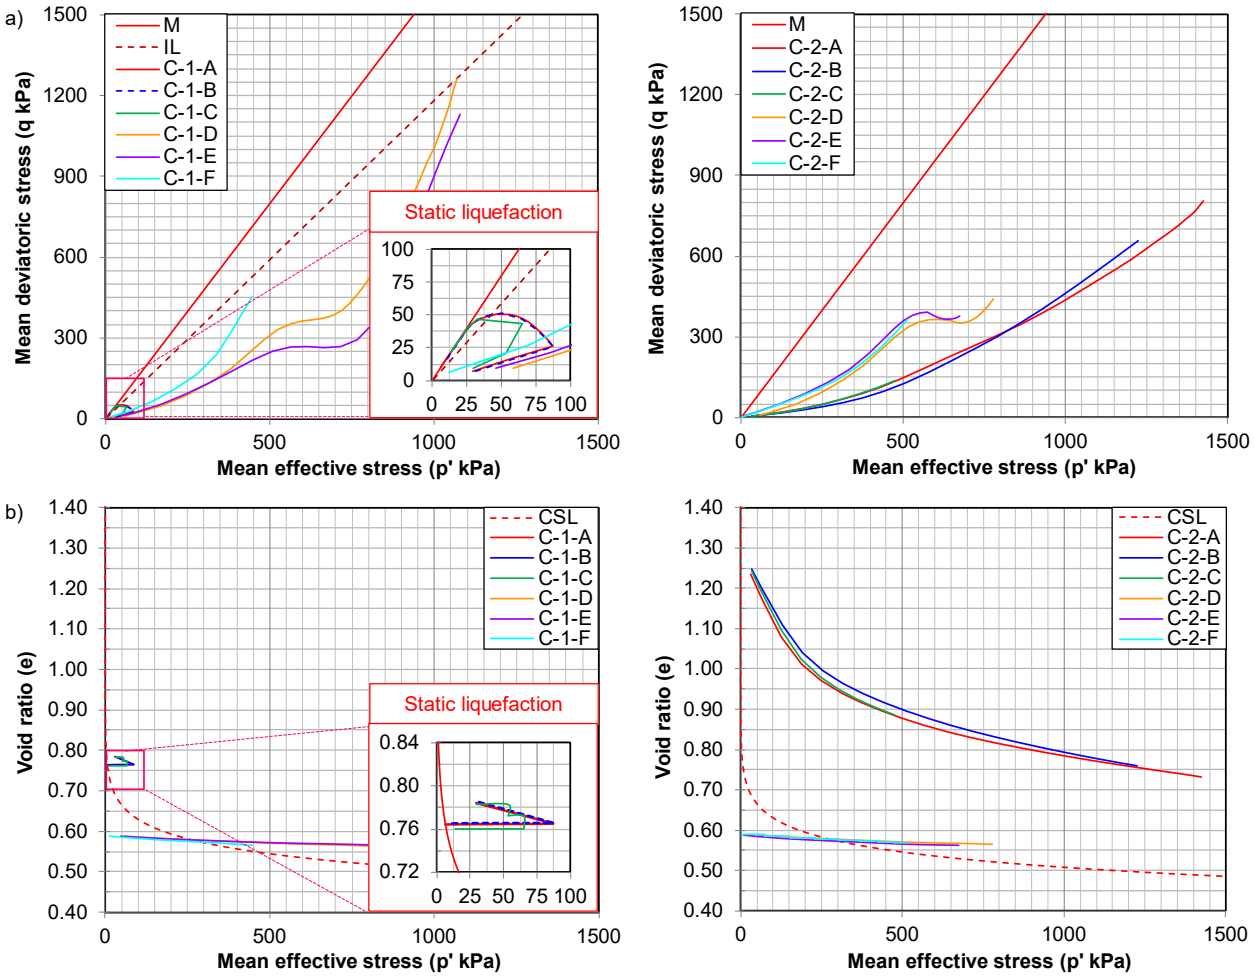

Figure 7: a) p'-q and b) p vs. e, during filtered tailings disposal for Case 1 and Case 2

Other criteria for identifying zones of static liquefaction were based on the failure criteria proposed by Geostudio (2022), as presented in equations 1 and 2.

$$|\psi| < 0.001 \quad (1)$$

$$|\eta\text{-}M_i| < 0.1 \quad (2)$$

Where ψ is the state parameter.

Figures 8a and 8b show the evolution of the above failure criteria per lift during the FTSF raise. Figure 8a shows that points A and B (Tailings NC-U) reach a $|\psi| < 0.001$ condition for lifts 22 and 32, respectively, predictably achieving the critical state (liquefaction) and fluctuating within a range from 0 to -0.05, while point C does not reach this condition. However, points A, B, and C adhere to the second criteria ($|\eta\text{-}M_i| < 0.1$) for lifts 16, 22 and 29, respectively, indicating liquefaction at that specific raise.

Figure 8c shows the FTSF raise versus η/M, displaying a rapidly escalating mobilized strength in the Tailings NC-U, particularly after reaching the instability line (η/M=0.74), approaching 1.0 (critical state) indicating liquefaction. Figure 8d shows the rapid increase of the pore water pressure during the FTSF raise.

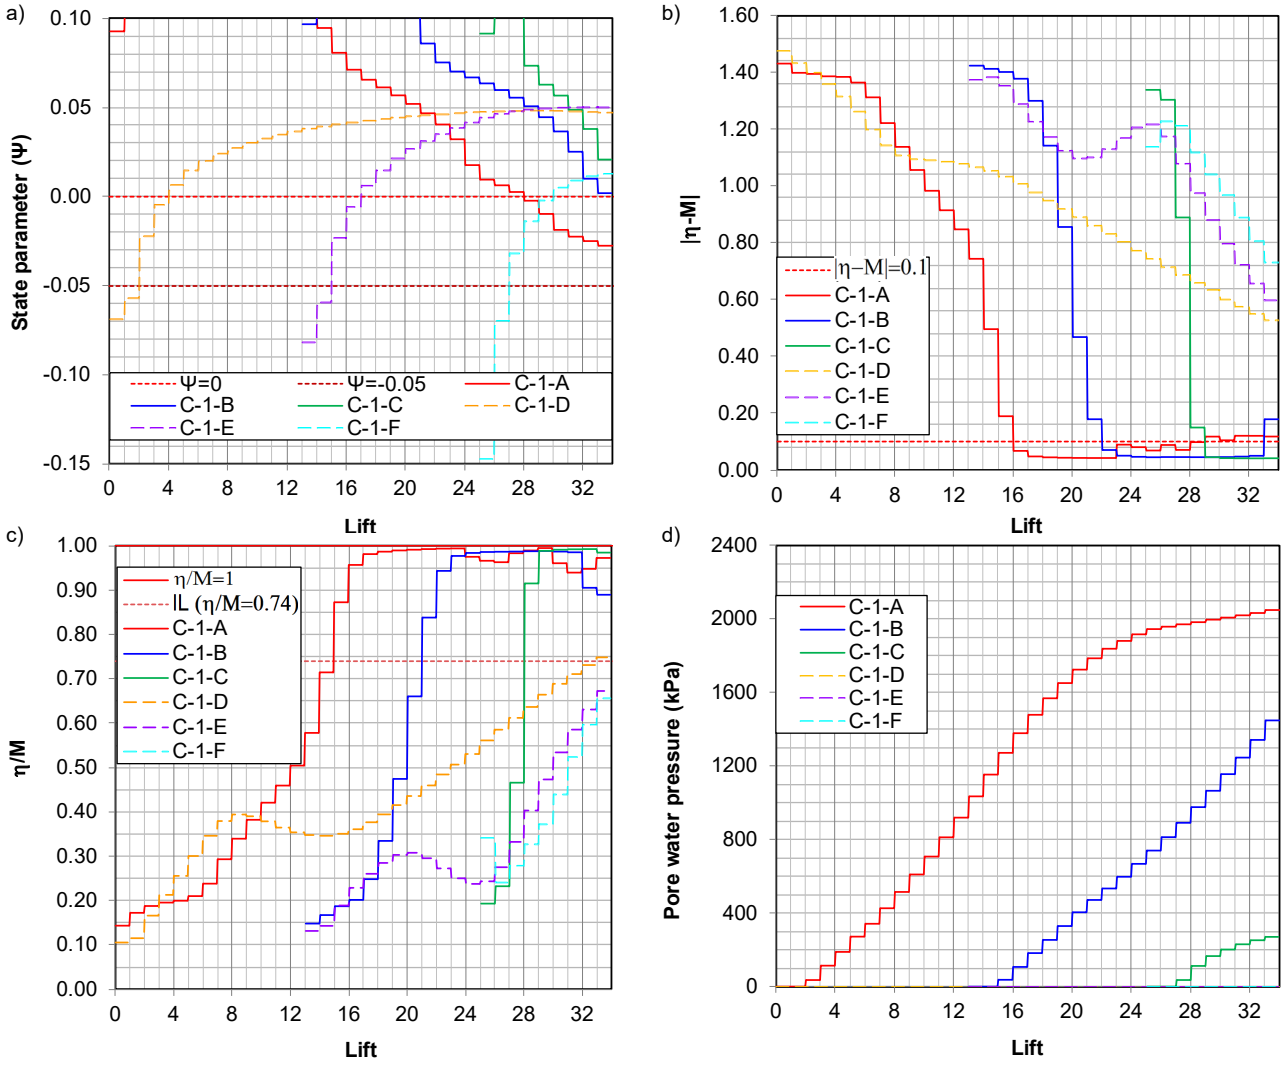

Figure 8: Variation of a) Ψ, b) |η-M|, d) η/M and c) pore pressure, during Case 1 FTSF raise

Figure 9 shows that the NC-U tailings have reached a mobilized strength, η-M, greater than 0.74, surpassing the instability line, indicative of static liquefaction and approaching the critical state.

Horizontal and vertical displacements were calculated at each raise. Figures 10 and 11 illustrate the displacements at the maximum height of the FTSF for Case 1 and Case 2, respectively. For Case 1, maximum horizontal and vertical displacements of 10.3 and 4.3 m, respectively, were obtained, which occurred in the middle and upper part, respectively, of the FTSF at Tailings C. For Case 2, maximum

horizontal and vertical displacements of 2.0 and 8.8 m, respectively, were calculated. As expected, horizontal displacements in Case 1 are larger than in Case 2, due to an undrained condition that generates predominantly shear strains and liquefaction of uncompacted tailings, while the drained conditions of the uncompacted tailings in Case 2 predominantly generate volumetric strains and vertical displacements (settlements).

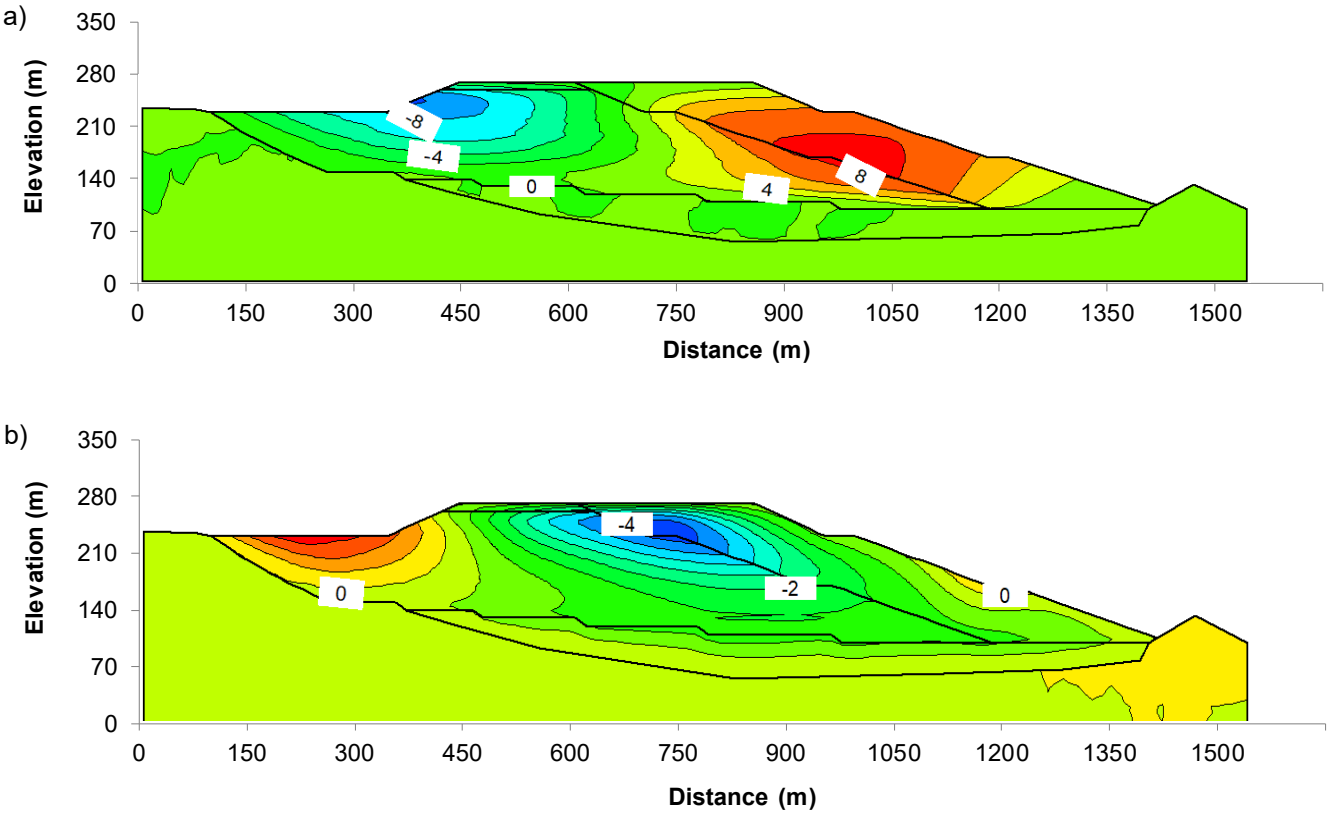

Figure 10: a) horizontal displacements and b) vertical displacements. Case 1

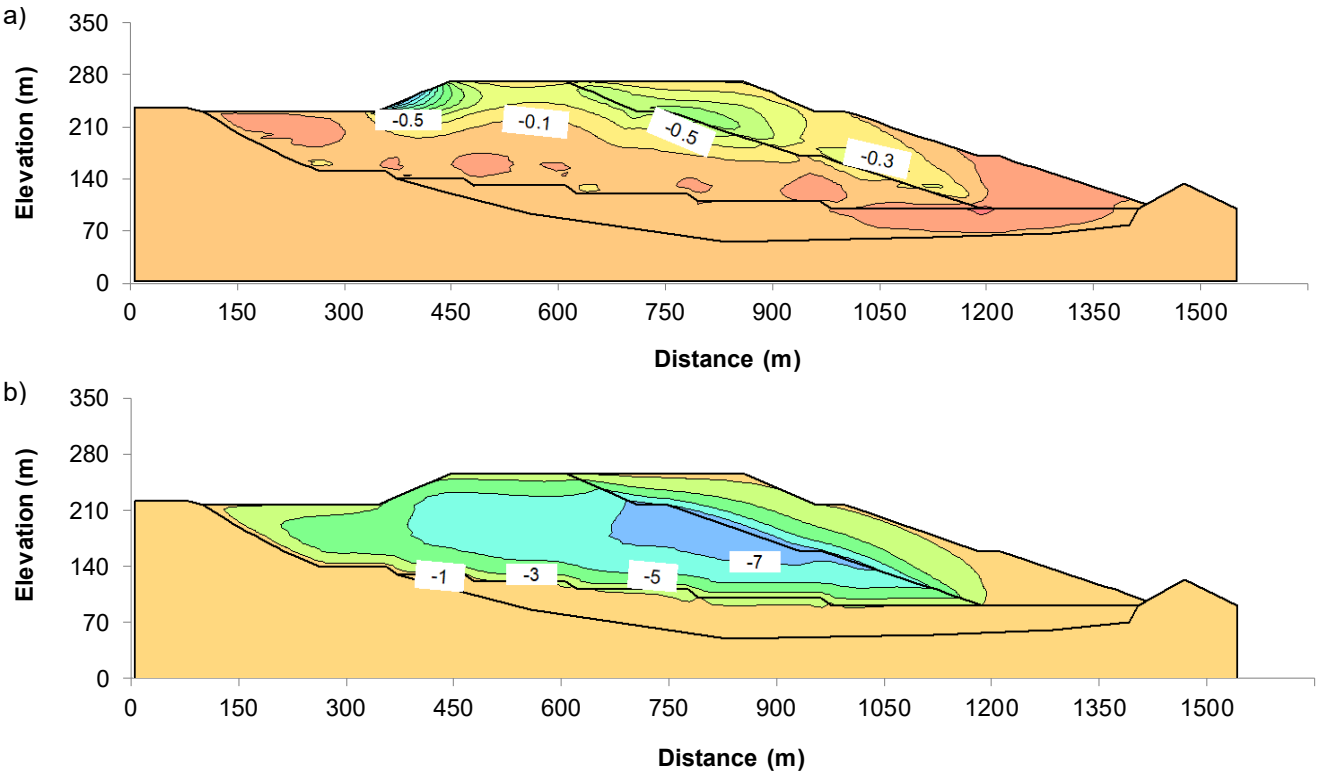

Figure 11: a) horizontal displacements and b) vertical displacements. Case 2

Final limit equilibrium analysis

As a final step, a stability analysis was carried out using the limit equilibrium method (LEM) to complement the performance evaluation previously performed through the numerical analysis. The stability analysis considers the geotechnical parameters shown in Table 3. The post-liquefaction strength of Case 1 Tailings NC-U were estimated from Equation 3 derived from the Norsand model (Jefferies and Been, 2016) when contractive material meets critical state conditions, and based on best practices recommended by Jefferies and Been (2016) considering historical cases. It should be noted that any particle crushing effect due to the maximum loading of the ultimate FTSF configuration, that may influence the shear strength of the uncompacted tailings, has not been considered.

$$\frac{Su_{liq}}{\sigma'_v} = \frac{1+2*K_0}{3} * \frac{M}{2} e^{\frac{-\Psi}{\lambda}} \quad (3)$$

Table 3: LEM summary parameters

Case	Material	ɣ (kN/m³)	c (kPa)	ϕ (°)	Sur/σ'	Color

All	Bedrock	26	230	28	–	

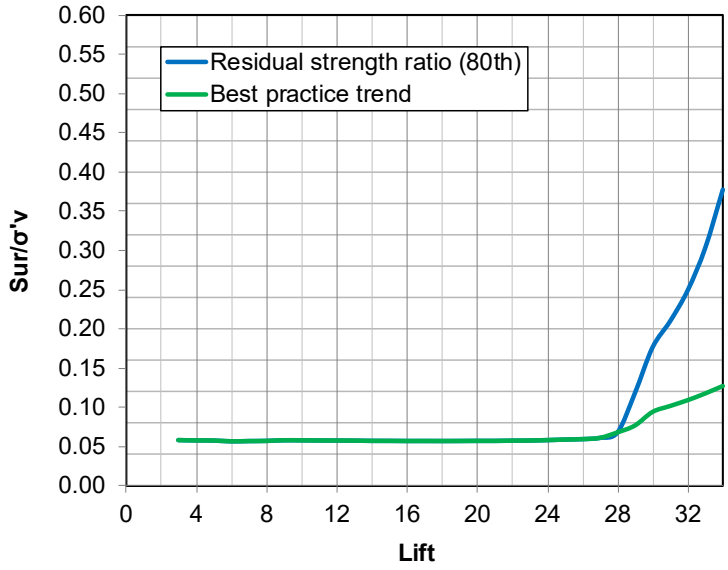

Figure 12: Post-liquefaction strength ratio for contractive uncompacted tailings for Case 1

Figure 12 shows the variation of the post-liquefaction strength, which represents the evolution of the 80th percentile of the state parameter at each lift and is based on best practices recommended by Jefferies and Been (2016) considering historical cases. It is interesting to note that the two post-liquefaction strength adjustments indicated above are equal up to lift 28, from which point the post-liquefaction strength from historical cases is noticeably lower. The increase in pore water pressure during the FTSF raise was incorporated from the numerical analysis (FEM) for the estimation of the effective vertical stress. For Case 1, a minimum FoS of 1.2 is assumed. For Case 2, the minimum FoS should be 1.5.

Figure 13 shows the limit equilibrium analysis results. As can be observed for Case 1 and Case 2, the FoS are similar up to approximately lift 16 (approximately 80 m high). This is because the failure surface develops only in Tailings C. For Case 1, with the following lifts the failure surface extends towards Tailings NC-U, which mostly presents a liquefaction condition, which significantly reduces the FoS, reaching the

minimum required (FoS=1.2) for lift 24. A further raise causes FoS below the minimum required. For Case 2, the static FoS reaches a value of 2.54 for the maximum height of the FTSF.

It is important to mention that to reach at least a FoS=1.2 for Case 1 for the maximum height of the FTSF, it would be required to enlarge the structural zone (Tailings C) to more than 250 m in length, resulting in a more robust configuration. Furthermore, the high values of FoS shown in the stability analyses of Case 2 indicate that the structural zone may eventually be reduced.

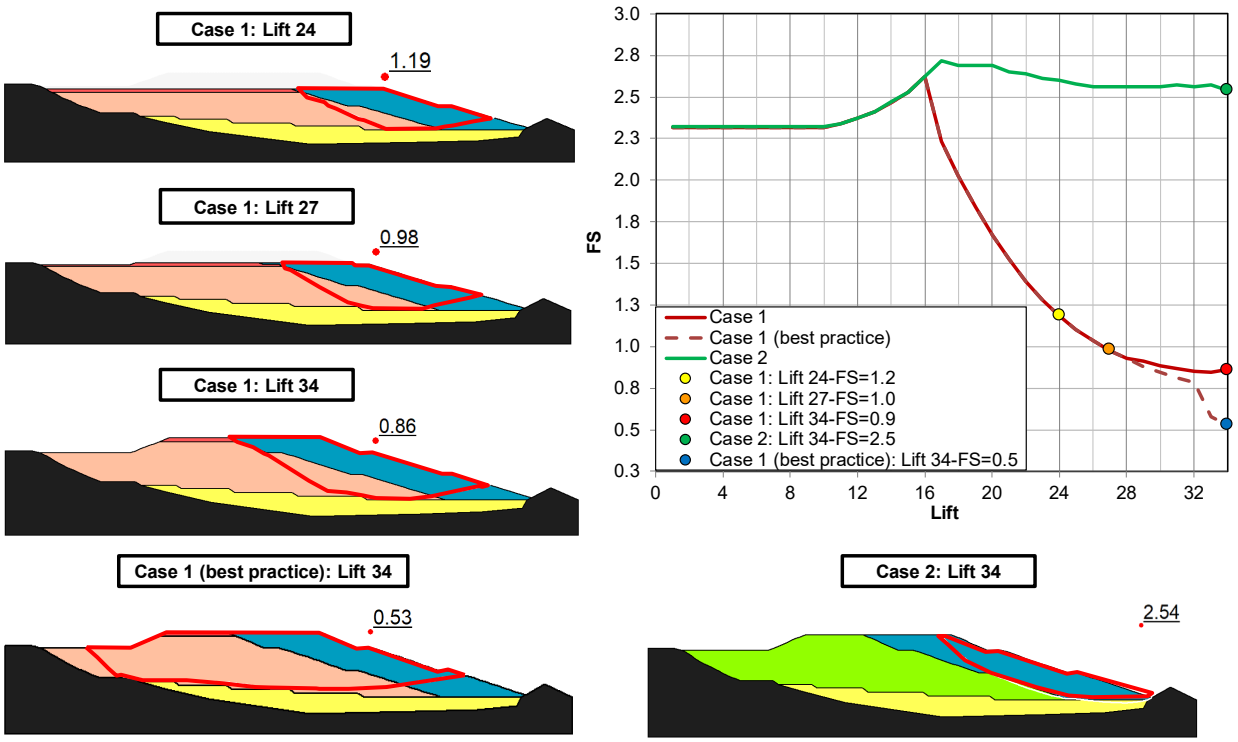

Figure 13: Limit equilibrium analysis results

Conclusion

Oedometer tests on uncompacted tailings showed that the filtered tailings exhibit a clear trend to more contractive behavior at high moisture content. Therefore, reducing the moisture content either at the filtration plant or by in-situ aeration will improve the strength of the filtered tailings.

In a FTSF project, the construction of a shell or a structural zone composed of compacted filtered tailings is required, which guarantees the stability of the entire facility, since uncompacted tailings will be placed behind this zone. The structural zone may be sized based on a limit equilibrium analysis considering the most critical conditions of the uncompacted tailings.

Numerical simulation using the Norsand model indicates that for Case 1, the uncompacted filtered tailings with the filtration plant moisture (20%) quickly reach a degree of saturation of 80% for a load equivalent to two lifts (10 m), exhibiting a contractive behavior, generating excess pore pressure and

liquefaction from lift 16. However, for Case 2 when the moisture content is equal to the optimum (16%), the initial degree of saturation is very low, not reaching 80% saturation for the maximum height of the FTSF, so there are no excess pore water pressures and therefore, no liquefaction. In both cases, the compacted tailings exhibit a dilative behavior, as expected.

Case 1 corresponds to an undrained scenario where shear strains predominate, while Case 2 represents drained conditions where volumetric conditions will be predominant, which is why horizontal displacements are greater for Case 1 than for Case 2 due to the liquefaction of the uncompacted tailings observed in Case 1, while vertical displacements in Case 2 are greater than in Case 1.

For Case 1, the limit equilibrium analyses show a FoS=1.2 (minimum required) at lift 24, reducing to approximately FoS=0.9 and FoS=0.5 considering Norsand formulation (equation 3) and best practices post-liquefaction strength ratio, respectively, for the maximum height of the FTSF (lift 34). To achieve at least a minimum FoS, the structural zone must be enlarged. For Case 2, the FoS always remains above 2.3, indicating adequate stability conditions.

The results obtained indicate that the procedure presented is suitable for evaluating the performance of a FTSF partially constructed with uncompacted tailings.

Next-Gen Tailings Waste Management: Transforming Life-Cycle Strategies

Lakshmin Bachu, Tetra Tech Inc., Canada

Abstract

Ensuring the integrity of tailings waste (TW) facilities is crucial for public safety, environmental conservation, and socio-economic growth. The complexities stemming from operational demands, data management, socio-economic factors, and climate variability require innovative solutions. Generative Artificial Intelligence (GenAI) offers vast potential in this domain. With capabilities in text, vision, audio, video, programming, and numerical analysis, GenAI can revolutionize data management, provide data-driven predictions, and improve decision-making. This paper explores GenAI's transformative applications in tailings waste management, emphasizing its ability to process extensive data sets, integrate diverse data formats, and offer insights beyond conventional methods. Effective deployment requires high-quality data, bias mitigation, data security, and specialized expertise. The paper discusses GenAI's opportunities and limitations, providing an implementation roadmap and valuable insights for professionals, regulators, and researchers to enhance safety management and empower the future of tailings waste facilities globally.

Introduction

Effective management of tailings waste is crucial for safeguarding communities, protecting ecosystems, and ensuring the mining industry's continued acceptance by society. Figure 1, obtained from MEND (2001) and Snow (2022), shows a schematic of tailings waste facilities. Due to the complexity of processes such as hydrology and geoenvironment, infrastructure requirements, stakeholder involvement, and other variables, these sites encounter unique challenges.

LePoudre and Morrison (2022) proposed a framework for tailings management systems (TMSs), as shown in Figure 2. The framework emphasizes a comprehensive and integrated approach, covering corporate policy, resources, failure mode analysis, and a tailings management system. Key critical control areas include tailings storage facility integrity, operations, maintenance and surveillance, emergency preparedness and response, and governance and assurance. The framework operates within a continuous improvement cycle of planning, doing, checking, and acting, ensuring compliance with regulations and addressing the entire life of the mine, including closure planning, risk and change management.

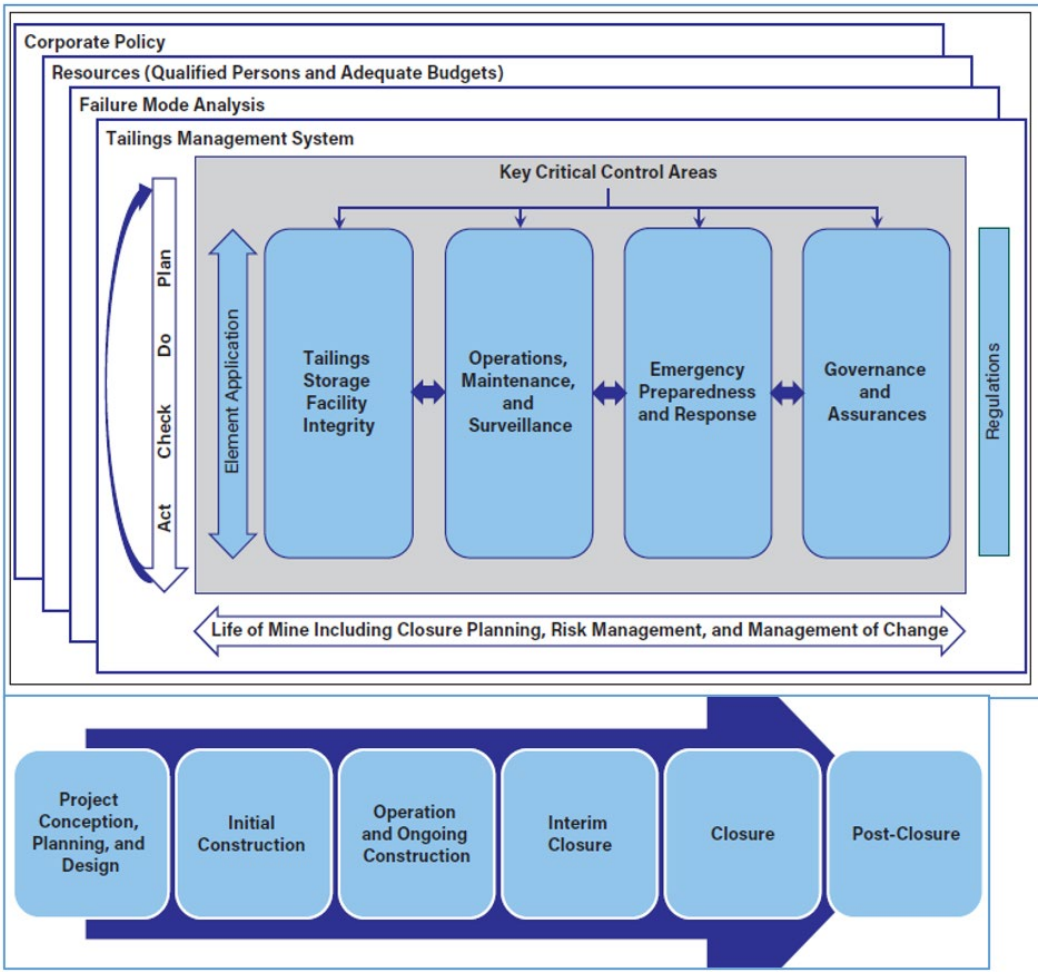

Figure 2: Tailings management system framework as proposed by LePoudre and Morrison (2022)

Hariri-Ardebili et al. (2023) highlight various technologies enhancing safety and operations of dam infrastructure, including digital twins, drones, Internet of Things (IoT), satellite remote sensing, and Building Information Modeling (BIM). However, to further alleviate the challenges in tailings management, advanced technologies are required. Key challenges in tailings waste management include: data management: vast amounts of siloed information that is difficult to integrate; operational demands: labor-intensive routine inspections and maintenance; climate variability: increasing risks from extreme weather events; and human error: complexity heightening risks during data interpretation and inspections. Traditional management methods are labor-intensive and prone to human error, highlighting the need for advanced technologies to streamline operations and improve predictive capabilities.

Generative Artificial Intelligence (GenAI), a branch of artificial intelligence, offers a transformative solution by analyzing vast amounts of data both off-line and in real time, collating various sources of data (e.g., text, images, numbers, audio), detecting patterns and anomalies, enhancing predictions and forecasting, and improving decision-making processes. GenAI has the potential to elevate tailings waste management to new levels of efficiency and reliability. Implementing GenAI requires a strategic approach, including stakeholder involvement, compliance with regulations, and addressing ethical considerations. By embracing these advancements responsibly, the tailings waste community can usher in a new era of infrastructure resilience, ready to face the challenges of operations, extreme weather events, and aging facilities.

The objectives of this paper are to:

1. Provide an overview of GenAI.
2. Detail how GenAI can be applied to tailings waste (TW) management.
3. Identify the challenges and future opportunities using GenAI.
4. Summarize the conclusions with best practices.

Generative Artificial Intelligence

GenAI is a versatile technology capable of producing various types of content, such as text, images, numbers, audio, and video, including segmenting objects in videos. It can also generate programming code and interact with users. These models, known as large language models (LLMs), are trained on vast datasets, including both private and publicly available information from the internet. The training process involves passing input data through multiple layers of neurons in a neural network, where each neuron's weight is adjusted using complex mathematical algorithms to minimize errors and enhance accuracy. These LLMs predict the next word in a sentence based on probabilistic estimates and other sophisticated processes.

GenAI models are designed for understanding and generating human-like text, particularly useful for processing large text data and providing contextually accurate responses. Models like GPT-4o (Omni) by

OpenAI (2024), Llama 3.1 by Meta, and Gemini by Google are increasingly becoming popular. These models excel in processing extensive datasets, identifying patterns, and generating actionable insights. The field of GenAI is rapidly evolving, with new architectures and hybrid approaches continually being developed to address specific challenges and improve performance across various domains. Leveraging GenAI may allow TW management to transition from reactive to proactive strategies, improving the resilience and reliability of tailings infrastructure.

Tailings waste management applications

GenAI distinguishes itself not only by its ability to create, simulate, and predict, thereby surpassing the capabilities of traditional data analysis, but also by encompassing a wide range of features including text, vision, listening, voice recognition, programming, graphs, and numerical acumen. The multifaceted nature allows it to interact and interpret various forms of data, enhancing its applicability and effectiveness across diverse data sources and scenarios. This technology may enable a paradigm shift from reactive to proactive strategies, which would be crucial for ensuring long-term safety and efficiency of tailings waste infrastructure.

The power of GenAI lies in its ability to process vast datasets, collating information, and deriving insights that could elude conventional methods. In the context of TW management, where numerous and intricate variables interact, this is particularly valuable. GenAI can analyze data from multiple sources, including previous reports, historical data, sophisticated sensor networks monitoring critical conditions and AI-augmented drone inspections, to offer predictive insights and decision-making support in uncertain scenarios. GenAI LLM capabilities are categorized into basic, emerging, and augmented levels as shown in Figure 3, each of which can be crucial for proactive TW management.

Basic capabilities include comprehension, multilingual processing, world knowledge, and coding. These foundational skills enable LLMs to perform tasks such as summarization, translation, and function calling, which are essential for managing diverse data sources in tailings management. Emerging capabilities encompass instruction following, reasoning, and in-context learning. Instruction following allows LLMs to execute complex tasks based on specific guidelines, enhancing the precision of operational procedures. Reasoning capabilities, including symbolic and logical reasoning, enable the models to solve problems step-by-step and make informed decisions. In-context learning allows LLMs to adapt to new information quickly, making them valuable for dynamic environments like mine waste management. Augmented capabilities involve interacting with users, self-improvement, and tool utilization. These advanced features enable LLMs to engage in physical and virtual interactions, continuously refine their performance, and effectively utilize various tools. For instance, in tailings management, LLMs can assist

in real-time monitoring, predictive maintenance, and emergency response planning, thereby improving overall efficiency and safety.

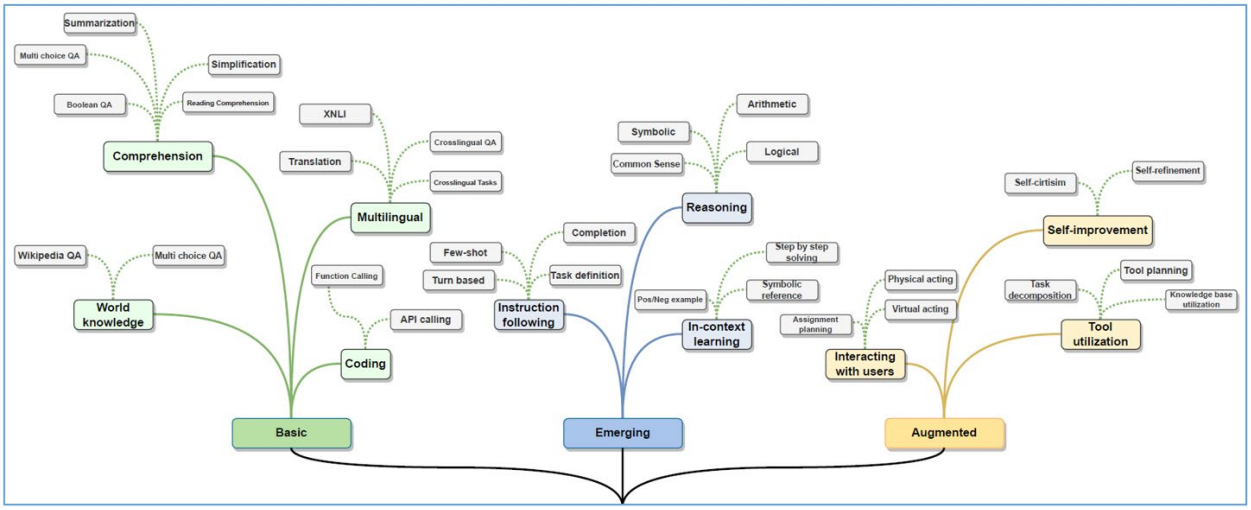

Figure 3: GenAI LLM capabilities (source: Minaee et al., 2024)

Developing and fine-tuning GenAI models enhances TW management. As shown in Figure 4, the process starts with data documentation and governance, collecting historical performance data, inspection reports, and real-time monitoring data from IoT sensors and drones.

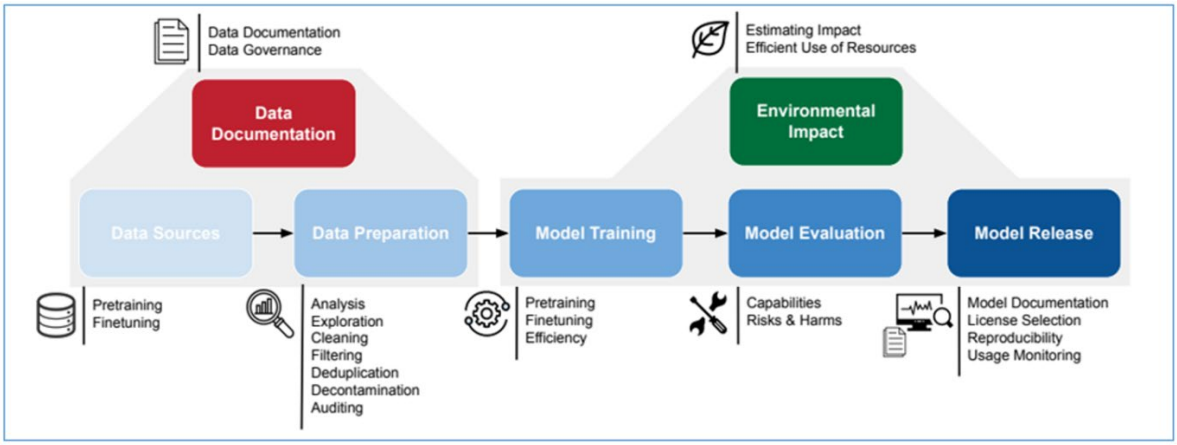

Figure 4: An overview of GenAI development (Source: Foundation Model Cheatsheet, 2024)

Next, data preparation involves cleaning, filtering, deduplication, and auditing to ensure quality and relevance. The data preparation phase of GenAI model development also aligns with the Integrated Knowledge Base concept in the Global Industry Standard on Tailings Management (GISTM) (GTR 2020) as it emphasizes the importance of data quality, relevance, and continuous updating, which are essential for both effective tailings management and the development of robust AI models. The prepared data is used

for model training, including pretraining and fine-tuning, to handle individual TW management tasks like dam safety reviews (DSRs), predicting structural issues, optimizing maintenance schedules, and simulating scenarios. Tasks are compartmentalized into modules for independent development and optimization.

Model evaluation assesses capabilities, risks, and potential harms, ensuring the model supports proactive tailings safety management. The final phase includes thorough documentation, regulatory compliance, reproducibility checks, and usage monitoring to ensure reliability. Environmental impact and resource efficiency are considered throughout. This modular approach enhances precision, reliability, and continuous innovation in tailings waste management. Integrating conventional approaches and advanced technology with GenAI offers transformative potential for enhancing completion of tailings DSRs. This integration can make the process more efficient, accurate, and comprehensive with proper risk management in place. For example, GenAI can be integrated into the tailings DSR processes (i.e., integral part of tailings management) that are outlined in the CDA Dam Safety Guidelines (CDA, 2013), and noted as a requirement of the GISTM, and the integration potential is described in the following.

Data and records review, and data book update

Integrating GenAI with traditional procedures may significantly enhance the data and records review process. Traditionally, this task involves manually reviewing historical data, inspection reports, and maintenance logs, which can be time-consuming and prone to human error. GenAI can streamline this process by summarizing large datasets, extracting key insights, and identifying patterns of concern. For instance, GPT-4o can quickly analyze and summarize documents containing historical data, while GenAI spatial tools like the ChatGPT plugin for Quantum Geographic Information System (QGIS) can visually present data, making it easier to identify patterns and areas of concern. Fine-tuning GenAI models with specific tailings DSR reports and data could improve the quality and accuracy of outputs tailored to each dam's unique characteristics, significantly reducing review time and overall tailings DSR completion time.

Site inspection and staff interviews

Site inspections and staff interviews traditionally require extensive manual effort and can result in delays and potential human errors. GenAI can automate the creation of comprehensive inspection checklists based on historical data. During inspections, AI-enhanced drones and sensors capture high-quality images and data, which are processed by Generative Adversarial Networks (GANs) to detect structural defects. GenAI spatial tools provide real-time geospatial visualization, enabling prompt assessment of issues. Additionally, GPT-4o models can transcribe and analyze verbal interviews with staff, efficiently extracting key information. Images from site inspections can be automatically processed (Figure 5) for potential TW management concerns. Fine-tuning these models with data from previous inspections and interviews provides more accurate and relevant outputs. This integration can significantly reduce the time required for

site inspections and staff interviews, enhancing the efficiency of TW management engineers without replacing their expertise.

Based on the attached image of the tailings dam, here are some technical observations:

1. **Dam Type and Condition**: The dam appears to be an earthen embankment, likely designed for tailings storage. The embankment slope is relatively steep, and the surface appears to be primarily composed of rock fill, which provides stability but might be prone to erosion without proper maintenance.
2. **Erosion and Stability**: No visible erosion control measures, such as riprap or vegetation, were observed. Regular inspections and maintenance are necessary to prevent erosion, particularly during heavy rainfall.
3. **Water Management**: The ponded water level seems relatively low, which is favorable for reducing hydraulic pressure on the dam. However, ongoing water management is crucial to prevent overtopping, especially during storm events.
4. **Safety Concerns**: It's essential to monitor for any signs of seepage, slumping, or erosion, especially near the dam crest and toe, as these could indicate potential failure mechanisms.

Figure 5: Demonstration of ChatGPT interaction using a tailings dam picture (source: Logan, 2022)

Tailings dam safety review and analysis

GenAI can enhance tailings dam safety analysis and review by analyzing large datasets from historical data, inspection reports, and real-time sensor inputs to identify potential issues. Engineers can use GPT-4o for querying specific aspects of dam performance and summarizing key findings. GenAI spatial tools provide advanced geospatial visualizations, helping simulate flood scenarios and assist in geotechnical assessments, improving TW management accuracy and efficiency. The Hydat-FlowGPT program shown in Figure 6, developed using GPT-4o, acquires hydrometric flow data and performs flow-frequency analysis to help estimate inflow design floods (IDFs).

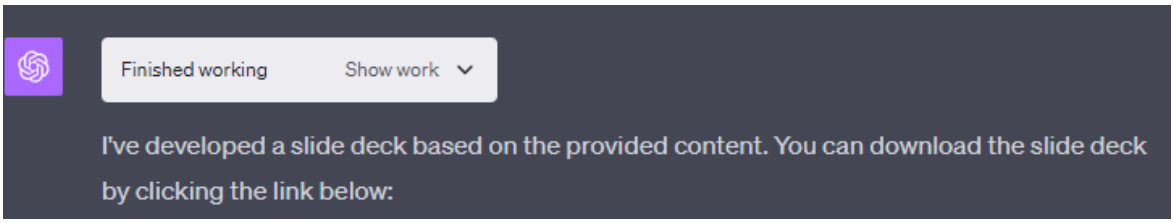

Figure 8: An overview of GPT4o's ability to create MS PowerPoint slides with tailings DSR workshop template

Challenges and opportunities

The effectiveness of GenAI in TW management relies on high-quality datasets. Poor data quality and biases in AI models can lead to inaccurate predictions. Mitigating biases requires detection algorithms, diverse training datasets, and continuous evaluation. Robust cybersecurity measures, including encryption, access controls, and regular audits, are essential to protect sensitive data. Compliance with data privacy regulations is crucial to safeguard personal and sensitive data, ensuring legal compliance and stakeholder trust. Implementing GenAI systems demands specialized skills in AI, data science, and TW management engineering. Collaboration between AI specialists and TW engineers is necessary for accurate application and interpretation of AI models.

GenAI enhances tailings management efficiency but cannot replace human judgment and experience. Over-reliance on AI risks missing critical issues detectable only through on-the-ground inspections. Human oversight remains essential to interpret AI outputs and maintain safety standards. Continuous training and support for personnel are essential to stay updated with AI advancements. Despite these challenges, GenAI holds significant promise for transforming TW management practices (but not limited to):

- Enhanced Prediction and Analysis – Improved predictive models can be used to better forecast structural issues, maintenance needs, and environmental impacts. Real-time analysis of data from IoT sensors and drones could enable rapid detection of anomalies and potential problems.
- Customized AI Models – Developing and fine-tuning AI models with dam-specific historical data and inspection reports may provide more accurate and relevant recommendations.
- Advanced Monitoring and Maintenance – Integration with IoT devices creates a more interconnected monitoring approach, feeding continuous real-time data to AI systems. AI-driven robotics can be used to conduct detailed inspections and perform minor repairs in hard-to-reach or hazardous areas, enhancing safety and efficiency.
- Proactive Management – Continuous data streams could enable AI to provide timely alerts and recommendations for maintenance and emergency response. AI can be used to help optimize water usage, energy consumption, and environmental impact, supporting more sustainable tailings waste management.
- Climate Resilience – AI can be used to provide predictive insights into extreme weather events and long-term environmental changes, helping develop adaptive strategies for dam infrastructure.

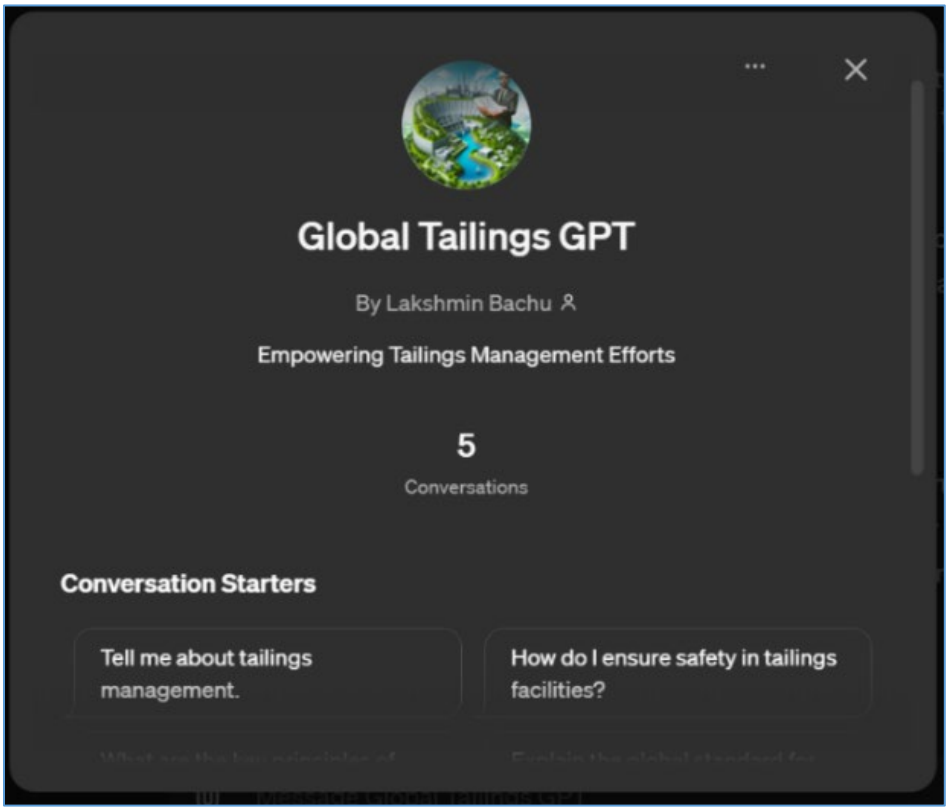

Figure 9: Global tailings GPT developed in ChatGPT for the public to learn about GISTM guidelines

- A multimodal LLM, ChatGPT enables users to create specialized GPTs using custom knowledge bases and instructions, particularly useful for reviewing tailings DSR reports and related information. Users can compare tailings DSRs with regulatory guidelines like CDA, the Mining Association of Canada (MAC), and the GISTM for comprehensive evaluations (e.g., Figure 9). Multiple team members can interact with GPTs simultaneously, streamlining information exchange and DSR completion. These GPTs can identify potential deviations or compliance issues based on TW management guidelines, allowing engineers to evaluate them more efficiently. GPTs also serve educational purposes for dam professionals, and organizations like CDA can deploy them for advisory purposes.
- AI Agents – These are autonomous software entities designed to perform tasks, make decisions, and interact with their environment with minimal human intervention (Figure 10). Leveraging GenAI, these agents may one day transform TW management by automating data reviews, analysis, document preparations, continuously monitoring conditions, analyzing structural integrity, and predicting potential failures with reasonable accuracy. For instance, AI-enhanced drones equipped with high-resolution cameras can capture detailed images of tailings dam and other structures, while IoT devices provide real-time data on environmental and structural parameters.
- Small Language Models (SLMs) – These are specialized AI systems trained on focused datasets with fewer than one billion parameters, unlike LLMs which exceed 100 billion parameters. In TW management, SLMs offer distinct advantages where targeted training allows them to excel in TW engineering and safety protocols, potentially outperforming larger models in this niche. SLMs require less computational power, making them suitable for on-site deployment, even in remote areas. They process data and generate insights rapidly, enabling near real-time monitoring crucial for TW management. SLMs are effective with smaller datasets, beneficial for mine sites with limited data.
- Retrieval-Augmented Generation (RAG) – RAG models combine retrieval-based and generation-based AI to enhance decision-making by integrating diverse data sources like structural health and environmental information, generating alerts, simulating emergency scenarios, and assessing risks, as well as automating report generation for thorough documentation and compliance. By improving efficiency, accuracy, and proactive maintenance, these AI technologies may lead to better safety outcomes and decision-making, ultimately protecting public safety and the environment. RAGs are also integrated with Agents for improved efficiency, often referring to AgentRAGs.

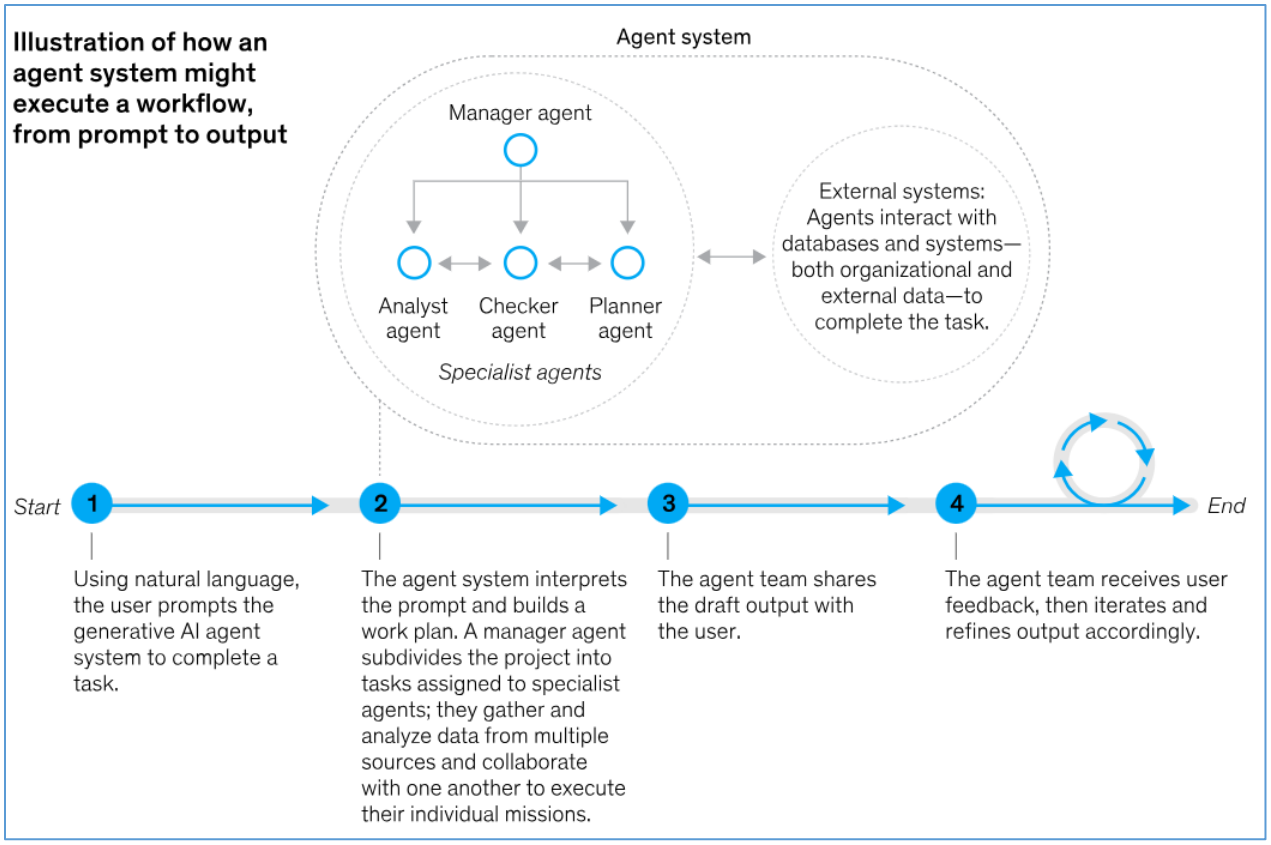

Figure 10: GenAI multi-agent system illustration (McKinsey and Company, 2024)

Implementing GenAI in TW management involves several strategic steps. A high-level roadmap is shown in Figure 11 and will encompass developing task specific SLMs and TW specific LLMs, revitalizing the models by using GenAI methods such as RAGs, ensuring robust cybersecurity to protect sensitive data, addressing potential biases in AI models, involving stakeholders and ensuring compliance with relevant regulations and standards. By following this roadmap, organizations can integrate GenAI into TW management, enhancing safety, reliability, and sustainability.

Conclusion

This paper explores GenAI for enhancing tailings waste management. Integrating GenAI can leverage safety, project management, reliability, and sustainability of tailings waste facilities. Advanced GenAI methods like GPT-4o, SLMs, RAG, Multi-AgentRAG systems developed based on a life-cycle approach have the potential to transform all the life-cycle strategies for sustainable TW management. GenAI augments human efforts and enhances efficiency in tailings management, complementing rather than replacing human expertise.

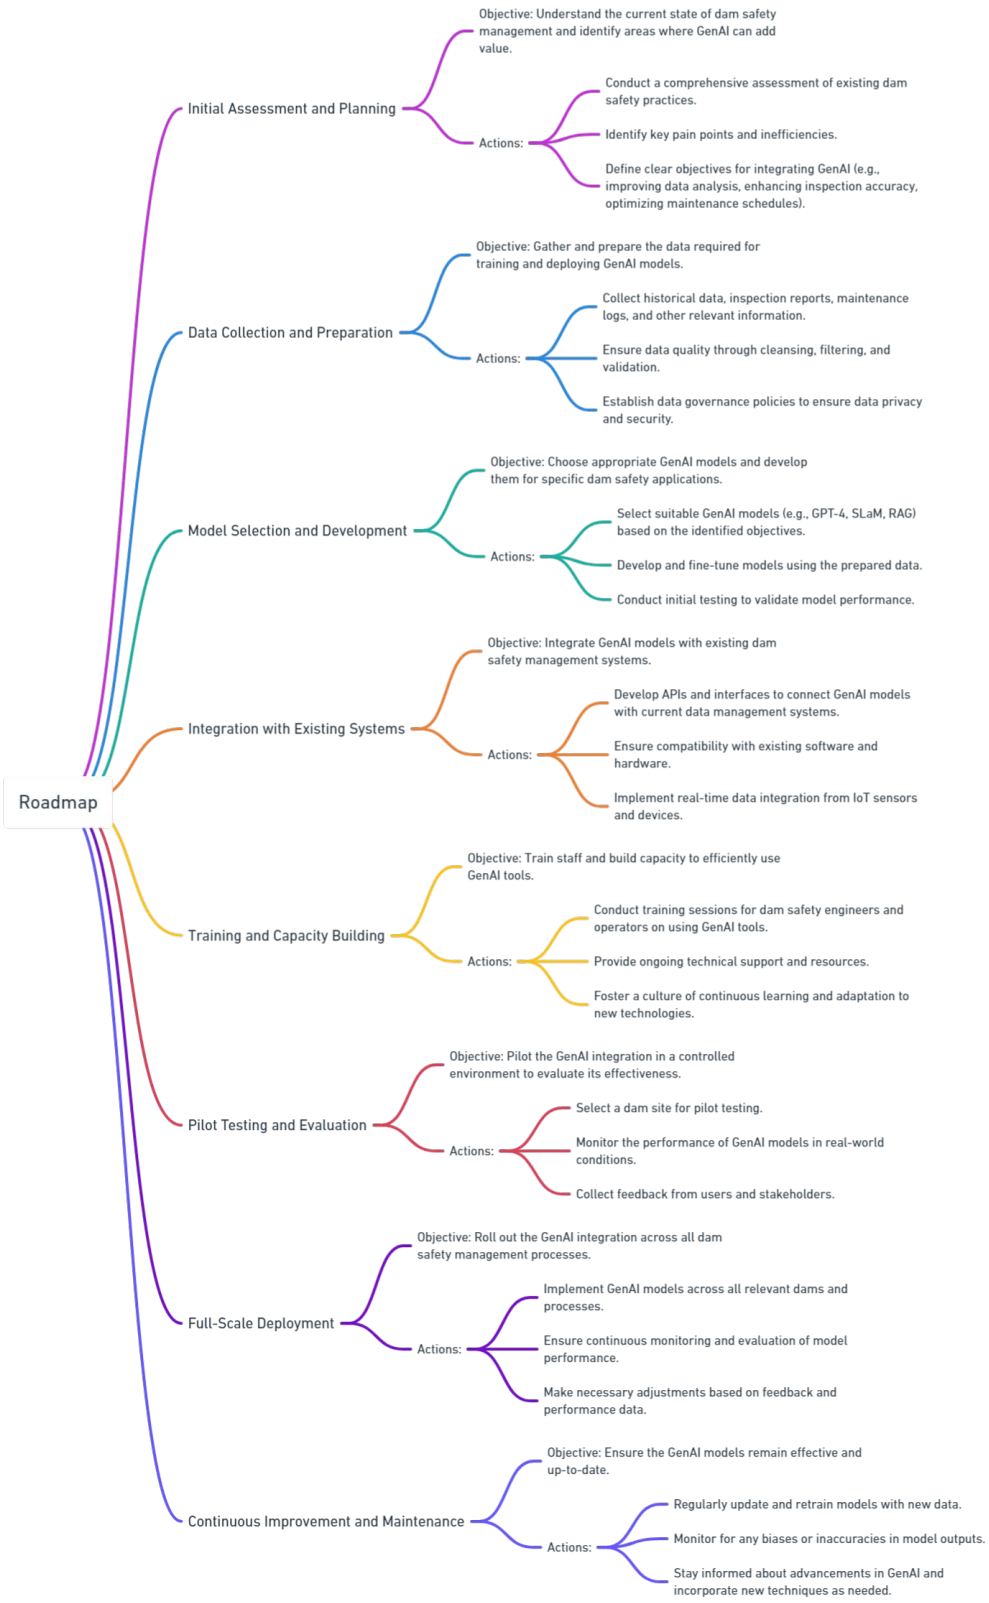

Figure 11: A high level roadmap of developing TW Management GenAI tools for life cycle phases

Responsible GenAI implementation requires attention to data quality, bias mitigation, cybersecurity, and specialized expertise. Collaboration between AI specialists, tailings waste engineers, and regulatory bodies is essential. The potential for TW management transformation through GenAI lies in integrating it with human expertise and physics-based models, empowering professionals to enhance management while maintaining ultimate responsibility. By responsibly embracing these advancements, the mining industry can address challenges like extreme weather and aging infrastructure. This paper provides insights and roadmap for integrating GenAI to enhance tailings waste management, and has potential use globally.

Evaluation of Biogeochemical Processes for Weak Acid Dissociable Cyanide

Larissa Smith, SiREM, Canada

Jeff Roberts, SiREM, Canada
Valerie Bertrand, WSP, Canada
Elizabeth Walsh, WSP, Canada

Abstract

Cyanide (CN^-) is a small, highly reactive, inorganic compound that readily forms metal-cyanide complexes and organic compounds. It is commonly used in the mining industry as a lixiviant to extract precious metals, including gold. The composition of cyanide in the environment can be affected by factors such as pH, temperature, and trace metal content. Free cyanide (HCN or CN^-) is extremely toxic to organisms due to its ability to bind metalloproteins. Weak acid dissociable (WAD) cyanide refers to metal-cyanide complexes that dissociate under weakly acidic conditions (pH 4.5-6) and release free cyanide. Remedial methods for cyanide include adsorption, oxidation, and bioremediation. The most common byproducts of cyanide biodegradation are ammonia, formic acid, carbon dioxide, cyanate, and thiocyanate. Abiotic reactions such as hydrolysis or oxidation can also occur naturally, forming ammonia, cyanate, or thiocyanate.

This paper discusses the assessment of natural biodegradation processes controlling the fate of WAD cyanide in tailings to be deposited in an open pit above backfilled stopes, where process water could potentially migrate through these infrastructures into the local groundwater. A laboratory study was designed to monitor changes in aqueous concentrations of key parameters, including aqueous concentrations of cyanide, cyanate, thiocyanate, and ammonia in laboratory microcosms that simulated tailing pore water contacting cement, tailings, and waste rock backfill. Tests over nine months were performed under aerobic and anaerobic conditions at 4°C and at progressively longer time intervals. The results showed that the total bacteria increased while the WAD and free cyanide concentrations initially varied, but ultimately decreased in the reactors. Thiocyanate was observed to increase in both the aerobic and anaerobic microcosms. The addition of cement to the microcosms increased the pH and slowed the rate of CN degradation. This suggested that a microbially mediated process was degrading the cyanide. Lessons learned will be discussed.

Introduction

Cyanide (CN^-) has been used by the mining industry for over a century as a powerful lixiviant during the gold extraction process. Due to its small molecular size and negative charge, cyanide is one of the strongest ligands in organometallic chemistry (Chadwick and Sharp, 1966). In the presence of gold and oxygen, it forms a soluble coordination complex that can be separated from other minerals. As lower grade gold ores are mined in order to meet increasing global gold demand, it has become increasingly important to improve the extraction yield. The cyanidation process has become a key method to efficiently extract and process gold.

However, the same chemical properties that make cyanide useful for gold extraction, also allow it to form strong bonds with other metals, including those incorporated in metalloproteins. This biotoxicity leads to even small concentrations of cyanide being dangerous to human health and damaging to the environment (Eisler and Wiemeyer, 2004). By keeping the pH of mining extraction solutions high, the risk of cyanide poisoning during the extraction process is low, as hydrogen cyanide (HCN), a gas, is not formed. Once the extraction process is complete, excess amounts of cyanide can be oxidized to a less toxic form: cyanate or thiocyanate. This oxidation can be done using treatment methods such as sulfur dioxide and air oxidation, alkaline chlorination, or electrochemical oxidation (Botz, 2001). Even with an oxidation process, however, small amounts of cyanide can still be released into tailings, which, in turn, can cause persistent release of other metals, such as mercury (Boyle and Smith, 1994) into groundwater. Additionally, some notable dam collapses, including that at Baia Mare in 2000, have caused large environmental impacts as cyanide was also released (Soldán et al., 2001).

Environmental cyanide can occur as free cyanide (CN^- or HCN), or in metal coordination compounds. Weak acid dissociable (WAD) cyanide compounds are metal-cyanide coordination compounds that release free cyanide under slightly acidic conditions (pH 4.5 – 6). Stronger metal-cyanide compounds, especially iron-cyanide complexes, are not usually environmentally degraded until the free and WAD cyanide compounds have been degraded, but these complexes may release free cyanide under strong UV light (Smith and Mudder, 1997). Once released into the environment, cyanide degradation can occur through abiotic or biotic mechanisms. Abiotic mechanisms include hydrolysis, which produces carbonate and ammonia, and oxidation, which produces cyanate that can be further broken down into carbonate and ammonia (Novak et al., 2013). Multiple different microbial species have been identified that can biodegrade cyanide, especially in aerobic environments. These biodegradation mechanisms are usually oxidative, reductive, hydrolytic, or substitution/transfer mechanisms that produce byproducts such as cyanate, formic acid, ammonia, carbon dioxide, and/or thiocyanate (Luque-Almagro et al., 2018). Anaerobic cyanide biodegradation has been observed under methanogenic conditions, although it is notably slower and often occurs alongside abiotic hydrolysis reactions (Novak et al., 2013).

Tailings from a mine using the gold cyanidation process were planned for deposition in an open pit above backfilled stopes, where process water could potentially migrate through these infrastructures and into the local groundwater. To determine if the cyanide in the tailings and process water could be naturally attenuated and monitored natural attenuation (MNA) could be considered for the site tailings area, a laboratory study was designed to monitor changes in aqueous concentrations of key parameters including cyanide, cyanate, thiocyanate, and ammonia in laboratory microcosms that simulated tailing pore water contacting cement, tailings, and waste rock backfill. The regulator specified that the total cyanide release limit was 5 micrograms per liter (µg/L). Tests over nine months were performed under aerobic and anaerobic conditions at 4ºC and at progressively longer time intervals, as determined in consultation with the Site consultant. This paper will discuss the methodology, results, and conclusions of the laboratory study.

Methodology

Reactors to evaluate the treatments were constructed by filling sterile 250 milliliter (mL) screw cap Boston round clear glass bottles with 100 g of tailings material and 200 mL of Site process water. The microcosms were then capped with 1" × 1" foam plugs (aerobic treatments) or Mininert™ caps (anaerobic treatments) to promote or prevent gas exchange and allow for repeated amendments or sampling throughout the incubation period. All controls and treatments were constructed in duplicate. Figure 1 shows the construction of the anaerobic microcosms under a nitrogen atmosphere.

Figure 1: Anaerobic microcosms were constructed in a glove bag under a nitrogen atmosphere

In order to provide sufficient sample volumes for analysis, additional sacrificial microcosms were constructed for each analysis timepoint throughout the study. Table 1 summarizes the details of microcosm construction for both treatment conditions.

Table 1: Summary of controls, treatments, and amendments

Control/Treatment	Amendments
Aerobic Control	Only Site process water
Aerobic Tailings	Site process water and tailings
Aerobic Tailings and Cement	Site process water, tailings, and 1% w/w cement
Anaerobic Control	Only Site process water
Anaerobic Tailings	Site process water and tailings
Anaerobic Tailings and Cement	Site process water, tailings, and 1% w/w cement
Anaerobic Waste Rock	Site process water and waste rock

All microcosms were incubated in an air-filled (or nitrogen-filled) autoclavable bag that was sealed. The air (or nitrogen) in the bag was refreshed every time sacrificial reactors were removed for sampling. During incubation, all microcosms were stored in a refrigerator at 4°C in the dark to prevent photodegradation. Microcosms were incubated for a period of up to 280 days.

Microcosms were sampled more frequently at the beginning of the study and less frequently near the end of the study. At each sampling event, the microcosms were analyzed for: pH, oxidation-reduction potential (ORP), dissolved oxygen (DO), ammonia, total, free, and WAD cyanide, thiocyanate, cyanate, and dissolved metals. Analysis of cyanides, thiocyanate, cyanate, and dissolved metals were performed at an external analytical laboratory using standard methods. Additionally, at Time 0 and at the endpoint of the study, the microcosms were sampled for analysis of total bacteria.

Results and discussion

Microcosms were incubated for up to 280 days. Due to the large sampling volumes required for analysis at each time point, sacrificial microcosms were constructed and sampled. The use of sacrificial microcosms increases the variability in the data compared to continuously samples microcosms, which is especially observed during the early sampling points in the study. However, clear trends existed in the cyanide, cyanate, thiocyanate, ammonia, and total bacteria results over the course of the study incubation period.

Cyanide trends

Similar cyanide degradation trends were observed in both the aerobic and anaerobic microcosms. Figure 2 shows the concentration of free, WAD, and total cyanide at each time point in the microcosms.

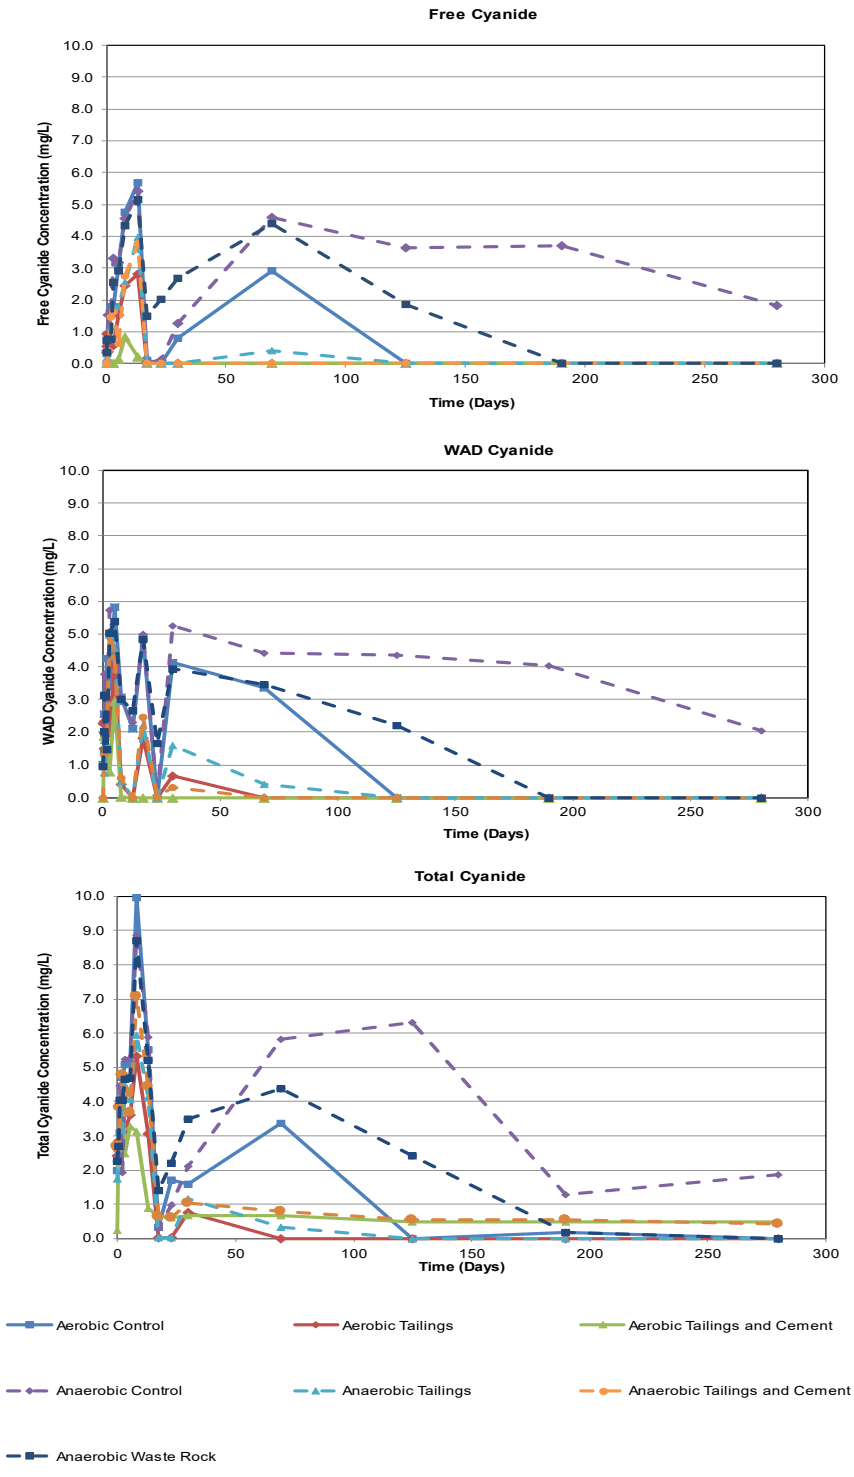

Figure 2: The concentration of free, WAD, and total cyanide in control and treatment microcosms

In general, cyanide in the control microcosms, with no tailings present, took the longest time to degrade and by Day 280, free, WAD, and total cyanide concentrations were still observed in the anaerobic control microcosms only. Aerobic and anerobic treatment microcosms with tailings present both showed similar trends: free cyanide was present until Day 13 and WAD cyanide was present until Day 30 in the aerobic treatment and Day 69 in the anaerobic treatment, while total cyanide was present until Day 69 in both treatments.

Microcosms amended with both tailings and cement had also removed all of the free cyanide by Day 13 and the WAD cyanide by Day 30. However, these treatments were not able to completely degrade all of the total cyanide and the concentration of total cyanide was relatively stable from Day 125 until the end of the study. It is possible the addition of cement, which increased the pH in the treatment microcosms, caused less favorable conditions for cyanide biodegradation. The addition of waste rock instead of tailings did not appear to improve the degradation conditions and free, WAD, and total cyanide were present in this treatment until Day 125. This may have been due to less microbial biomass associated with the waste rock.

Degradation byproducts

Degradation products of cyanide include cyanate, thiocyanate, and ammonia. Figure 3 shows the concentration trends of these products at each timepoint. The concentration of cyanate in the microcosms was already elevated at Time 0, but over the course of the study the concentration decreased in each control and treatment. Cyanate degradation can yield ammonia, which also increased in the microcosms during the study period. Thiocyanate was also present at Time 0 and slightly increased in the control and treatment microcosms over the duration of the study.

In the Aerobic Control microcosms, cyanate decreased slowly over the course of 280 days, while ammonia slowly increased. Conversely, cyanate had completely degraded by Day 125 in the Aerobic Tailings treatment, with corresponding increases in ammonia. This suggests that the presence of tailings material may be enhancing the rate of degradation, either by supporting a microbially mediated process or an abiotic hydrolyzing process. In the Aerobic Tailings and Cement treatment, cyanate only slightly decreased and ammonia did not significantly increase, suggesting that the increased pH was inhibiting the microbial growth or biological degradation process. A similar trend was observed in the anaerobic treatment microcosms, although the degradation rates were slower. In the Aerobic Tailings and Cement treatment, cyanate only slightly decreased and ammonia did not significantly increase, suggesting that the increased pH was inhibiting the microbial growth or biological degradation process. A similar trend was observed in the anaerobic treatment microcosms, although the degradation rates were slower.

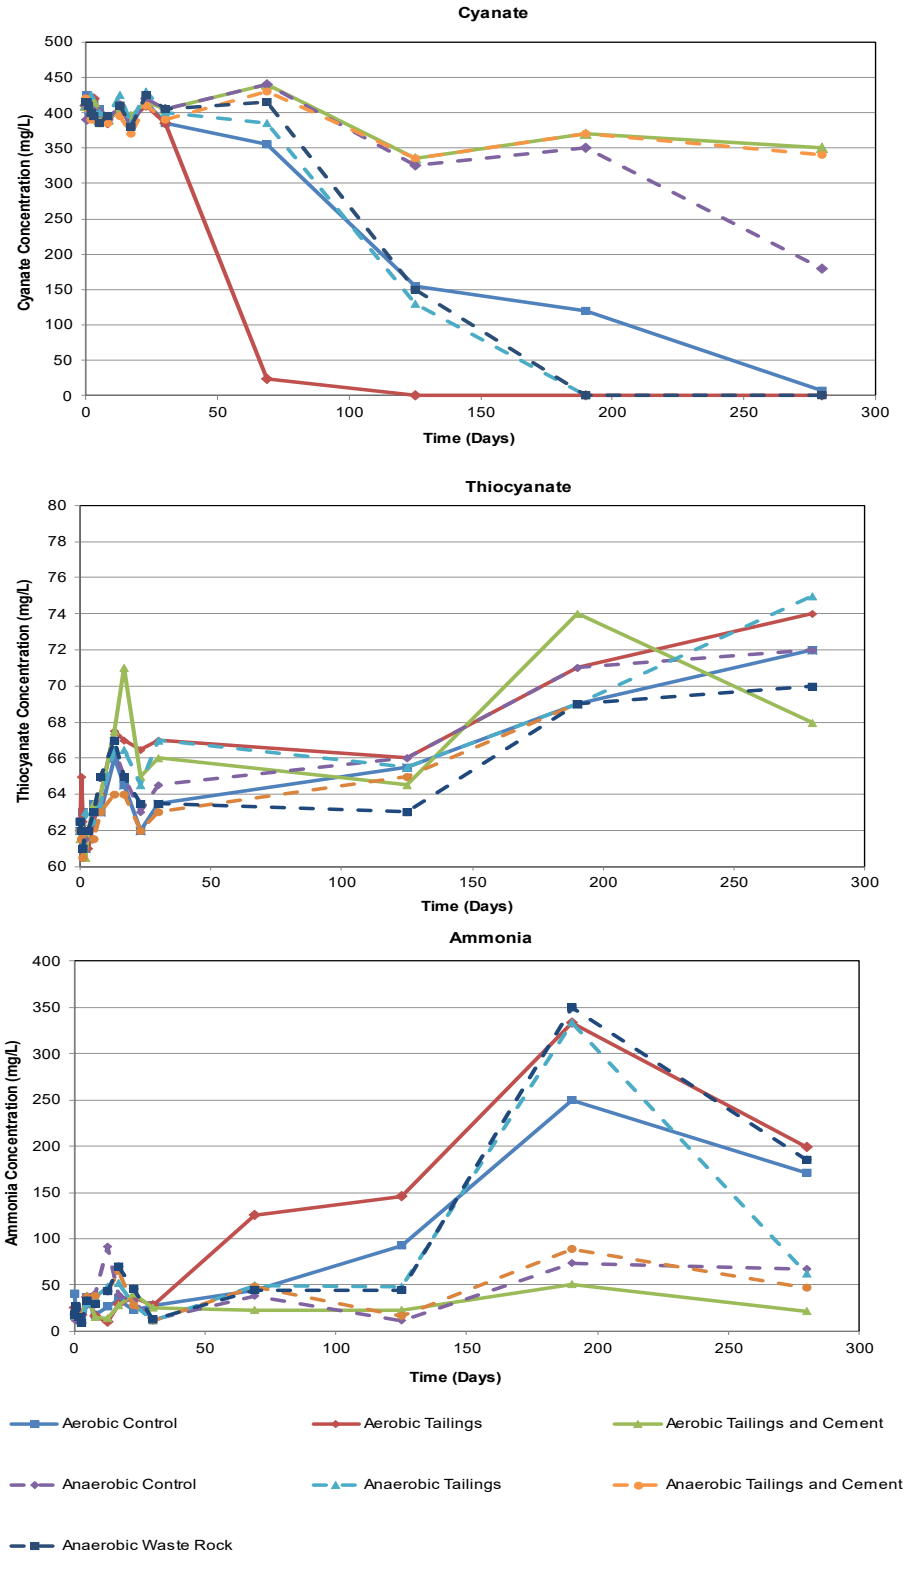

Figure 3: Concentration trends of cyanate, thiocyanate and ammonia in the control and treatment microcosms

Total bacteria

Analysis of total bacteria was performed at Time 0 (baseline) and at the endpoint of the study to determine the amount of total bacteria present in a sample. Table 2 shows the gene copies per liter (gene copies/L) present at both time points.

Table 2: Summary of total bacteria results

Control/Treatment	Gene Copies/L
Baseline	1×10^4
Aerobic Control	2×10^{11}
Aerobic Tailings	7×10^6
Aerobic Tailings and Cement	2×10^6
Anaerobic Control	2×10^{10}
Anaerobic Tailings	6×10^7
Anaerobic Tailings and Cement	1×10^5
Anaerobic Waste Rock	5×10^8

These results suggest that microbial growth occurred in all the controls and treatments, especially in the control reactors. The relatively smaller microbial growth that occurred in the tailings and cement treatments may be explained by the presence of cement, which increased the pH. Higher pH levels can impact the growth of non-extremophile microbial communities that cannot tolerate those pH levels. The anaerobic waste rock also showed significant microbial growth, although the cyanide degradation in that treatment was slower in comparison to the tailings treatments. The total bacteria results, in conjunction with the cyanide and degradation products results, suggest that the cyanide degradation occurring in the microcosm may have been microbially mediated.

Conclusion

A laboratory treatability test was conducted to determine if MNA of cyanide was possible using process water, tailings, and waste rock from a mine site. All the results combined indicated that cyanide degradation was occurring under aerobic and anaerobic conditions, likely due to a biological degradation. The byproducts of cyanide degradation, especially cyanate, were also being degraded. The total bacteria concentration increased over the course of the study, indicating that microbial populations were able to survive and potentially biodegrade cyanide and/or its degradation byproducts. The results also indicated that degradation would be slower in the presence of cement if it was used as a stabilizing agent. The Site consultant was able to use this data to complete their Site evaluation to support a natural attenuation recommendation.

Abstract

At the Igarapé Bahia Gold Mine, situated within the Carajás Mineral Province in Brazil, environmental rehabilitation initiatives have been implemented in waste piles (WPs) and tailings pounds (TPs) since the cessation of gold extraction in 2002. Monitoring soil and vegetative attributes within these areas is crucial to ensure the efficacy of the implemented intervention techniques, which can be done by integrating different approaches. Thus, the aims of this study were to (i) assess soil contamination and the associated ecological risks posed by potentially toxic elements (PTE); (ii) obtain a soil quality index based on soil chemical attributes; (iii) calculate Normalized Difference Vegetation Index (NDVI); (iv) show rehabilitation status based on vegetation parameters; and (v) combine these measures into a single index. For this, four TPs, two WPs, and an area of native forest from Igarapé Bahia mine in the Brazilian Amazon were assessed. The results of the single index indicate that the environmental conditions of the WPs are superior to those of the TPs. The WPs areas show positive signs that the activities developed for their rehabilitation were favorable, contributing to the development of vegetation and soil quality. On the other hand, the TPs exhibit low fertility and vegetation cover, in addition to elevated levels of PTE, signaling that their current attributes are far from ideal conditions. The ecological risk index indicates a low risk for all studied areas. The incorporation of soil conditioners and the planting of species tolerant to adverse conditions could enhance soil attributes and vegetation development in TPs areas. Finally, the integrative approach of the different indices proved to be a valuable tool for evaluating the rehabilitation status of the tailing ponds and waste piles.

Introduction

In the Amazon region, gold (Au) is mined in artisanal mining areas without environmental concern and supervision, resulting in significant environmental impacts (Teixeira et al., 2021). Conversely, mining corporations conduct industrial exploration with environmental and social responsibility, mitigating the impacts associated with mining activities and promoting the environmental rehabilitation of impacted areas (Gastauer et al., 2019).

The research on industrial gold mining is limited, but it can inform as to the benefits of environmentally responsible mining in terms of ecosystem quality and human health protection. In this context, several indices have been applied to monitor mining areas, including spectral indices, the soil quality index (SQI) (Ribeiro et al., 2022), and the ecological risk index. In order to provide a comprehensive representation of the overall soil and environmental status, these indices have been also compiled into a single, comprehensive index (Gastauer et al., 2020; Wang et al., 2018).

One example of an industrial mining complex is the Igarapé Bahia (IGB) located in Carajás Mineral Province (CMP), which is situated in the Eastern Amazon. The exploration activities in IGB stopped in 2002, when a rehabilitation process began in the tailings deposition ponds (TPs) and waste piles (WPs). The rehabilitation measures included geotechnical conformation, liming, fertilizer treatment (organic compost, NPK, and micronutrients) and planting a mix of exotic and native species seeds. After 20 years, to assess the effectiveness of the rehabilitation interventions, soil and vegetation attributes were collected in permanent plots (10 × 20 m), installed in two WPs (WP-1 and WP-2), four TPs (TP1-6, TP7, TP8, and TP9) (Figure 1), and a native forest area with a low degree of anthropic influence in the IGB mining complex.

This study examines the environmental rehabilitation activities in the IGB mining complex, assessing:

1. soil contamination and the associated ecological risks posed by potentially toxic elements (PTE);
2. SQI based on soil chemical attributes;
3. the Normalized Difference Vegetation Index – NDVI;
4. the rehabilitation status based on vegetation parameters; and
5. combining these measures into a single index.

The hypothesis of this study is that this single index can differentiate between TPs, WPs, and native forests.

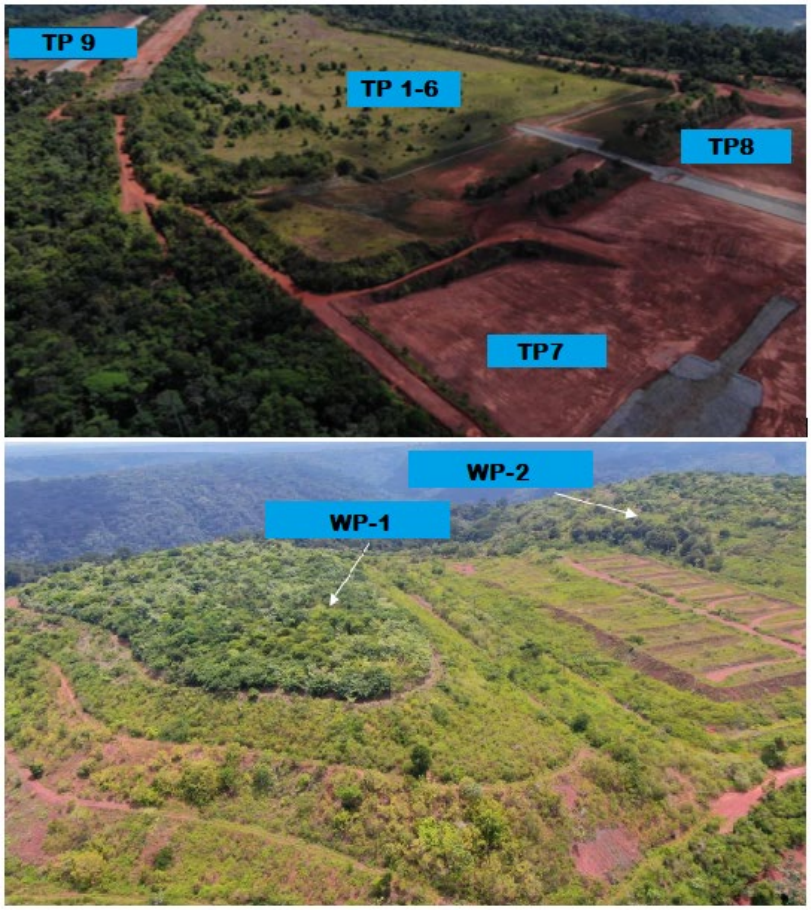

Figure 1: Tailings deposition ponds (TPs) and waste piles (WPs) in the IGB mining complex. Adapted from Oliveira et al. (2023)

Methodology

Soil characterization and SQI

Soil samples (0–10 cm) were collected from five points distributed within permanent plots. These samples were air-dried, sieved to the 2 mm fraction, and analyzed for chemical attributes following Teixeira et al. (2017): pH, soil organic matter (OM), sulfur (S), exchangeable calcium (Ca^{2+}), magnesium (Mg^{2+}), and aluminum (Al^{3+}), phosphorus (P), potassium (K^{+}), copper (Cu), iron (Fe), manganese (Mn), and zinc (Zn) and boron (B), sum of bases (SB), cation exchange capacity (CEC), and base saturation (V%).

The levels of arsenic (As), barium (Ba), cadmium (Cd), cobalt (Co), chromium (Cr), copper (Cu), iron (Fe), manganese (Mn), molybdenum (Mo), nickel (Ni), lead (Pb), selenium (Se), and zinc (Zn) were evaluated in soil samples sieved in the 80-mesh fraction and digested in *aqua regia* solution. The concentrations of PTE were determined by inductively coupled plasma–optical emission spectrometry

(ICP-OES) and Inductively Coupled Plasma – Mass Spectrometry (ICP-MS) or Cold Vapor Atomic Absorption Spectrometry (CV-AAS) for Hg.

An SQI was employed to assess the impact of revegetation progress on soil fertility. The soil properties included in the index were selected based on a principal component analysis (Mukhopadhyay et al., 2014). Soil parameters were converted into scores (S) ranging from 0 to 1 using the Wymore equation (Freitas et al., 2012) and methodology described in Ribeiro et al. (2022). The mean values observed in the reference areas were considered to be the optimal for each soil attribute. After determining the score, the SQI was calculated by multiplying the score value with the weight according to Equation 1.

$$SQI = \sum_{i=1}^{n} W_i S_i \quad \text{(Equation 1)}$$

where W is the weighting factor and S is the score for each variable. The SQI means were scaled by dividing the obtained values by the mean value of the forest area.

NDVI

Images of the WorldView2 satellite (July 2020) with a spatial resolution of 2 m (pixel size) and four spectral bands (blue, green, red, and near infrared) were acquired and used for the determination of the NDVI. This was made using the raster calculator of the QGis 3.10 software and the equation described by Rouse et al. (1974).

Environmental recovery status

The calculation of the environmental recovery status (ERS) followed methodology described by Gastauer et al. (2020, 2021). For this, in the installed plots, all trees with a diameter at breast height larger than 3 cm were tagged and identified. The following variables were considered in the index: species richness and tree density; basal area; above-ground biomass and functional diversity.

A principal coordinate analysis (PCoA) based on Gower distances was performed with scaled and centered variables. This approach accounts for possible autocorrelations between the measured variables and transfers the variation between plots to a Euclidean space. Based on that, the Euclidean distances between all rehabilitating plots and native forest plots were retrieved. The obtained distances were scaled between 0 and 1, where 0 corresponds to the average distance from all plots in areas with exposed soil to the reference plots, and 1 is the average distance between all reference plots. After, the average values for the different areas were calculated (Gastauer et al., 2020, 2021).

Contamination index and ecological risk assessment

The contamination factors of As, Ba, Cd, Co, Cr, Cu, Hg, Mn, Mo, Ni, Pb, Se, V, and Zn for the studied areas were calculated as the ratio between PTE concentration (mg kg^{-1}) in the soil and the PTE background value (mg kg^{-1}) established for the studied region using method mMAD (Sahoo et al., 2020). Then, the modified degree of contamination index (mCd) was calculated according to Equation 2 (Abrahim and Parker, 2007).

$$mC_d = \frac{\sum_{i=1}^{n} CF}{n} \quad \text{(Equation 2)}$$

where n is the number of analyzed pollutants and CF is the contamination factor.

The potential ecological risk index (ERI) was calculated according to Equation 3:

$$ERI = (CF_1 \times T_1) + (CF_2 \times T_2) + (CF_3 \times T_3) + \ldots + (CF_n \times T_n) \quad \text{(Equation 3)}$$

where CF is the contamination factor, T is the toxic response factor of As, Cd, Cr, Cu, Hg, Ni, Pb, and Zn (Hakanson, 1980), Ba (Yang et al., 2015) and Co (Zhang et al., 2017) and n is the number of PTE. The RI results were interpreted as follows: RI ≤ 150 suggests low risk, 150 < RI ≤ 300 suggests moderate risk, 300 < RI ≤ 600 suggests considerable risk, and RI > 600 suggests high risk (Hakanson, 1980).

Single index evaluation

The data from the five selected indices (SQI, NDVI, mCd, ERI, and ERS) were multiplied by a similar weight (0.2) and then summed. Prior to this, the ERI and mCd indices were converted through simple mathematical procedures to a scale ranging from 0-1, as they have different units and scales. The higher the single index, the better the results of the environmental index of the studied areas.

Statistical analyses

All analyses were carried out using the software R (R Core Team, 2023). The means of the SQI and mCd for the studied areas were compared by the Tukey test ($p < 0.05$).

Data and discussion

Soil quality and contamination by PTE

The SQI values ranged from 0.06 to 1 (Table 1). All studied areas had lower SQI values compared to the native area, indicating that the soil attributes included in the index (i.e., pH, OM, B, CEC, SB, Cu, and Mn)

are still far from the edaphic conditions of the forest area. The TP9 and TP8 had the smallest values of SQI among the evaluated areas, mainly due to the lower levels of OM and nutrients such as B and Mn (see Table A1 in Appendix).

Table 1: Soil quality, contamination, and ecological risk indices of the different sampled areas of tailing ponds: TP1-6, TP7-9; waste piles: WP-1 and WP-2, and forest areas.
Data obtained from Ramos et al. (2024). The classification of mCd values of the studied areas is as ollo s d 1. indi a es nil o e lo on a ina ion, 1. d indi a es lo on a ina ion, d 4 indi a es ode a e on a ina ion and 4 d 8 indicates moderate-heavily contamination (Abrahim and Parker, 2007)

Site	SQI	mCd	ERI
WP-1	0.46 (0.15)b*	1.99 (0.64)b	79.6
WP-2	0.42 (0.12)b	0.81 (0.41)cd	81.9
TP7	0.39 (0.05)b	4.51 (0.86)a	103
TP8	0.25 (0.13)bc	5.93 (2.14)a	123
TP9	0.06 (0.03)c	1.28 (0.15)bc	67.3

*Means followed by the same letter do not differ from each other according to the post hoc Tukey's HSD test
0.0 . eans and s anda d de ia ion

Concerning mCd, the TP1-6, TP7, and TP8 indicated a high degree of contamination (Table 1), which was mainly attributed to Cu and Mo levels (Table A2 from Appendix). The greatest contribution of these elements can be associated with the type of ore deposits (Fe oxide-Cu-Au type) and the presence of molybdenite (De Melo et al., 2019). Conversely, the WP-1 presented a low degree of contamination and WP-2, TP9, and forest had a very low degree of contamination. The WPs had low mCd values, probably because they received low-grade ores and materials from pickling, which present lower PTE contents. The low degree of contamination in TP9 may be related to the heterogeneity of processed ores, which is a common characteristic in mining areas. Despite the low level of contamination, this material is one of the most challenging to revegetate, which may be associated with its low OM content and other factors. Considering the ERI values, all analyzed samples represent a low environmental risk (Table 1).

Vegetation parameters and NDVI

The NDVI values extracted from the sampled area ranged from 0.10 to 0.92 (Table 2). Between the areas in recovery process, the highest NDVI values were found in the WP-1 and WP-2, while TPs showed low NDVI values. The lower NDVI values in TPs can be explained by the almost null vegetation cover in these areas. TPs come from various processes adopted in mineral beneficiation, and present low levels of OM and nutrients, impairing the regeneration of plant species. In addition, the TPs are covered by a waterproof

blanket below the waste. Some portions of TP8, for example, experience flooding during certain periods of the year, which favors the long-term retention of contaminants and can negatively impact plant growth.

Table 2: Environmental recovery status (ERS) and NDVI of the different sampled areas of tailing ponds: TP1-6, TP7-9; waste piles: WP-1 and WP-2, and native reference forest: Forest. Data obtained from Ramos et al. (2024)

Site	ERS	NDVI
WP-1	46	0.70
WP-2	38	0.59
TP7	0	0.10
TP8	0	0.10
TP9	0	0.12
TP1-6	12	0.40
Forest	100	0.92

When comparing with NDVI values, the findings from ERS showed a significantly low index for the TPs (Table 2), indicating the poor quality of these materials due to severe soil chemical limitations. These restrictions limit plant development and the restoration of ecosystem services. Therefore, it is recommended to consider alternate methods for reestablishing vegetation using plant species that are ideal to these specific conditions, such as with phytoremediation potential and the use of soil conditioners to improve the quality of the soil. This can enhance the soil's structure and fertility, enabling it to develop into a more resilient ecosystem. Conversely, it is possible to notice the recovery of WPs. However, efforts are still needed to achieve ideal rehabilitation status values due to the contrasting edaphic conditions observed in the examined areas compared to forested areas, which have an impact on the ideal targets of ecosystem services, carbon stocks, and forest communities.

Single index evaluation

The forest area had higher values for all the studied indices, resulting in the highest single index value (Figure 2). Moreover, forest area has ideal soil quality and vegetation cover. Conversely, the TPs exhibited the lowest single index, which was primarily attributed to the low values for SQI, NDVI, and ERS. This suggests that soil fertility characteristics in TPs diverge from those observed in forest areas, plant cover is scarce or absent, and the rehabilitation status remains poor.

The WPs exhibited intermediate single index values when compared to the TPs and the natural forest, indicating that the activities developed for their rehabilitation were helpful and are following the desired pathway. Finally, the variations between WP and TP results raise questions for future research. It is possible that the same restoration/rehabilitation targets may not apply to both locations.

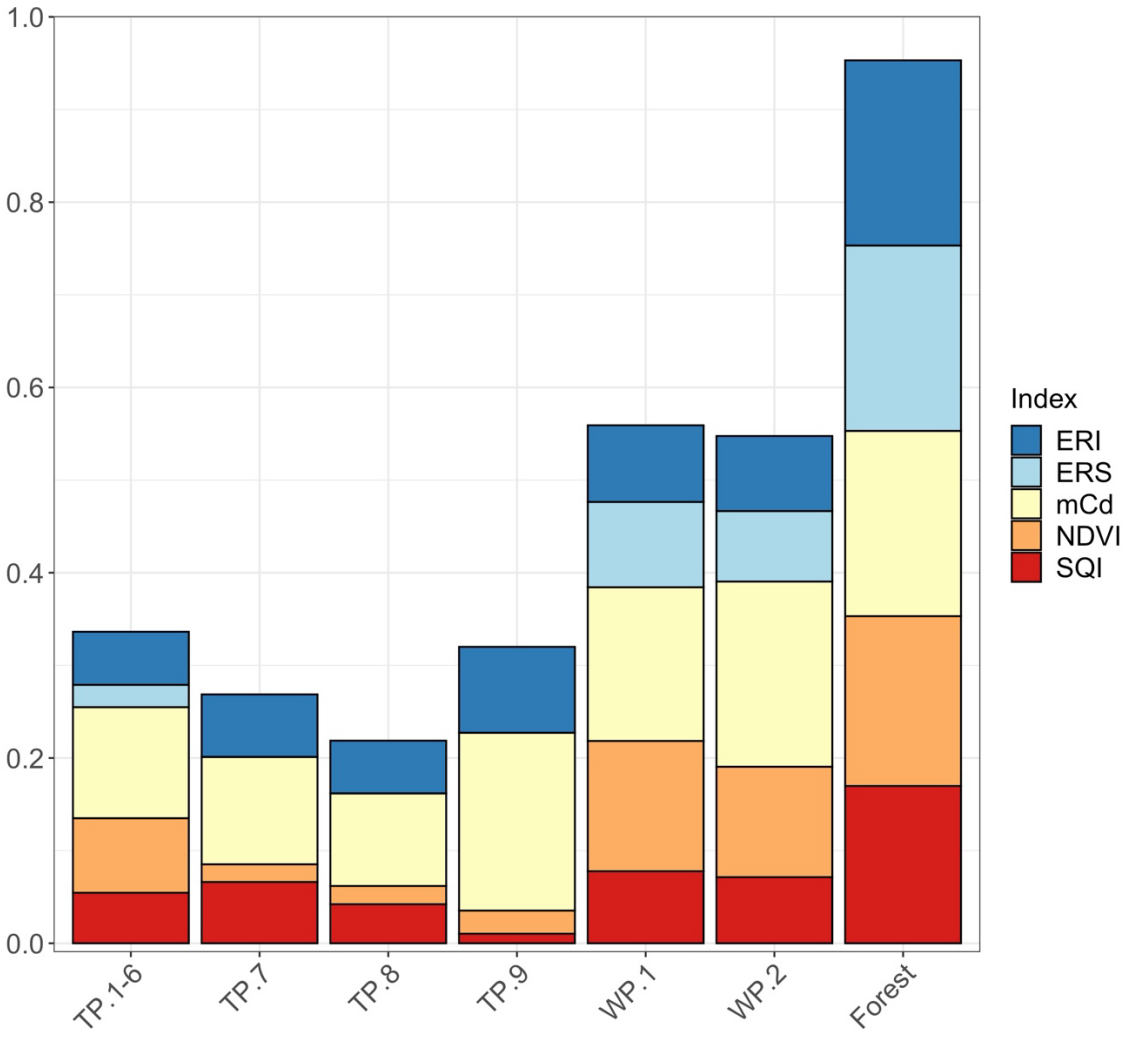

Figure 2: Single index for sampled areas of tailing ponds: TP1-6, TP7-9; waste piles: WP-1 and WP-2, and native reference forest: Forest at the Igarapé Bahia mining complex, Brazil.
SQI – Soil quality index; NDVI – Normalized difference vegetation index; ERS – Estimated rehabilitation status; ERI – Ecological risk index; mCd – modified degree of contamination. Data obtained from Ramos et al. (2024)

Conclusion

The integrated approach of the five indices has proven to be an effective tool for assessing the rehabilitation status of the sites. After twenty years of rehabilitation actions, the single index shows that these activities were beneficial in terms of vegetation development (higher NDVI values) and soil quality in WPs areas. On the other hand, TPs performed most poorly for the examined indices, indicating that their status was far from ideal and that steps must be taken to improve the quality of these materials, such as the application of soil conditioners and plant species. Finally, all analyzed areas presented low ecological risk indices.

Abstract

During Giant Mine's operation, 237,000 tonnes of arsenic trioxide (As_2O_3) roaster waste (ATRW) dust were generated. The current remediation plan for Giant Mine is the frozen block method to prevent migration of the dust, although the long-term performance of this method is a concern. An alternative approach to the long-term management of ATRW is incorporating the dust into cemented paste backfill (CPB) which may be capable of physically and/or chemically stabilizing the arsenic. Seasonal weather variations, permafrost and ground freezing for the frozen block method at the site could induce freezing and thawing of CPB deposited in near-surface underground workings or stopes, which has been known to decrease the strength of other cemented soils. Unconfined compressive strength (UCS) tests on small samples determined that using 10% ATRW and general use (GU) cement binder will optimize strength and dust content. To evaluate whether the CPB containing As_2O_3 dust can maintain strength after freezing, cylinders of CPB containing Giant Mine As_2O_3 dust were exposed to cyclic freezing and thawing conditions at -5°C and 20°C for 0, 1, and 5 cycles and a variety of long-term curing conditions. Samples from each test condition were tested for strength using UCS tests. The results show that one freeze-thaw cycle may decrease the strength by 26%; however, increasing to five cycles does not decrease the strength further. They also indicate that long-term storage decreases the strength regardless of time and temperature and has a lower effect than freeze-thaw cycles.

Introduction

Giant Mine is a former gold mine located 5 km north of Yellowknife, NWT, Canada. The gold was produced by roasting arsenopyrite (FeAsS) and arsenian pyrite (FeS_2) that hosted the gold. This process produced not only SO_2 emissions, but also precipitated arsenic trioxide (As_2O_3)-rich dust (Bromstad et al., 2017). During its 50 years of operation, the site produced 237,000 tonnes of this dust which contained 60

wt% arsenic (Arcadis, 2017; Bromstad et al., 2017). The dust mixture was collected in baghouses and stored on-site in chambers and mined-out stopes beginning in 1951 (Arcadis, 2017). Being one of the most toxic and bioaccessible forms of arsenic, As_2O_3, the dust poses high risks to the environment and human health (Bromstad et al., 2017). Also concerning, As_2O_3 can dissolve in water, so there is potential risk to human health and the environment by transport to surrounding water bodies (Arcadis, 2017).

Due to the quantity of dust, dust-like physical characteristics, and current storage in subsurface stopes and chambers, the long-term management of the dust is complex. Many methods or technologies have been investigated to assess the effectiveness of treatment. The chosen method to manage the dust involves using passive thermosyphons to freeze the ground surrounding the dust, which is currently stored in underground chambers. This will freeze the surrounding bedrock and fill around the chambers to prevent the release of arsenic. However, this is not a long-term solution as it requires ongoing maintenance and is suspected to last up to 100 years (Arcadis, 2017). Therefore, a long-term management approach is necessary to successfully manage the ATRW dust.

Backfilling is a process in mining of placing hazardous waste in underground mine cavities referred to as "stopes." Underground mining produces large quantities of waste material from excavating and processing the ore. The underground mine cavities are also susceptible to failure if not properly supported. Backfilling is used to reduce surface storage waste, reduce surface subsidence, and improve stability, which reduces the environmental and economic impacts of a mine site (Zhang et al., 2020; Zhou and Fall, 2023a, 2023b). There are three types of backfilling: hydraulic fill, rockfill, and cemented paste backfill (CPB) (Mohammadi et al., 2023). CPB is a heterogeneous, non-Newtonian mixture of dewatered tailings, cement binding agents, water, and sometimes admixtures (Sivakugan et al., 2006). In the mixture, the cement binder stabilizes tailings in place once it is hardened (Fall et al., 2008). Tailings account for 70% to 85% of the total mass of the CPB with a fines content (<20 μm) greater than 20% (Belem, 2023; Chang and Fall, 2022; Oke et al., 2021; Zhang et al., 2020; Zhou and Fall, 2023a). Whereas the binder usually accounts for 3% to 7% of the total mass of the CPB (Cheng and Fall, 2022). Binding agents allow for chemical stabilization and physical solidification, thereby contributing to much of the strength of the CPB (Tariq and Yanful, 2013).

CPB has been used in the past to physically and chemically stabilize pollutants and reduce the reactivity potential of sulfides. CPB has been proven to successfully stabilize other arsenic-bearing materials, but little has been researched on stabilizing arsenic trioxide with CPB (Mohammadi et al., 2023). Mechanical strength can be used as an indicator of cementation reactions that favor the stabilization of arsenic trioxide (Mohammadi et al., 2023). UCS tests are the most common method of testing the strength of CPB in the laboratory (Chen et al., 2017). Although the addition of arsenic trioxide into CPB has been

determined to decrease the strength, with the right mix design of the CPB based on solids content, binder content, and dust content, the strength decrease of the CPB can be minimized (Mohammadi et al., 2023).

The Frozen Block method will involve freezing the underground chambers, stopes, and surrounding rock to a temperature of -5˚C or lower, which will isolate the ATRW dust from the environment (CIRNAC, 2018). This ground freezing, coupled with discontinuous permafrost around Yellowknife at around -5 ˚C and seasonal temperature variations, could induce freeze-thaw cycles for CPB deposited near the surface or freezing for CPB in existing stopes (Kokelj and Wolfe, 2018). Previous research on the mechanical response of CPB, cemented paste tailings, or cemented soils suggest that with increasing freeze-thaw cycles, the unconfined compressive strength will decrease (Ding et al., 2018; Liu et al. 2022; Liu et al., 2023; Xu et al 2020). However, it is unknown how the addition of arsenic trioxide will impact the mechanical response of CPB after freezing and thawing.

Materials and methods

Materials

The materials used in this study for the cemented paste backfill include a binding agent, mine tailings, ATRW dust, and deionized water. Tailings originate from the north pond at the Giant Mine site, outside of Yellowknife, Northwest Territories. The tailings have previously been dried at 40˚C for 48 hours (Mohammadi et al., 2023). Four binding agents were used; general use (GU) Portland cement supplied by Bomix (Quebec, Canada), fly ash (FA) supplied by Lehigh Cement (Alberta, Canada), lime (LI) and lime kiln dust (LKD) both supplied by Graymont (Quebec, Canada). The ATRW dust originated from different stopes and chambers at the Giant Mine. This dust was sent in eight samples and homogenized to create a representative sample for use in characterization and the CPB samples (Mohammadi et al., 2023). To minimize the effects of water chemistry on the strength of CPB, deionized water was used. These materials have been previously characterized in Mohammadi et al. (2023).

Methods

Determination of ATRW dust content and binder selection

To define the appropriate ATRW dust content as well as the potential binders, some small initial cemented paste backfill samples prepared at various ATRW dust contents (4%, 6%, 8%, 10%, 12%, and 14% wt.) at solid content of 74% wt. using four different binders (GU cement and a mixture of GU cement with fly ash (GU/FA), lime (GU/LI) and lime kiln dust, (GU/LKD) all in the proportion of 50/50) and Giant Mine tailings. All binder contents for these tests were fixed at 5% wt. These samples were prepared in the molds with a diameter of 3.4 cm and height of 6.2 cm and cured up to 28 days (Figure 1). After curing, UCS tests were done on these samples to determine the optimal dust content and binder selection for strength.

Figure 1: A photo of the prepared CPB samples using various types of binders and ATRW dust contents

Preparation of cemented paste backfill samples

According to Mohammadi et al. (2023) and the preliminary assessment for ATRW dust and binder content, using a mix of 6% GU cement, 10% arsenic trioxide and 76% solids is best to maximize the strength of CPB. Knowing these mix proportions, the specific gravity of the tailings, binder, and ATRW dust, and the required total volume, the mass of each material required for a given batch can be calculated according to equations in Mohammadi et al. (2023). For each variation in testing, 3 cylindrical samples were prepared using 2 × 4-inch (diameter × height, 50.8 × 101.6 mm) molds with an extra 20% of material to accommodate for the potential losses during preparation and molding.

To prepare the samples, the mass of each material was measured. Dry materials including the tailings, binder, and ATRW dust were mixed on a large piece of paper by folding the corners into the middle 80 times. The dry materials were added to the bowl of a 4.8L Hobart mixer. The water was gradually added while the mixer was on low. After about 1 min, the mixer was stopped so the sides could be scraped into the bowl, then turned back on for 2-3 minutes until a homogenous paste was formed. Using a ½ tablespoon, the paste was scooped into the molds. To rid the paste of air pockets in the mold, a 3/8-inch (9.53 mm) rod was used to hammer the paste 25 times, then the same rod was used to tap around the sides of the mold. The samples were then labelled, sealed with a lid, and stored at 20˚C and 90% relative humidity in a humidity chamber to cure for 14 days, which has been previously determined to be adequate for strength development (Mohammdi et al., 2023).

Freeze-thaw testing and long-term storage

Next, samples were separated into groups based on the curing condition they would undergo, or the number of freeze-thaw cycles they would be exposed to. For each group, three samples were prepared so that triplicates could be tested during the UCS tests. Table 1 shows the variation in curing temperature, curing time, or freeze-thaw cycles.

Table 1: Groups of CPB samples based on storage time, storage temperature, and/or number of freeze-thaw cycles

Group #	Storage Time (days)	Batch #	Long-term Temperature (˚C)	Number of Freeze-Thaw Cycles
1	42	1	20	0
2	40	2	20	0
3	268	1	20	0
4	203	2	5	0
5	42	1	20	1
6	268	1	-10	1
7	40	2	20	5

Samples maintained at approximately 20˚C were cured using a temperature bath to maintain humidity of approximately 90%. Following the initial 14 days of curing, samples from group 6 were placed in a freezer to maintain a frozen temperature at or below -10˚C and samples from group 4 were placed in a humidity-controlled room with a relative humidity of 80% and a temperature of 5˚C. Before long-term storage, all samples were sealed in two Ziplock bags to ensure moisture did not influence the curing.

For the freeze-thaw testing of groups 5 and 6, samples were sealed in two Ziplock bags before being placed into the reservoir of a Fisher Scientific Isotemp 1028S chiller. All three samples from each group were placed in the reservoir at the same time. Each group was exposed to a temperature of -5˚C for 24 hours, to simulate the anticipated frozen conditions on site, then allowed to thaw at 20˚C for 24 hours (CIRNAC, 2018). This method is based on previous freeze-thaw testing of other cemented soils (Liu et al., 2022; 2023). For group 6, samples were frozen for 266 days, to simulate a long-term frozen period, then thawed in the same Isotemp 1028S chiller reservoir for 48 hours.

Unconfined compressive strength tests

Samples from each test condition were tested for strength using UCS tests based on ASTM C39 standard. These tests were performed using a mechanical press with a loading capacity of 50 kN and a rate of 1 mm/min. After each curing period was completed, samples were taken out of their molds, and the top and bottoms of each sample were flattened parallel to the mechanical press plates. The UCS was measured as

the maximum stress value that was reached before failure during the UCS tests. The average of each triplicate was taken as the final strength for a given group. The ultimate strength of each set of samples will help determine how multiple freeze-thaw cycles affect the CPB mixture compared to none.

CT scanning

Micro-Computerized Tomography (μ-CT) scanning was used to assess the 3D internal structure of long-term curing samples before and after freeze-thaw cycles, and before UCS testing. This method extracts a set of 2D X-ray radiographs of an object at multiple angles (typically 180˚ or 360˚), then reconstructs the 2D slices using a mathematical algorithm. A 3D image can be created by stacking the 2D slices and allows the viewer to analyze the internal structure of the samples. One sample from group 6 was scanned before and after thawing, and one sample from each of group 3 and 4 were scanned at 20℃.

Scanning was performed on a Nikon XTH 225 ST industrial CT scanner with an exposure time of four frames per second for the frozen sample and two frames per second for all samples at 20℃. All samples had a voxel size of 33 micrometers (size of the pixel resolution and slice thickness of a 3D volume element). The reconstruction was done using Nikon CT pro 3D software and analyzed using Dragonfly 2022 software.

Results and discussions

ATRW dust content and binder selection

Figure 2 presents the results of UCS tests on the small CPB samples prepared using four various binding agents to define maximum probable ATRW dust in the main samples as well as the desirable binding agents after 7 and 28 days of curing. Generally, the samples prepared using the GU cement showed the highest strength followed by the GU/LI, GU/LKD, and GU/FA samples. Increasing the curing time did not greatly increase the strength of the samples, except for the samples prepared using GU/LKD binder and most of the samples gained their strength in the initial days of curing. The strength behavior of the samples was different after 7 and 28 days. After 7 days, the strength of GU samples increased up to 10% ATRW dust and then decreased; however, after 28 days, a decreasing trend was observed by increasing the ATRW dust content. For the other binding agent, a complex trend was observed. Based on these results, it was decided to prepare the main CPB samples using GU cement and 10% dust since these conditions revealed the highest strength with the maximum applicable ATRW content.

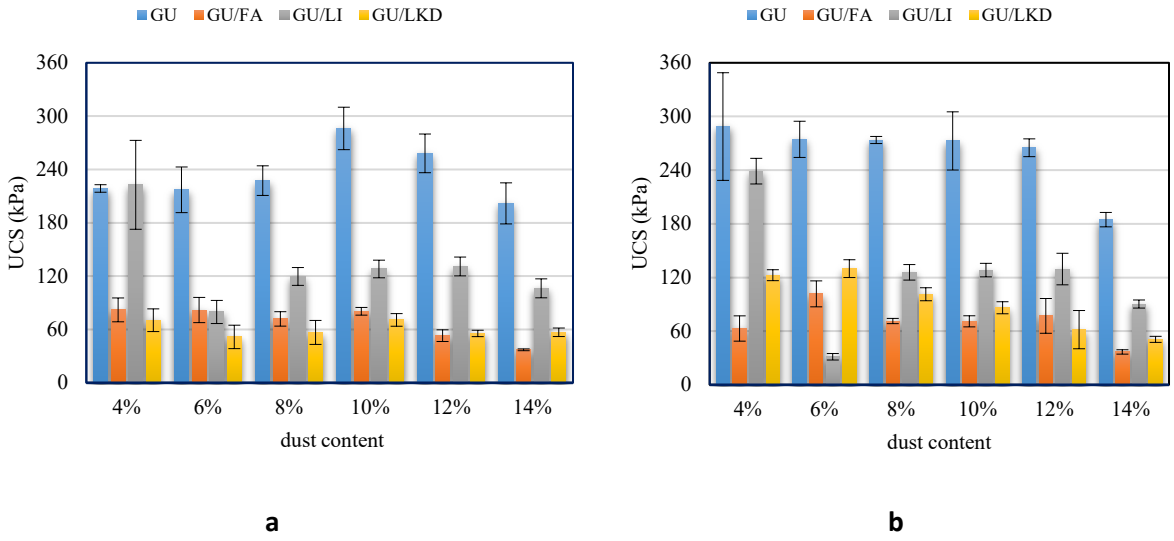

Figure 2: The UCS of small CPB samples prepared using General Use (GU) cement and a mixture of GU cement with fly ash (GU/FA), lime (GU/LI) and lime kiln dust, (GU/LKD) after a) 7 days and b) 28 days of curing

Mechanical strength results

Figure 3 presents peak average strength results from triplicate UCS tests for each group of samples used to test the effects of freeze-thaw cycles and long-term storage temperature. Generally, with increased storage time there is a decrease in strength. When comparing the same batches, group 3 shows an average decrease of 21% compared to group 1. Decreasing the storage temperature long-term shows a slight decrease in average peak UCS values when comparing group 2 and 4, however this is a smaller decrease than increased storage time. This suggests the strength will continue to decrease with increased storage time, regardless of temperature.

These results also show that regardless of storage time or storage temperature there will be a decrease in strength with freeze-thaw cycles. One freeze-thaw cycle after short term storage decreases the strength on average by 26%, however increasing the number of freeze-thaw cycles does not show a further decrease in strength. This suggests that the first freeze-thaw cycle has the largest impact on damage of the samples, subsequent freeze-thaw cycles do not further decrease the strength. Group 6 shows that long-term freezing and one thaw cycle shows an average decrease in strength of 20%, similar to long-term, unfrozen storage. This suggests that the storage time has a greater influence on the strength than the storage temperature. Overall, freeze-thaw cycles after short term storage decreases the strength the most, compared to other variables.

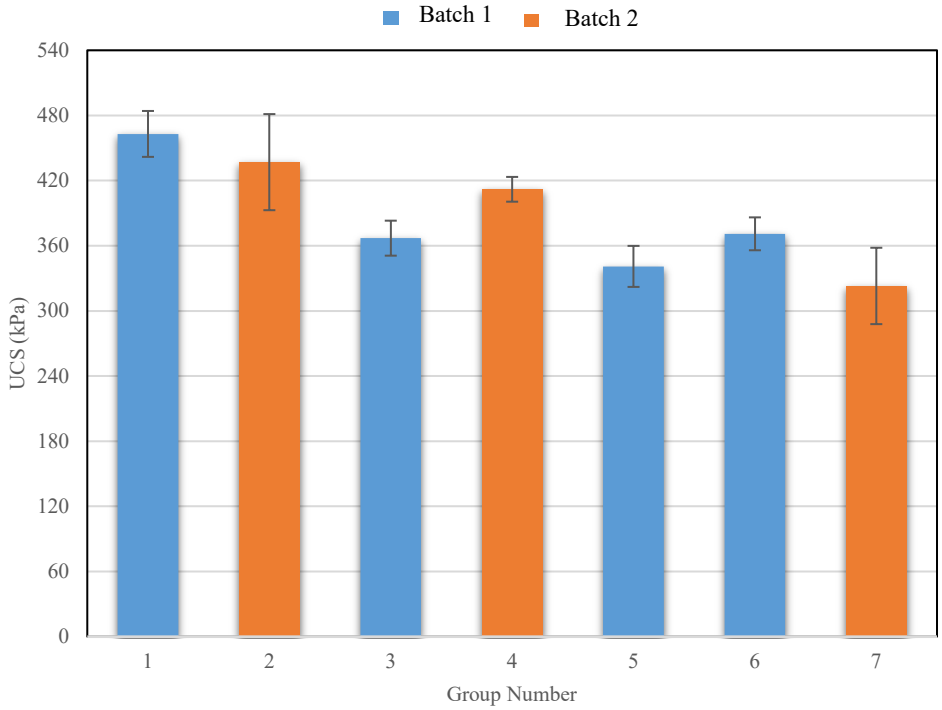

Figure 3: The UCS of samples based on storage temperature, storage time, and/or number of freeze-thaw (F/T) cycles. Test conditions for each group can be found in Table 1

Qualitative CT scan observations

A qualitative analysis was conducted on images rendered from the CT scanning of four samples (Group 3, 4, 6 frozen and 6 thawed, as shown in Figure 4). The longitudinal slice taken in the middle of the sample from the aerial view was examined for each sample. All four samples show similar shape and size of pores, and no visual differences between the internal structure of the samples. The only visual difference between these samples is a slight density contrast in Figure 4d, the frozen sample. Surrounding the edges, there are lower density areas shown by slightly darker sections. This does not appear in the other samples and suggests that perhaps the sample's core did not freeze completely, or moisture entered the edges of the sample from the environment. As shown in Figure 4c and d, freezing and thawing did not induce fracturing in the sample from group 6. A lack of fracturing indicates that leaching of the arsenic dust may not increase after freezing and thawing. Quantitative analysis is being undertaken to confirm that temperature and freeze-thaw did not influence the porosity of these samples.

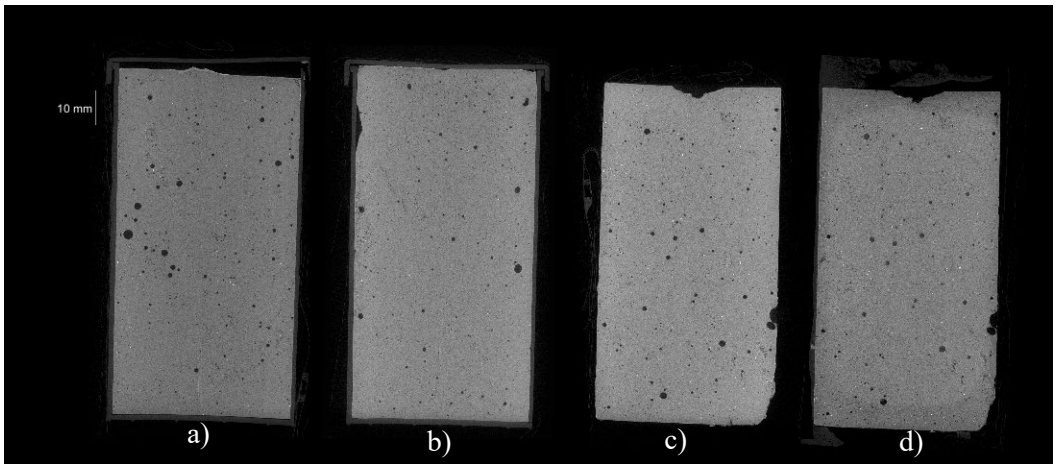

Figure 4: Images of the longitudinal middle slice from CT scans of a) Group 3, b) Group 4, c) Group 6 thawed, d) Group 6 frozen

Conclusion

The results of this study showed that samples prepared with GU cement maintain the highest strength compared to those with a mix of GU cement and other binders. Most samples will gain their strength in the initial 7 days of curing, and increasing the curing time did not increase the strength, except for GU/LKD samples. For samples with up to 10% arsenic dust and GU cement, increasing the curing time increased the strength slightly, but for samples with greater than 10% arsenic dust, increasing the curing time decreased the strength. Based on these results it is recommended to prepare samples with GU cement and 10% ATRW dust.

For long-term storage, increasing the storage time before UCS testing leads to a decrease in strength. However, this is not dependent on storage temperature, and storage time may have a greater influence on strength than temperature does. For short-term stored samples, one and five freeze-thaw cycles show a similar decrease in strength, suggesting that the first freeze-thaw cycle has the greatest influence on strength of the sample and does the most amount of damage. Overall, freezing and thawing have the greatest influence on strength compared to other variables tested.

Based on qualitative analysis of CT scan images, there is no visual difference between the pore size or shape of samples stored long-term at 20°C, 5°C, or -10°C. Also, freezing and thawing did not induce fractures or other visual differences, except for density changes in the frozen sample. Quantitative analysis is being undertaken and will confirm whether the changes in temperature and freeze-thaw have an impact on the porosity of these samples.

Alex Fitzpatrick, Klohn Crippen Berger, Australia

Abstract

Klohn Crippen Berger Ltd. (KCB) developed an integrated water balance and water quality model ("the model") in GoldSimfor the provincial Environmental Assessment of the proposed Cariboo Gold Project ("the Project") at the Quesnel River (QR) Mill site near Quesnel, British Columbia, Canada.

Previous operations at the QR Mill site from 1994 to 2022 processed and stored conventional tailings under a water cover designed for geochemical control in the Tailings Storage Facility (TSF) and Main Zone Pit. For the proposed Project, the existing TSF pond water will be drained down, treated, and discharged. New tailings generated from the Project will be filtered and placed in lifts over the existing TSF tailings. However, the Project's filtered tailings will be highly sulfidic and potentially acid generating. As a result, proactive water management is required during the Project to achieve environmental discharge criteria.

KCB used the model to assess required water management and treatment, control measures, and facility design for each project phase, including closure. Discharge flow and water quality predictions for the Project footprint and receiving environment were used to support the Project effects assessments for the Environmental Assessment. This process evaluates how the proposed strategies will meet regulatory criteria and provincial guidelines. The Project Environmental Assessment started shortly after the 2018 revision to the British Columbia Environmental Assessment Act. The timing of the assessment provided unique challenges for the owner, regulatory agencies, stakeholders, and consultants navigating the updated Act.

To assess a range of potential conditions, KCB conducted sensitivity scenarios on the control measures, climate conditions, and geochemical conditions. Water treatment, geomembrane covers, and seepage interception were identified as important control measures to meet water quality requirements.

Key takeaways from the application of the model for the Project include the importance of proactive risk management, early consideration of best available technologies, communicating with regulators and other consultants, and planning for closure in a changing climate.

Introduction

Osisko Development Corp. (ODV) is currently proposing to develop and operate the Cariboo Gold Project ("the Project"), located in the Cariboo Regional District of British Columbia (BC), Canada (ODV, 2022a). This paper describes the development and application of the Quesnel River (QR) Mill water balance and water quality model ("the model") to support the Project application for an Environmental Assessment Certificate under the BC Environmental Assessment Act. The Project was the first project entirely assessed under the new 2018 Environmental Assessment Act (EAA, 2018) and was granted an Environmental Assessment Certificate in 2023 (EAO, 2023). The model has since been updated to support permit applications and will be improved and utilized as the Project continues to construction and operations.

For the EA, the model was used to assess the water treatment requirements, seepage control measures, water demand requirements, discharge flows, and water quality concentrations within the QR Mill project footprint and at the receiving environment during Project startup, operations, closure, and post-closure. The model output is intended to inform water treatment and management strategies and evaluate whether regulatory criteria and provincial guidelines will be met under these strategies.

Existing site conditions

The QR Mill site is located approximately 58 km southeast of Quesnel, British Columbia, above the north side of the Quesnel River valley at an elevation of about 1000 meters above sea level. Temperatures are typically around 15°C to 25°C in the summer and 0°C to -10°C in the winter, with extremes ranging from over 30°C in the summer to below -30°C in the winter. The estimated mean annual precipitation and mean annual lake evaporation at the QR Mill site are 670 mm and 440 mm, respectively (KCB, 2022a). The QR Mill site straddles a watershed boundary: runoff to the north eventually joins Rudy Creek, and runoff to the south joins the Quesnel River, via Creek No. 3. The QR Mill site is currently in a care and maintenance phase. Existing site conditions are shown in Figure 1 (modified from KCB, 2022b) and described below.

- Past operations at the QR Mill site from 1994 to 2022 processed and stored conventional tailings under a water cover in two tailings storage facilities, which are the Tailings Storage Facility (TSF) and Main Zone Pit (MZP). The TSF is unlined and has a net negative average water balance. It is confined by the Tailings Dam to the north and the Cross Dyke to the south. The MZP is a depleted open pit with its southern wall located near the Quesnel River valley.
- The two seepage collection ponds, the North Seepage Collection Pond (NSCP) and South Seepage Collection Pond (SSCP), are at the toes of the Tailings Dam and Cross Dyke, respectively. The NSCP and SSCP are unlined. Weir 2 is the discharge point for the NSCP. The SSCP discharges via Weir 9 (to the MZP) or Weir 8 (to Creek No. 3).

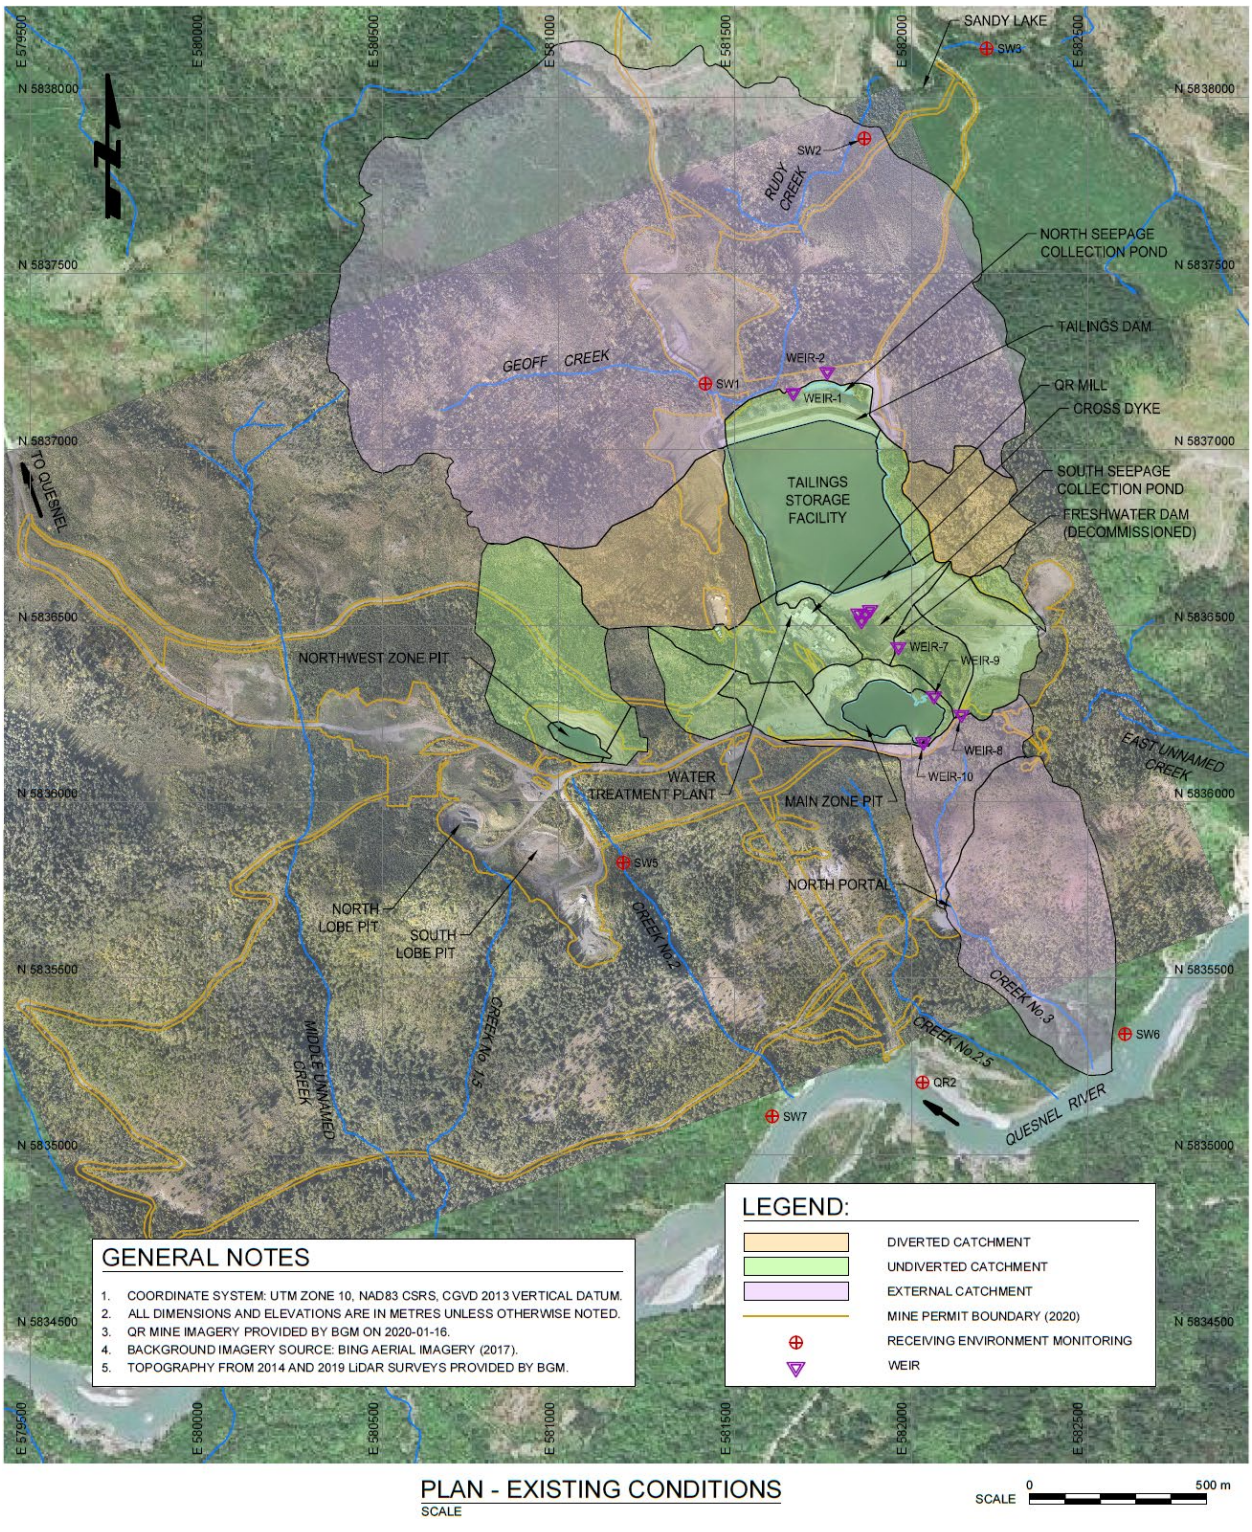

Figure 1: Existing site conditions with modelled catchment areas

- With a net-positive site water balance, contact water is actively managed in the TSF, MZP, and seepage collection ponds. Excess contact water is treated at the water treatment plant (WTP) and discharged into Rudy Creek. The WTP retentate is returned to the MZP.
- There are other legacy mine components on site, including waste rock piles (WRPs), the Northwest Zone Pit, North Lobe Pit, and South Lobe Pit; and inactive underground workings (via the Mid-West Portal, West Zone Portal, and North Portal). Excess water from these legacy mine components meets the permit limits and discharges into the Quesnel River.

A simplified schematic of the existing sources, pathways and receptors is included in Figure 2 (modified from KCB, 2022a). The model boundary is shown as a red dashed line.

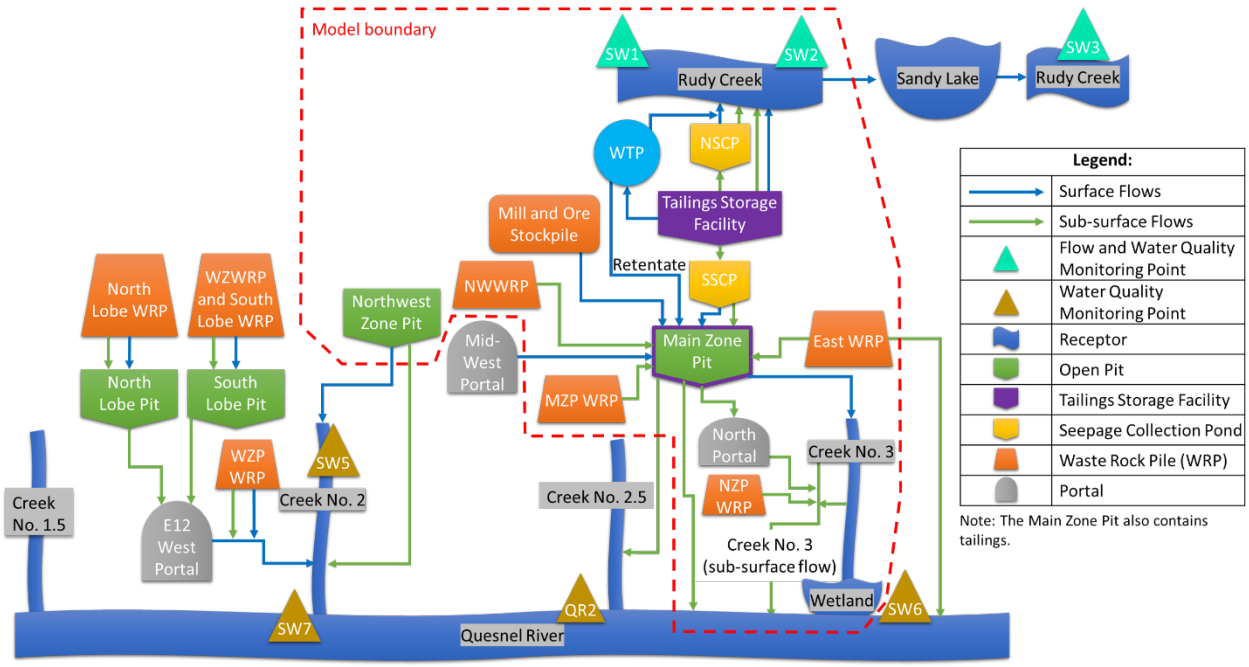

Figure 2: Schematic of the QR Mill existing sources and pathways to receptors

Proposed project description

The Project is located in the traditional territories of the Lhtako Dené Nation, Xatśūll First Nation (Xat ūll), and Williams Lake First Nation. The Project includes the development of the Mine Site Complex near the District of Wells, BC, and the QR Mill. Ore produced at the Mine Site Complex will undergo crushing, ore sorting, milling, flotation, and dewatering before the concentrate is trucked to the QR Mill for the final stage of processing. The mine has an estimated operational mine life of 16 years (ODV, 2022a).

Most of the Project tailings will be stored underground at the Mine Site Complex as paste backfill (ODV, 2022b). The final Project tailings produced from the concentrated ore at the QR Mill site will be

filtered to 90% solids content by weight. The Project tailings will then be placed over the existing TSF tailings following TSF pond drawdown, forming the Filtered Stack Tailings Storage Facility (FSTSF) (ODV, 2022b). Applying filtered tailings technology in this configuration achieves ODV, Indigenous and other stakeholder end land use objectives with the following strengths (KCB, 2021 and Golder, 2022):

- The FSTSF will form a geotechnically stable landform with a low risk of failure. The fully reclaimed FSTSF will result in a landform akin to the pre-mining land use, which is the primary end land use goal for the Project.
- Tailings are stored in the existing TSF, which minimizes new disturbance areas.
- Seepage and loading from the TSF to Rudy Creek are reduced due to removal of the TSF pond.
- Progressive reclamation can occur during the Project by building parts of the FSTSF to their ultimate configuration early in the mine life.

The QR Mill Project tailings are highly sulfidic and have high potential for acid generation (neutralization potential ratio of 0.26) and metal leaching (KCB, 2022b). Storing these tailings in a filtered state can lead to oxidation and generation of poor water quality without adequate controls. The evaluation of control measures is discussed in later sections of this paper.

Model approach

Model structure

KCB developed the model using GoldSim software (Version 14), which is a dynamic simulation software frequently used in the mining industry for water balance and water quality modelling. The model is an integrated water balance and water quality model based on a daily time step, allowing for assessments of daily maximum flows and concentrations. The model was developed based on the conceptualization in Figure 2. To represent the complex relationships, the model was developed as a network of independent subsystems, as follows (KCB, 2022a):

- The hydro-climatology subsystem processes weather data (measured on-site or adjusted from nearby climate stations) to generate rainfall, snowmelt, runoff, and evaporation rates. These rates are multiplied by the catchment and pond areas to estimate catchment flows and losses.
- Water bodies such as the TSF and MZP are modelled as reservoirs with their storage represented by their stage-storage curves obtained from bathymetric surveys and 3D modelling. Pump capacity and pond level triggers are included in the model to reflect operational conditions.

- Subsurface flow information incorporated in the model, such as seepage rates and pathways from source to receptors, is from 2D and 3D hydrogeological modelling. This includes seepage rates through the Project tailings and existing TSF tailings.
- The void spaces within the Project tailings and the existing TSF tailings are modelled as reservoirs. Seepage outflows occur when the predicted moisture content exceeds the materials' residual voids saturation. If the saturation exceeds the maximum reservoir size, based on the material porosity, additional water will not infiltrate and is directed to surface flow.
- The water quality of the surface and subsurface flows is linked to the chemistry simulation systems:
    - Load generation is modelled for the tailings, waste rock and milling operation products using site-specific source terms and scaling factors calibrated with site monitoring data.
    - Chemical mechanisms that reflect the thermodynamics of likely geochemical processes are incorporated into the site reservoirs (ponds and tailings pore space). These include calculations of ionic strength and activity coefficients, pH and alkalinity/carbonate buffering, and the chemical equilibrium state resulting in precipitation or dissolution of minerals.

The subsystems are calibrated using site monitoring data and are subsequently used for future predictions.

Model calibration

The model was calibrated using site monitoring data from 2020 to 2022, including weather data, deposited tailings, flow rates, water levels, and water qualities. In general, the model water balance and water quality predictions are intended to provide conservative estimates for water management requirements in on-site reservoirs (e.g., treatment). The site water balance calibration was completed by adjusting the watershed runoff assumptions so the modelled site reservoir water levels and discharge rates resembled measured data (Figure 3). The average overall site water balance error was 4%.

The water quality was calibrated by assessing the load sources, source terms, chemistry mechanisms, groundwater attenuation factors, and other scaling factors. The proportion of load generating material was the main calibration variable for water quality (e.g., generating load from the top 2 m of waste rock piles, instead of the full pile).

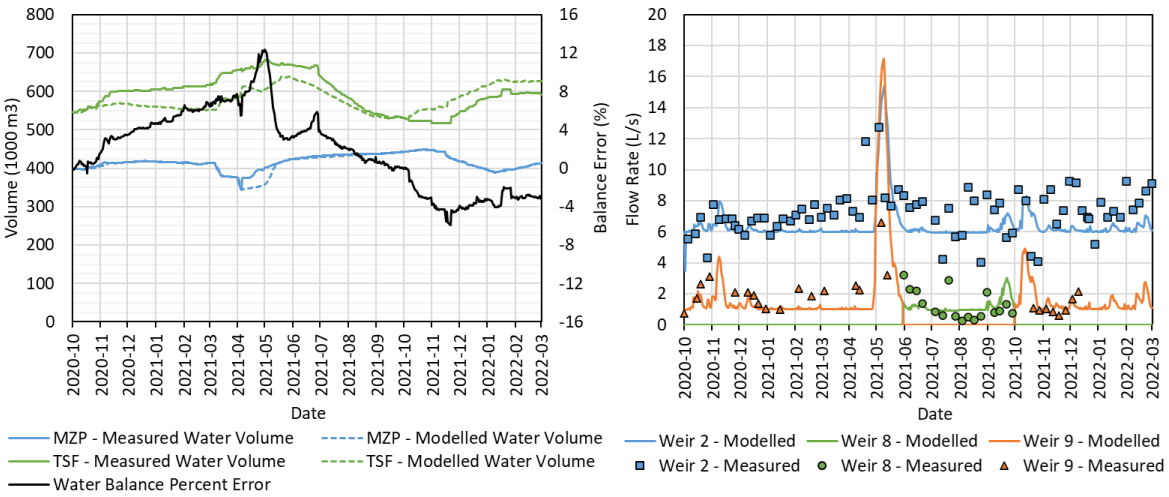

Figure 3: Water balance calibration plots for the MZP, TSF, and discharge weirs

Model inputs and assumptions

For the EA, the modelled period was July 1, 2023, to December 31, 2060. KCB developed a long-term daily climate sequence by transposing 105 years of daily precipitation and temperature data recorded at the Environment Canada Barkerville climate station (1889 to 2006) to the QR Mill (KCB, 2022b). This approach allows for realistic fluctuations in weather conditions, such as alternating dry and wet years, which occurred prior to commissioning the QR Mill weather station in 2018. Table 1 lists the model scenarios included in the final EA report. The selected climate change scenario was based on the Centre National de Recherches Météorologiques Climate Model version 5; using the Representative Concentration Pathway (RCP) of 8.5. This was the most extreme scenario in the Golder climate assessment (Golder, 2021c).

Table 1: Environmental assessment model scenarios

Scenario name	Description
Base Case	Typical climate conditions during Project operations, ranging from 10-year dry to 30-year wet years
Wet	Contains a 500-year wet year during Project operations
Dry	Contains a range of 20-year dry to 10-year wet years during Project operations
Base Case with Climate Change	Same climate sequence as base case, but with linearly applied increases of precipitation by 24% and temperature by 4.2°C between 2010 and 2085
Base Case Climate with No Chemistry	Same climate sequence as base case, with model chemistry mechanisms disabled to assess chemistry modelling impacts on results

The source terms for geochemical load sources were not varied between scenarios because the model is intended to produce conservative water quality results for assessing required controls. The source terms for existing load sources which would not be impacted by the proposed Project, such as pit walls, waste

rock piles and existing tailings in the MZP, were assessed using the calibration model period and retained for the Project predictive modelling.

KCB applied conservative assumptions for load generation from the existing TSF tailings. The top 2 m of the existing tailings are assumed to generate load using loading rates based on saturated and unsaturated kinetic column testing results. For the existing tailings, the saturated testing load rates are applied prior to TSF drawdown, and the unsaturated rates are applied following TSF drawdown. The existing tailings generate load until the existing tailings are covered by 2 m of filtered Project tailings.

The first three cycles of the kinetic column testing for the Project tailings showed acid generation consistent with static test results (KCB, 2022a). However, subsequent cycles showed increasing pH due to neutralization from the available neutralizing minerals. Prior geochemical assessments indicated that the Project tailings are expected to generate acidity once the neutralizing capacity is depleted (KCB, 2022a). Results from the first three cycles were applied to represent a conservative model scenario for operations.

Model applications

Many iterations of the model were developed throughout the EA process to support the development of the Project. During the EA process, regulatory and Indigenous review groups emphasized the importance of producing conservative model results to assess that the Project "will not have a significant adverse environmental, economic, social, cultural or health effect" (EAA, 2018). Indigenous engagement was a central part of the EA and model refinement, but this is not the focus of this paper. The following sections discuss the application of the model for effects assessment, control measure development, facility design, and closure planning as part of the EA process.

Effects assessment

The model was used during the EA process to inform the effects assessment, documented in the human health and ecological risk assessment (Golder, 2021a), and the surface water chapter of the EA application report (ODV, 2022c). During this process, KCB assessed the model results for each Project phase against the applicable regulatory requirements, such as discharge permit criteria, Metal and Diamond Mining Effluent Regulations (MDMER, 2002), and the receiving environment water quality guidelines for the protection of aquatic life (KCB, 2022a). Due to the conservative nature of the model, some exceedances of these requirements were flagged for the effects assessment team to further investigate. If the exceedances were expected to negatively impact the environment, the facility design was revised with control measures discussed in the following section. This iterative process was conducted until the design for the Project achieved the objectives for the protection of human and ecological health.

Control measures

Earlier versions of the model predicted that without water quality controls, there would be chronic water quality guideline exceedances at the receiving environment nodes from uncaptured site seepage, with sources attributed to milling activities and Project tailings reactivity. KCB assessed different combinations of water quality control measures as part of the EA process and Project development. The control measures selected to meet water quality criteria at the discharge points and receiving environment include:

1. Various water treatment components to target contaminants of potential concern. These include the WTP, retentate management system, FSTSF runoff liming system, and treating excess mill process water with iron co-precipitation and a moving bed biofilm reactor.
2. Temporary geomembrane covers over the Project tailings during operations to reduce contact water runoff from Project tailings surface, reduce uncaptured seepage to the environment, and minimize water treatment effort.
3. Permanent closure cover to reduce long-term infiltration and seepage through the FSTSF.
4. Groundwater interception wells downstream of the NSCP to intercept TSF/FSTSF seepage that bypasses the NSCP before it reaches Rudy Creek (SW2).

Water treatment design

Active water treatment controls identified during the EA process include the WTP, liming of the FSTSF runoff, and the iron co-precipitation and moving bed biofilm reactor treatment units for excess process water to the MZP (Golder, 2021b). The water treatment design process involved iterations between KCB, ODV, and the water treatment design team (Golder), to align the water treatment design effectiveness with the model predictions. The model predictions provide the operational flow rate and water quality ranges, which inform the design requirements for the treatment system. The treatment system revisions change the subsequent model predictions because most of the waste removed by the treatment system is returned to the MZP/FSTSF, forming a feedback loop. To break this loop, we (KCB, ODV and Golder) decided on a simplified approach: the water treatment system in the model would calculate and apply the required effectiveness to meet the discharge requirements, rather than applying the design treatment effectiveness which may not be sufficient. The model outputs were then provided to Golder to review and adjust the water treatment design as required. This greatly reduced the model iterations required to achieve a suitable treatment design and made it easier to identify other controls required. The water treatment strategy proposed in the EA will be further optimized in subsequent design stages.

Project temporary and permanent tailings covers

Water contacting the Project tailings is expected to result in poor quality runoff and seepage due to the

Project tailings' high potential for acid generation and metal leaching. To reduce this risk, temporary geomembrane covers will be placed daily over the Project tailings. The primary purpose of the covers is to reduce infiltration into the Project tailings. This reduces the quantity of seepage exiting the TSF, which is more difficult to capture and treat than surface runoff. The covers will also improve the water quality of the FSTSF surface runoff by reducing contact between the tailings and precipitation. The model was used to assess the impact of the temporary cover system on the receiving environment predictions. This assessment informs the cover selection (e.g. material type and permeability) and procedures during operations (e.g., staging and sequencing of the FSTSF construction, and the surface area coverage requirements).

The permanent closure cover was assessed in the model like the temporary geomembrane covers. The modelling of the permanent cover considered progressive reclamation of the FSTSF, and the associated impacts to the water management strategy. If the temporary and permanent covers perform poorly, additional seepage loading from the TSF to the receiving environment at SW2 will occur. To mitigate this risk, a seepage interception system will be implemented between the TSF and SW2.

Seepage interception system

The Tailings Dam containing the north side of the TSF is a rockfill dam with a till core founded on till overburden and weathered bedrock (KCB, 2022a). Most of the north TSF seepage reports to the NSCP near the Tailings Dam toe. However, a portion of the seepage through the Tailings Dam foundation bypasses the NSCP and reports to Rudy Creek downstream. Although the Project involves removing the TSF pond and implementing temporary covers, which will greatly reduce the magnitude of seepage, there is potential for this seepage pathway to impact the receiving environment, particularly during dry summer months. As part of the EA process, ODV conducted feasibility level studies and site investigation work for a seepage interception system (SIS) just downstream of the NSCP. This will consist of a network of pumping and monitoring wells that capture seepage and return it to the MZP for treatment. The model outputs were used to inform the SIS required pumping rates, capture efficiency to meet environmental criteria, and operational duration. The current model assumes a capture efficiency of 70%, which is sufficient to achieve environmental requirements and is expected to be realistically achievable with the SIS.

Water management design

In addition to the control measures, the model also informed other aspects of the water management design for the Project. For example, the mill process water requirements are generally consistent throughout the year, however, the availability of water is impacted by seasonal climate variations. The dynamic nature of the model was useful for assessing mill process water quantities available from the Northwest Zone Pit and SSCP, particularly for extremely dry years.

The TSF and MZP ponds are currently both required to provide flood storage for the site's environmental design flood (EDF), which is "the hydrological event that is to be managed without release of untreated water to the environment" (EMLI, 2022). When the TSF pond is removed during the Project to build the FSTSF, the SSCP and MZP will need sufficient capacity to store the site's EDF. The model was used to size the SSCP to provide adequate operating pond volume (for mill operations) and flood storage. To provide additional flexibility managing the EDF, a one-meter-high concrete sill was designed for the existing MZP spillway invert to provide an additional 33,000 m^3 of EDF storage. The EDF event was modelled with the revised SSCP and MZP capacity to confirm the EDF could be managed without discharge to the environment. For events exceeding the EDF, the model was used to assess the quantity and water quality of discharges from the site. This information was provided to the effects assessment teams.

Closure planning

Closure planning was an important consideration for the regulatory and Indigenous reviewers during the EA process. The long-term liability of the site is governed by the duration of the post-closure active care phase. The post-closure active care phase involves active water treatment, water management (including operation of the SIS), maintenance of the site, and environmental monitoring. When reclamation is complete and active management is no longer required to meet receiving environment criteria, the site will transition to the post-closure passive care phase (Golder, 2022).

The model was utilized to inform the expected duration of the post-closure active care phase and potential residual effects from the Project. By applying the proactive control measures during the Project operations phase, the site is expected to be able to transition to passive care relatively quickly. The closure plan and timeline will continue to be assessed as the Project design stages progress.

Key takeaways

Key takeaways from the application of the model for the Project include the importance of proactive risk management, early consideration of best available technologies, communicating with regulators and other consultants, and planning for closure in a changing climate.

The risk management system applied for the Project aligns with the Risk Management Framework for Mining in BC, which states, "Risk management is the practice of reducing uncertainty wherever possible, and evaluating the effectiveness of mitigating actions on either preventing the risk or reducing the impacts if the risk were to occur to an acceptable, or tolerable, level" (EMPR et al., 2018). As discussed in this paper, proactive risk management measures were assessed throughout the Project, such as implementing temporary covering over the Project tailings daily. Iterating through the control development and modelling results provided valuable risk management experience to apply to other projects and technologies.

Risk management for the Project also includes the application of best available technologies, particularly the use of filtered tailings and water treatment. From a modelling perspective, it is easy to see the benefits of filtered tailings by comparing the existing TSF seepage outflows to the predicted FSTSF seepage outflows. Considering the use of best available technologies early in the Project, such as the tailings alternative assessment in KCB (2021), can reduce design and modelling effort by avoiding reassessments during the design process. This can reduce cost and time for engineering work during the EA application process, and ideally for the Project itself.

Due to the interdisciplinary nature of mining projects, they are susceptible to conflicts (and potentially delays) arising from coordination with other consultants and regulatory reviewers. As the first project to be assessed under the new 2018 Environmental Assessment Act (EAA, 2018), this Project was no exception. The 2018 EAA is more extensive and stringent than previous regulations, which resulted in more iterations between consultants, ODV, and the regulatory reviewers to confirm the Project application meets the regulatory requirements. ODV's planning and coordination helped sustain positive relationships between consultants and regulatory reviewers during the EA process. Modelling for the Project required consistent, timely communications between the design teams, which was achievable in most instances. Clear planning and documentation of scope boundaries/responsibilities, design bases/criteria, and dependencies between scopes was critical to meet the Project application schedule. With the model results being used by the treatment and effects assessment teams, it was especially important to prioritize model checks and minimizing revisions to the issued results.

When receiving regulatory comments, it was useful to address the comments with individual scenarios compared to the original baseline, rather than attempting to quantify the impact of many changes in one set of model results. The regulatory reviewer comments focused on the development and application of loading source terms, scaling factors, control measures, and the potential impacts to the receiving environment. The EA process also highlighted the importance of planning for closure in a changing climate. Planning for closure requires a thoughtful approach considering Indigenous end land use objectives and realizing a resilient and robust plan to continue achieving these objectives for future generations.

Conclusion

The QR Mill water balance and water quality model successfully supported the application for an Environmental Assessment Certificate for the Project under the BC Environmental Assessment Act. The model will continue to be updated and utilized in future design stages, and as the Project moves into operations. The model includes the existing site conditions and infrastructure, as well as the proposed configuration for the Project. The model has been calibrated using site monitoring data, including climate data, flow measurements, and water quality testing. Kinetic column test data was used for the Project

geochemical load sources, which are intended to produce "worst-case" water quality predictions for the EA process. The model was an integral component of the design process for water management infrastructure and associated control measures during the Project. Results from the model were reviewed during the effects assessment to identify and minimize risks to human and ecological receptors related to the Project. The key takeaways from the EA process are related to early planning to account for risks for all stages of a project, from design, to operations, and onwards into post-closure.

Acknowledgements

We would like to thank ODV for their support in the development of the many iterations of this model and for allowing us to share our experience in this paper. We would also like to acknowledge the efforts of the Indigenous groups, regulatory agencies, and other stakeholders who provided invaluable feedback during the EA process. Lastly, a big thank you to our colleagues at KCB who made this work possible.

Development of a Calibrated Seepage Model to Predict Pore Pressure Reduction to Inform Tailings Storage Facility Closure Planning

W.E. Rouncivell, SRK Consulting, South Africa
R.L.C. James, SRK Consulting, South Africa
S.A. Lorentz, SRK Consulting, South Africa

Abstract

The long-term stability of tailings storage facilities (TSFs) is largely dependent on the pore pressure regime. If the tailings are contractive, and thus susceptible to liquefaction, knowledge of the phreatic surface and extent of the partially saturated zone of tailings above this are particularly critical to inform the slope stability of the TSF. The reduction of this saturated and partially saturated zone over time will reduce the risk from the TSF to the environment, both from a slope stability and seepage to groundwater perspective. Numerical seepage drain-down analyses predict the reduction of pore pressures and saturation over time. In this case study, monitoring data from a recently closed upstream platinum TSF are used to calibrate 2D transient models in the Hydrus software. Tailings particle size distributions, a Cone Penetration Test with pore pressure measurement (CPTu) dissipation field test results, standpipe piezometers, and drain flows are utilized.

Zoning is incorporated in the model based on the CPTu and grading data. The predictive scenario results are dependent on numerous key variables, including the hydraulic conductivity of the foundation and tailings material the horizontal versus vertical hydraulic conductivity anisotropy ratio of the tailings material, as well as surface infiltration on the tailings beach. The Soil Water Characteristic Curve (SWCC) of the tailings and its variability across a TSF are also important in such analyses. The SWCC is estimated based on the tailings particle size distribution. A model calibration framework is developed to improve the confidence of the parameters used for predicting the drain-down profile. It is shown that the tailings SWCC and foundation hydraulic conductivity are central to the drain-down modeling, which is critical for TSF closure planning.

Introduction

A case study of a platinum upstream tailings storage facility (TSF) is presented in this paper. Deposition

has ceased for 2two years on the TSF, which is currently in a care and maintenance phase while closure options are evaluated. In addition to slope stability, surface water management is a key focus in the long term. Currently, no water is released from the top surface except via penstocks to the return water dam (if required), which is part of the contaminated water circuit. The penstocks are planned to be sealed in the medium term; therefore. a sustainable surface stormwater management solution is required. The options include a "store and evaporate" and/or "removal via spillway" strategy. If storage results in recharge to the saturated tailings, then the phreatic surface rise will increase the stability risk of the TSF.

The publication of the Global Industry Standard on Tailings Management (GISTM) standard brought all TSFs, particularly upstream constructed facilities, under the microscope. In some cases, improved analysis and design methods are required to validate their performance. Pore pressures play a significant role in slope stability analyses, therefore understanding of the seepage regime over the life of a facility is imperative. Numerical seepage analyses have been undertaken to model the effect of potential stormwater storage on the TSF as well as the anticipated timeframe in which drain flows can be expected, which will require a form of treatment. GISTM highlights the importance of closure and post-closure in many of its principles, including developing an interdisciplinary knowledge base, having a robust design, and proactively managing risk. Advanced seepage modeling and integration of ongoing monitoring data for regular model calibration refinements will improve the confidence of the predictive capability.

The goals of this study were threefold. Firstly, to estimate the drain-down period for water treatment planning purposes; secondly, to determine whether storing stormwater on the TSF in evaporation paddocks in the short term, with no cover design or vegetation plan, is feasible without compromising long-term closure objectives. Lastly, if water can be stored, the study aims to identify the location in the basin that poses the lowest risk to recharging the saturated zone.

TSF description

The TSF was operated for 18.5 years with an average deposition of 140,000 tonnes per month and a maximum rate of rise of 2.5 m per year. The average outer slope is 1V(vertical):4H(horizontal) and the average Natural Ground Level (NGL) slope is 1V:45H. At final height, the TSF is 42 m high at the main embankment; this includes a starter wall of 13 m. Figure 1 and Figure 2 show the plan layout and downstream portion of the transect, respectively, including the monitoring and sampling locations.

Spigot deposition promotes significant segregation along the beach, resulting in approximately 80% of sand near the crest to near zero percent sand at the centralized pool low spot. The pool has reduced significantly over the period since deposition stopped. The phreatic surface, measured by standpipe piezometers, has dropped by approximately 0.5 m along the perimeter.

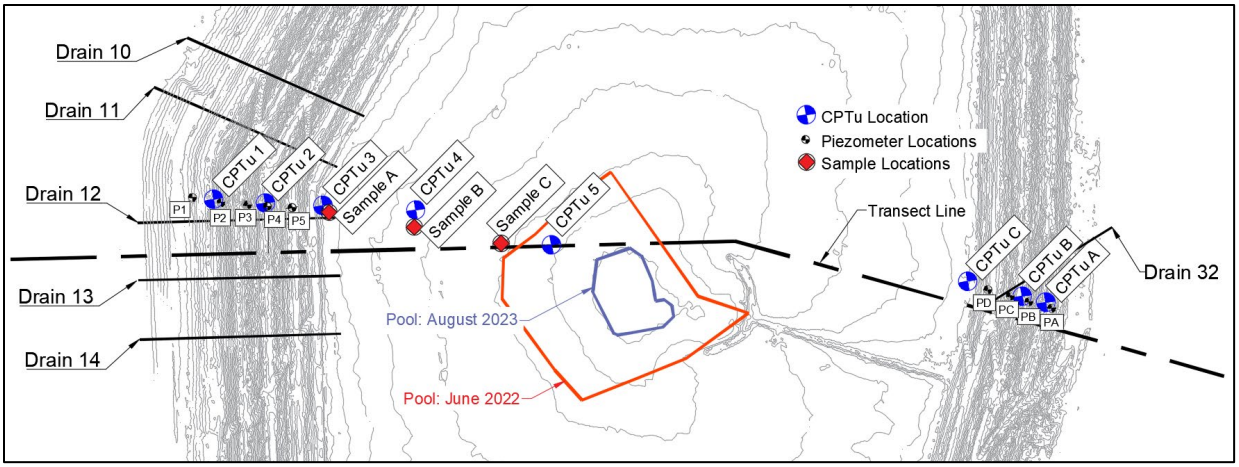

Figure 1: TSF layout

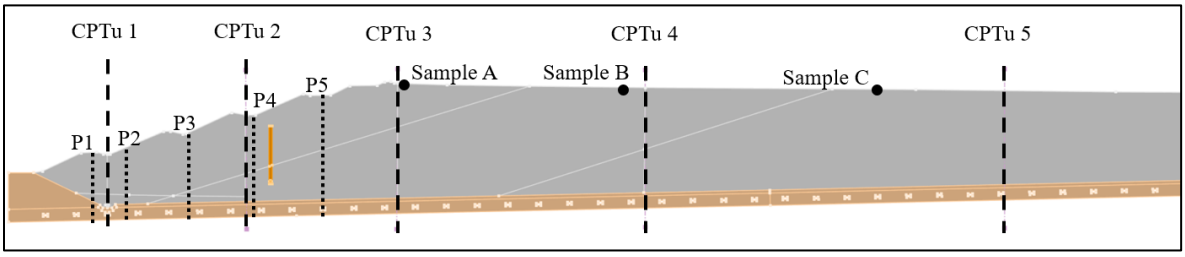

Figure 2: Transect (downstream portion) with monitoring data locations

The site is situated in South Africa in the highveld region with a mean annual precipitation (MAP) of 436 mm, 1:50 yr storm depth of 120 mm and average annual evaporation of 1,316 mm. Site rainfall data was available for the previous 16 years from the mine site (Figure 3).

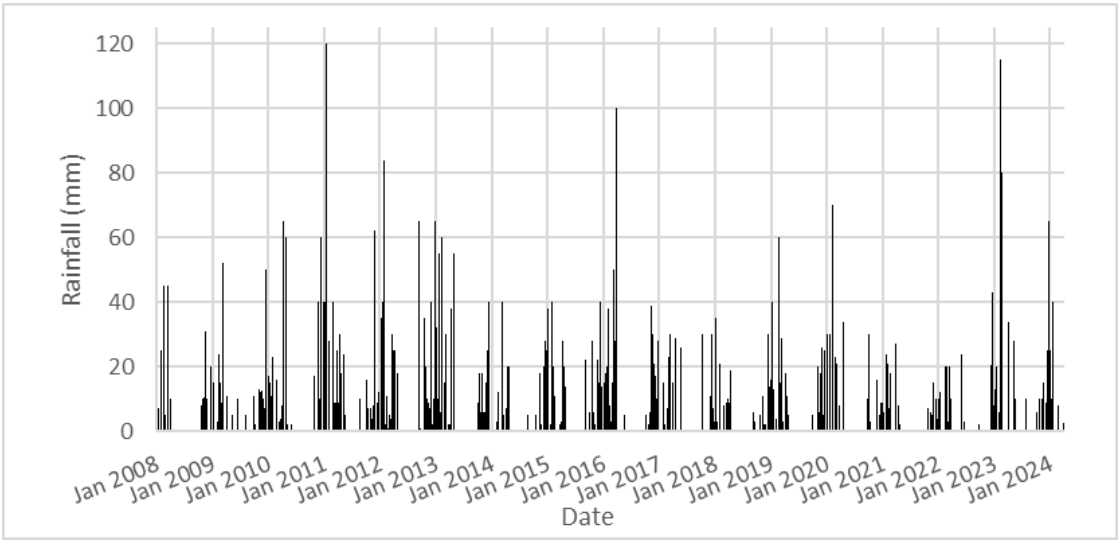

Figure 3: Site rainfall record (recorded at the mine's weather station, gaps filled using CHIRPS data)

Gaps were filled using the Climate Hazards Group Infrared Precipitation with Station data (CHIRPS). Evapotranspiration rates were estimated based on two years of A-pan data, which ranged from 4 mm/day in the summer to 2.5 mm/day in the winter.

Calibration data

Standpipe piezometer levels and drain flows are measured monthly. The toe drain and curtain drain flows per meter along the transect were determined from the monitoring data. Drain 12 flows decreased from 0.22 m^3/day/m and 0.49 m^3/day/m for the toe and curtain drain respectively to 0.08 m^3/day/m and 0.44 m^3/day/m over the transient calibration period. Drain 13 toe drain flows decreased from 0.85 m^3/day/m to 0.60 m^3/day/m over the transient calibration period. The standpipe piezometric levels dropped, on average, by 1.5 m. A CPTu campaign was undertaken 14 months after deposition stopped, which provided confirmation of the phreatic surface as well as vertical pore pressure gradients. Tailings samples were obtained near the surface to determine the particle size distribution information from the crest to the pool.

The pool on the TSF varies in size based on rainfall and evaporation. The stage capacity characteristics of the basin were determined from the freeboard survey and the pool area from monthly satellite imagery. Since deposition ceased, the pool volume has ranged between 0 to 10,000 m^3 (with an average of 4,420 m^3), and the pool area ranged between 0 to 29,980 m^2. The horizontal extent of the pool across the transect was modeled as a head condition in 4 size steps over the transient calibration period.

Methodology

A 2D transect across the TSF, including footprint and starter wall geometry, was imported into HYDRUS-2D and appropriate mesh and boundary conditions were applied. Steady state conditions (at the time deposition ceased) were established by adjusting certain boundary conditions and foundation hydraulic properties to align the phreatic surface and drain flows with monitoring data.

The transient simulation in Hydrus was undertaken using four distinct constant head conditions to mimic the changing pool size over the transient period. These pool sizes were determined by averaging similar-sized pools over a specific timeframe, as direct implementation of varying pool sizes in the model was not feasible. To maintain the continuity between phases, the pore pressure regime from the final day of each pool size/constant head simulation was imported into the next pool size model, using it as the initial condition to commence the subsequent transient phase. An atmospheric boundary condition was applied to the remaining surface nodes of the TSF to apply the rainfall and evaporation for the specific time period being modeled.

The feasibility of an evaporative paddock was investigated using a HYDRUS-1D analysis initialized with the head condition from the transient calibration model.

Tailings characterization

Hydraulic properties

Particle size distribution results of the tailings (Table 1) show clear segregation along the beach. Samples were taken at locations A, B, and C at 7 m, 110 m, and 210 m from the outer crest, respectively. The tailings material classifies in the range between SM to ML (sand with silty fines to fine-grained sands), according to the Unified Soil Classification System (USCS).

No water retention laboratory testing was undertaken on the tailings. The Soil Water Characteristic Curve (SWCC) is estimated based on the tailings particle size distribution using the Hydrus neural network prediction tool, which uses pedotransfer functions (Schaap et al., 2001) to predict van Genuchten (Van Genuchten, 1980) water retention parameters and hydraulic conductivity. Data from a nearby platinum TSF (Site B) where water retention testing was conducted on cycloned tailings material were plotted as reference curves (Figure 4). The overflow and underflow sample (coarse and fine material) results compare reasonably to the Zone A and Zone C material, respectively. The model transect was zoned horizontally based on this grading variation into Zone A, B, and C.

The hydraulic conductivity characteristic curves were derived using the Van Genuchten/Mualem model (Table 2). Qr and Qs denote the residual and saturated water contents respectively, Alpha (1/m) and n are empirical coefficients affecting the shape of the hydraulic functions. Ks is the saturated hydraulic conductivity (m/day). *l* is a pore connectivity parameter; a value of 0.5 was used. The water content and hydraulic conductivity versus suction pressure are shown in Figures 4 and 5 respectively. The hydraulic conductivity determined for tailings ranged from $1.5e^{-5}$ m/s to $1.9e^{-6}$ m/s.

Table 1: Material properties

Zone	% Sand	% Silt	% Clay	USCS Classification	Bulk Density (g/cm³)	Dry Density (g/cm³)
Tailings Zone A	78.6	19.4	2.0	SM/SC	2.1	1.9
Tailings Zone B	25.8	71.3	3.0	ML	2.1	1.7
Tailings Zone C	0.4	89.6	10.0	ML	2.0	1.6
Foundation 1	14.6	21.4	64	CH	1.6	1.3

Table 2: Hydraulic parameters

Material	Name	Qr (-)	Qs (-)	Alpha (1/m)	n (-)	Ks(m/day)
1	Tailings Zone A	0.04	0.38	4.59	1.76	1.30
2	Tailings Zone B	0.04	0.34	0.93	1.55	0.35
3	Tailings Zone C	0.06	0.43	0.68	1.61	0.16
4	Foundation 1	0.06	0.43	0.68	1.61	0.02

The curtain and toe drains were modeled with an opening in the mesh surrounded by a seepage face. During calibration the number of faces activated around the opening was adjusted to limit or increase flux to the drain. Although the drains are surrounded by filter aggregate, this was not included in the model setup.

Foundation 2 has similar parameters to Foundation 1, except that the hydraulic conductivity is half that of Foundation 1. The Zone C material was assigned as a layer over the toe drain to simulate a lower hydraulic conductivity material during the early stages of deposition when segregation is limited due to a short beach and high rate of rise. This impacts the flattening of the phreatic surface near the starter wall.

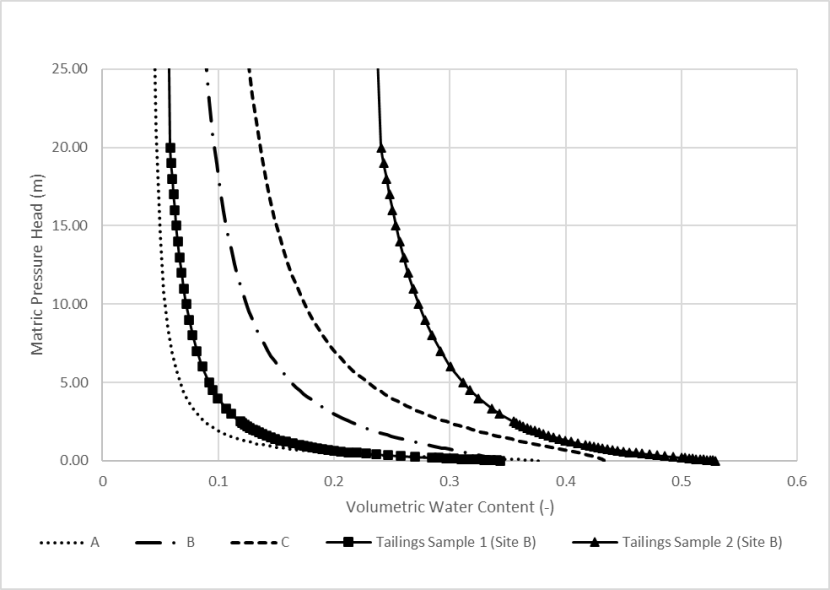

Figure 4: Tailings hydraulic properties: pressure head vs. volumetric water content

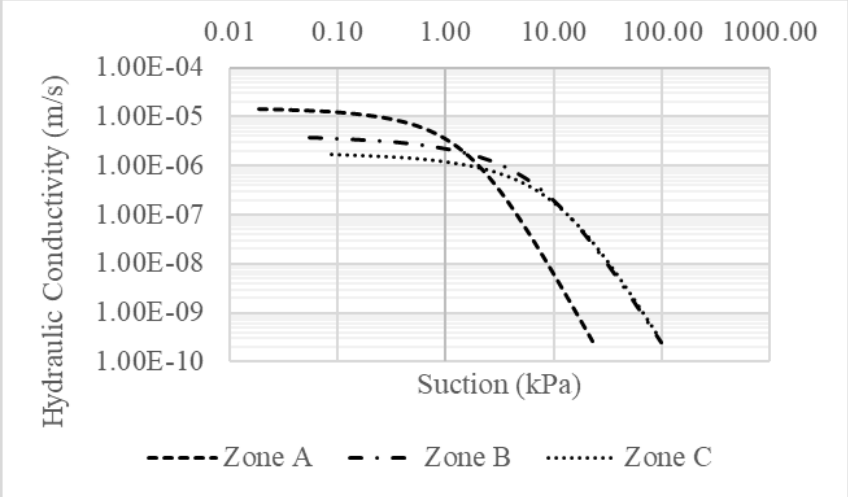

Figure 5: Tailings hydraulic properties: hydraulic conductivity vs. suction

Model setup and calibration

Each model was formulated in the 2D finite element software package, HYDRUS 5.03.0290, to simulate water movement and numerically solve the Richard's Equation for variably saturated flow. The model contained 5,824 nodes with a total of 10,800 triangular elements. Material zoning and boundary conditions are shown in Figure 6.

Model calibration

Model calibration is required to account for unmeasured, unknown, or unrepresented conditions or processes and for uncertainty in measured input data. To calibrate the model, hydraulic conductivity and certain boundary conditions were adjusted until the calibration criteria was met and the model was deemed "fit for purpose" and for use as a predictive tool. Two stages of calibration were undertaken:

- A steady state calibration to simulate the state of the TSF pore pressure regime at the end of deposition. A head boundary condition was applied across the pool area and a flux applied across the beach. This "infiltration" represents the net effect of deposition, rainfall, and evaporation. The flux boundary value was adjusted iteratively until observed phreatic surface, vertical pore pressure gradient, and drain flows were closely matched.
- A transient model calibration from the end of deposition till the CPTu testing date (456 days) was undertaken, initialized by the results of the calibrated steady state model. The flux boundary was replaced with an atmospheric boundary condition while the pool size was gradually reduced in line with the satellite imagery. The reduction of the phreatic surface and drain flows were used as criteria.

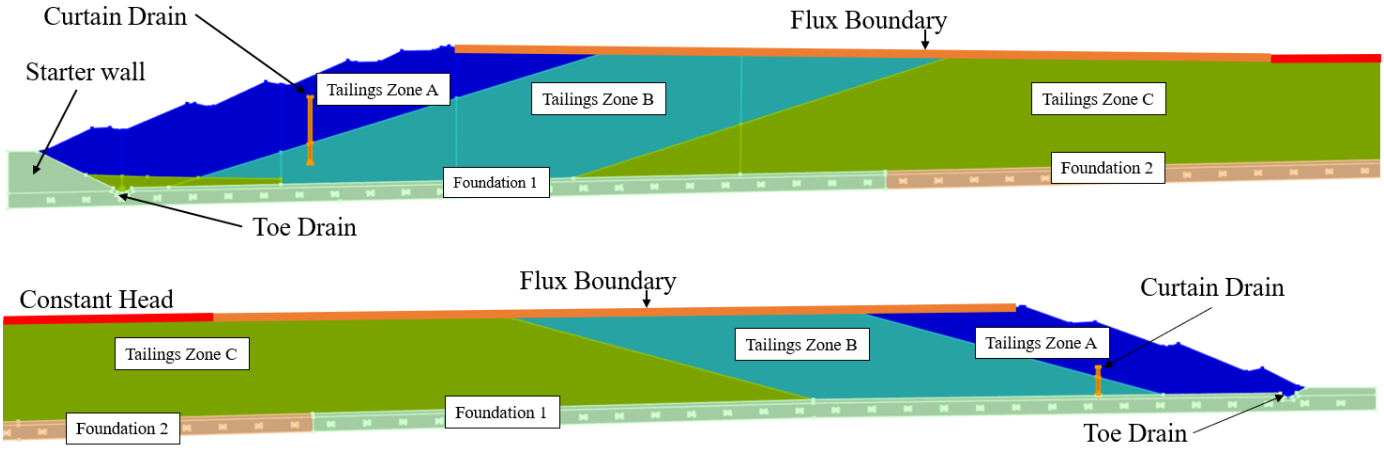

Figure 6: 2D Hydrus Model setup

Results and discussion

The results of the steady state and transient calibration period aligned well with observed CPTu and monitoring data. The model phreatic surface location (Figure 7) aligned very closely with the observed location at each time period since this was a calibration criterion. The vertical hydraulic gradient comparison (Table 3) shows the same trend of overall decreasing gradients towards the center of the TSF. The drain flows (Table 4) show reasonable alignment, particularly for the curtain drain flows, which include drain 32 flows (no toe drain flows observed at drain 32). The correlation improves if the average flow of drains 12 – 14 are used for comparison, considering the model as representative of that flank of the TSF. The average flow of these drains was 0.54 m^3/day/m and 0.40 m^3/day/m for the start and end of the calibration period, respectively. Some cross flow from Drain 12 towards drain 13 is believed to occur, which is not captured in the 2D model.

Storage in the original pool area recharges the saturated zone directly, therefore stormwater should be decanted promptly via the penstocks.

Table 3: Vertical hydraulic gradient comparison

	CPTu 1	CPTu 2	CPTu 3	CPTu 4	CPTu 5
Model Vertical Hydraulic Gradient (m/m)	0.7	0.91	0.81	0.68	0.49
CPTu Vertical Gradient (m/m)	0.67	0.74	0.43	0.5	0.3

Table 4: Drain flow comparison

	Toe drains: End of deposition	Toe drains: End of transient period	Curtain drains: End of deposition	Curtain drains: End of transient period
Actual (Drain 12 and 32) (m^3/day/m)	0.22	0.08	1.50	0.96
Model (Drain 12 and 32) (m^3/day/m)	1.22	0.42	1.21	0.71

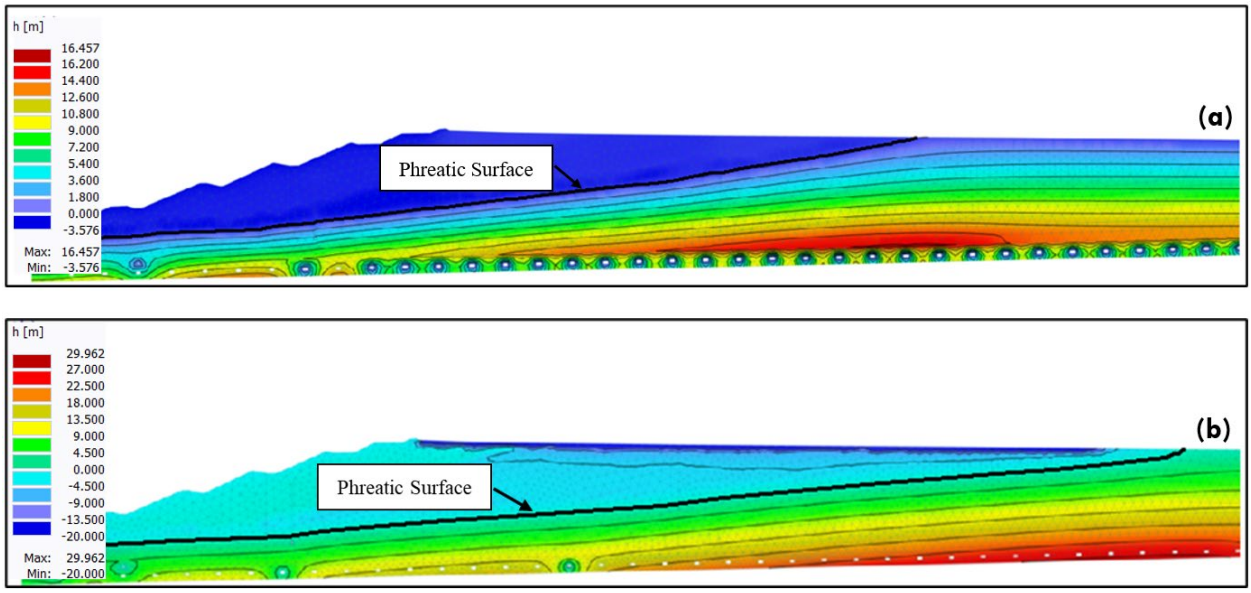

Figure 7: Pressure heads (a) steady state (start of transient calibration period) (b) end of transient calibration period

Drain-down profile

The calibrated model was used to run a scenario in which the pool has reduced significantly and then been removed, based on the assumption that stormwater reporting to the pool area will be decanted via the penstock in the future. The model was then run with an atmospheric boundary condition until drain flows reduced significantly. In addition to the zoned TSF model, a scenario where Zone C material was applied throughout the tailings body was run. This was motivated by the fact that the porosity and hydraulic conductivity of this material more closely matched the porosity and hydraulic conductivity of the tailings observed on similar TSFs. The drain-down profile of both scenarios is shown in Figure 8, each near five years. The use of a single material did not make a significant difference to the result.

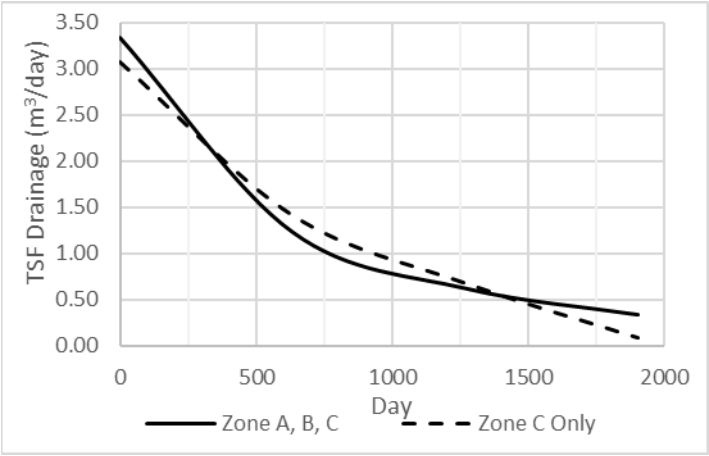

Figure 8: Drain-down profile

This predicted drain-down period is considered an underestimate. Since the transient calibration period was relatively short, a longer period is recommended to improve the confidence of the model parameters, particularly the foundation hydraulic conductivity and drainage conditions.

Evaporation paddocks

To reduce the volume of discharge via the penstocks, storage of stormwater in evaporation paddocks away from the pool area was investigated. Location B was interrogated via a 1D simulation over a 16-year rainfall period. The model was initialized from the pore pressure profile from the 2D transient model (Figure 9). The bottom boundary head condition was kept constant, i.e., the phreatic surface was not permitted to reduce. This is considered conservative since the phreatic surface is expected to drain-down according to the 2D transient model. Over the simulation period the water content of the unsaturated zone increased, and the phreatic surface increased by 2 m. Therefore, a trial over a short period will not rapidly impact the saturated zone. However, this should be closely monitored.

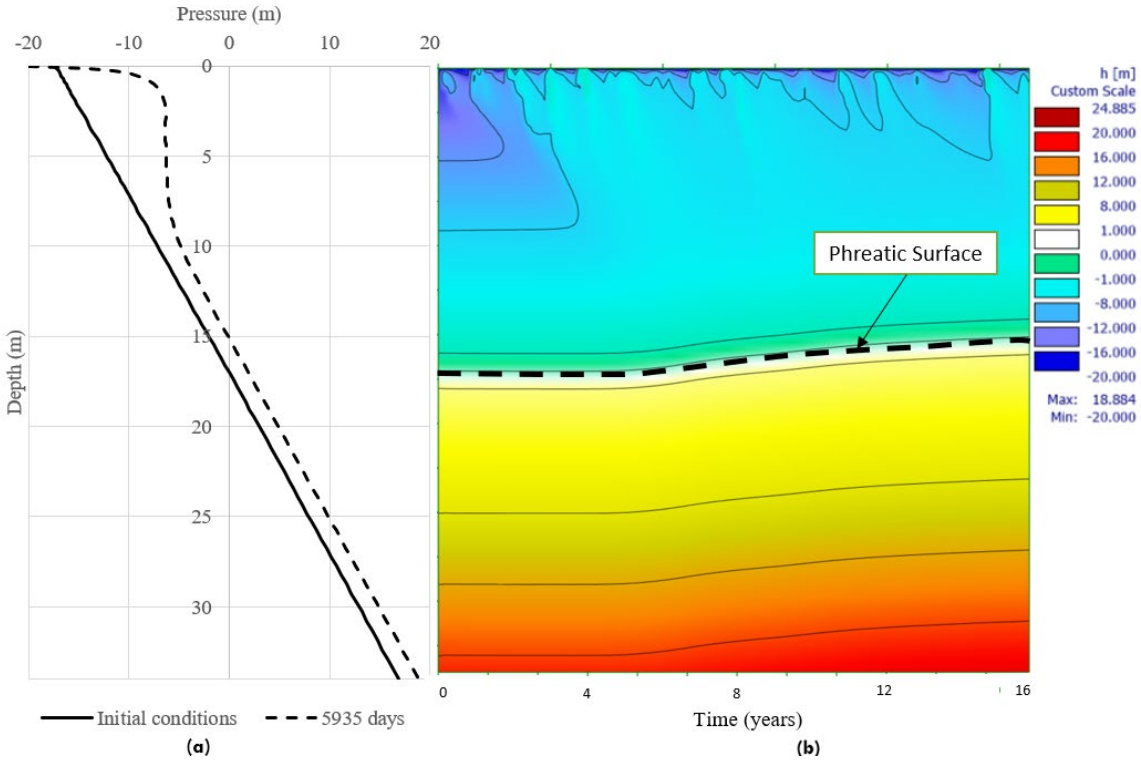

Figure 9: (a) Pressure head changes over 16 years of rainfall and evaporation. (b) Initial and final pore pressure distributions at sample B location

Conclusion and recommendations

TSF 2D Hydrus seepage models were calibrated using monitoring and CPTu data. The SWCC, derived from tailings particle size distribution data (pedotransfer functions) provided a reasonable prediction of

hydraulic parameters that resulted in drain flows and pore pressure gradients matching reasonably the monitoring data for the calibration periods, both steady state and transient.

The outcomes included the estimation of the drain-down period and the feasibility of storing stormwater in evaporative paddocks during the TSF care and maintenance phase. Evaporation paddocks away from the pool area are recommended, but can potentially re-saturate the unsaturated zone and recharge the phreatic surface. A trial over a relatively small area of the TSF, at different distances from the crest, is recommended to test their performance. Cover design and vegetation options could be incorporated into the trial.

A CPTu campaign is recommended in future to enable calibrating the transient model over at least 4 years to improve the confidence of the predicted drain-down period. Drain flows, standpipe piezometers and pool size data should be collected monthly to support this analysis.

Rapid Water Table Response to Transient Pressure Wave Generation in the Unsaturated Zone of Tailings Dams

Charné Theron, Hanze University of Applied Sciences, Netherlands
Simon A. Lorentz, SRK Consulting, South Africa

Abstract

Recent years have seen a global rise in the failure of tailings dams. Studies investigating the causes of slope failure often recognize that high intensity rainfall events significantly contribute to liquefaction, erosion, and overtopping. This study aims to investigate the influence of alternative physical and geohydrological processes that, under tension saturation conditions, contribute to slope instability in tailings dams. It has been suggested that the generation of transient pressure wave mechanisms by high intensity rainfall events, surface ponding, and wetting front advancement result in the formation of an induced pressure head that triggers the mobilization of pre-event water. In order to quantify these physical processes, this study included the analysis of rapid transmission conditions in a silica fines mix, with similar physical and hydraulic characteristics as platinum tailings. A tall leak-proof soil column, containing the soil sample compacted to in-situ dry bulk density, was fitted with seven observation ports. Each port consisted of a pore air pressure probe, a mini tensiometer, and a time domain reflectometry probe. After set-up and initial stabilization, three separate artificial high intensity rainfall events were applied to the surface. Monitoring of hydraulic state variables was recorded at 30-second intervals by automatic logging, thereby enabling the analysis of measured outcomes. Observations showed instant spikes in pore air pressure ahead of the wetting front, as well as a number of delayed responses. The interpretation of laboratory results led to the conclusion that pressure diffusion mechanisms throughout the porous medium could result in the rapid release and mobilization of previously stagnant antecedent moisture, thereby enabling phreatic levels to rise rapidly and in excess to the amount of surface infiltration. Also, since an increase in pore water pressure is likely to cause a reduction in shear strength, it is suggested that these physical and geohydrological processes could have an adverse impact on the stability of tailings dams.

Introduction

Ng and Shi (1998) proposed that slope stability of tailings dams is not only affected by high intensity rainfall events, but that pre-event water makes a significant contribution to a reduction in the factor of safety. Based

on this premise, it is suggested that preceding rainfall events contribute significantly to the establishment of the tension saturated continuous pore water phase, which enables rapid transmission of the induced pressure head to a potential failure plane. This study intends to demonstrate pressure diffusion mechanisms throughout the porous medium. It was previously suggested that these physical processes, known as Groundwater Ridging (GWR) and the Lisse Effect (LE), are largely responsible for the rapid release and mobilization of previously stagnant antecedent moisture, thereby enabling groundwater levels to rise in excess compared to the amount of water infiltrating the soil profile (Theron et al., 2022). The increase in pore water pressure contributes to stresses that reduce shear strength and lower the factor of safety. It could therefore have an adverse impact on the stability of tailings dams (Theron, 2023).

Ground water ridging

Abdul and Gillham (1984) describe the physical process of GWR as occurring near a stream, and allowing for the rapid rise of the water table to the surface. The rise occurs due to the conversion of pre-event water held in tension in the unsaturated zone to water contained within the phreatic zone. According to Cloke et al. (2006) the addition of rainwater and a small amount of infiltration relieves tension in the tension saturated capillary zone and instantly converts the negative pressure head to a positive pressure head (Theron and Lorentz, 2023). The release of antecedent water occurs due to the development of a steep hydraulic gradient that is directed towards the stream. According to Zang et al. (2018) the rise in the water table is dependent on the amount of pre-event water already held in the capillary zone, and not on how much water is infiltrating the soil profile during or shortly after the rainfall event. The rise in the water table is therefore inconsistent with the amount of infiltrated water (Theron et al., 2022). According to Waswa and Lorentz (2016) the rapid and exaggerated rise in the phreatic surface occurs since such a small amount of water is required, through infiltration, to fill the capillary menisci. The process of GWR is shown in Figure 1 and is recognized by the rapid uneven rise in the water table after the occurrence of a high intensity rainfall event (Theron, 2023).

It is further recognized that diminished GWR responses are closely related to rainfall events of low intensity. This is also suggested by Zang et al. (2018), who found that low intensity rainfall events result in lower pore air pressure in the vadose zone and diminished transient pressure waves. According to Abdul and Gillham (1984) GWR is entirely dependent on rainfall intensity, adjacent surface slope, and soil hydraulic conductivity. Adding to this, Ng and Shi (1998) mention that the presence of antecedent water within the soil profile and the position of the initial water table before occurrence of a rainfall event, would also be required for GWR to occur. This is confirmed by Cloke et al. (2006) who found a strong relationship between riparian characteristics and GWR and suggested that the development of a positive ridge would also be dependent on soil type.

Coarse soils allow for higher levels of infiltration, while fine-grained soils, such as tailings, enable the extension of the capillary fringe (CF) and therefore provide conditions required for GWR to occur (Theron, 2023). As pore size, and inversely particle size of soil, will determine the height of the capillary fringe above the water table, it is suggested that the fine nature of tailings would contribute to higher rising water levels in the capillary zone. However, Zang et al. (2018) mention that the capillary fringe is only an influence factor, and not a controlling factor in the generation of GWR.

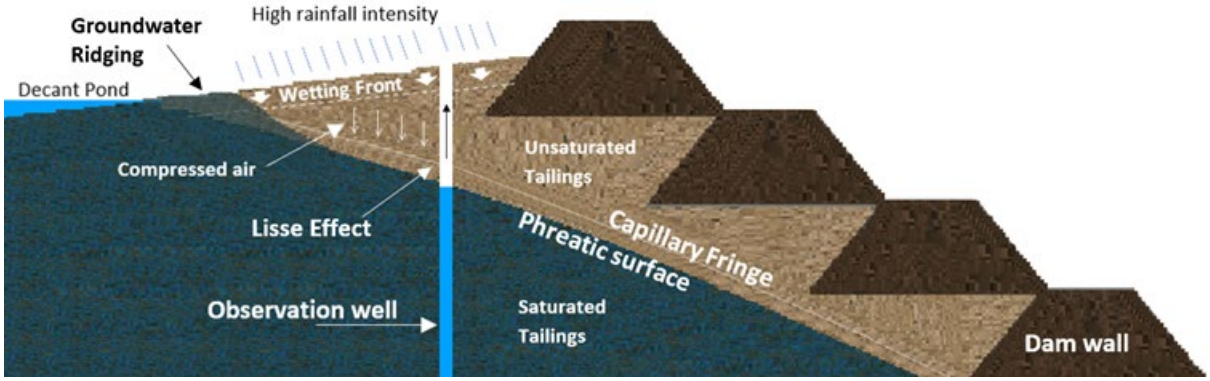

Figure 1: Schematic depiction of GWR and the LE (Theron, 2023)

Lisse Effect

The LE, illustrated together with GWR in Figure 1, happens as a result of the accumulation of air pressure between the approaching wetting front and the water table (Guo et al., 2008). After infiltration of rainfall at the soil surface, the downward moving wetting front functions as an impermeable cap that limits the outflow of air, thereby causing an increase in pore air pressure (Meyboom, 1967). According to Weeks (2005) pressure at the top of the capillary fringe will continue to rise until entrapped air pressure is higher than the pressure head of the infiltration profile above. The process is likely more pronounced if soil air content is high in the unsaturated zone above the capillary fringe and the phreatic surface is located at a sufficient depth. Fayer and Hillel (1986) suggest that some entrapped air will eventually escape, and some will remain in the soil profile, reducing saturation moisture content. However, it is possible that the brief increase in saturated zone pressure may be of sufficient magnitude to induce slope instabilities. Cloke et al. (2006) hypothesize that the increase in pore air pressure generates a downward transient air pressure wave that causes an increase in pore water pressure, which enables the formation of a continuous water phase in the capillary fringe (Theron and Lorentz, 2023). This event is discernible because there is an almost instant rise of the water level in an observation well, indicating the rapid transmission of antecedent water. Similar to GWR, this mechanism is dependent on certain variables, including whether rainfall intensity exceeds infiltration capacity (leading to ponding), ponding depth that prevents air from escaping and results in

compression in the unsaturated zone, pore size distribution, permeability that inhibits infiltration rates and pre-event water conditions (Theron, 2023).

Laboratory experiments

Similar to Waswa (2013), this study's experimental design included infiltration experiments in a tall sand column under controlled boundary conditions. After the application of artificial rainfall events, responses were recorded by automatic logging, and analyzed to determine the physical response of hydraulic state variables. The analysis of this data was used as an indication of the physical generation of transient pressure waves associated with water flow in an unsaturated soil medium (Theron, 2023).

Laboratory apparatus

Apart from the much larger scale of the laboratory experimentation, the 2.85 m high tall soil column, with an internal diameter of 600 mm, was set up similarly to studies conducted by Waswa (2013) and Salas-García et al. (2017). It was filled up to 2.65 m with a tailings substitute of similar physical properties and bulk density. Due to the intricate nature of physical and hydrological processes in the unsaturated zone, the column was fitted with sensing devices at seven data ports spaced 500, 600, 700, 800, 1,100, 1,400, and 1,700 mm from the bottom of the column. Each of the seven ports consisted of three different instruments that included a time domain reflectometry (TDR), a 1 bar mini-tensiometer (MT) and a 0.1 bar pore air pressure probe (PAPP) to measure pore air pressure (Theron, 2023). A drainage tube and piezometer were installed at a distance of 200 mm from the base of the pipe to discharge water and monitor the phreatic surface (Theron and Lorentz, 2023).

Sensor development

Volumetric water content (VWC) was measured by a custom-made time-domain reflectometry (TDR), shown in Figure 2. The probes consisted of three (5 mm ø) 200 mm long stainless-steel rods (50 mm c/c). A CR1000 Campbell Scientific data logger was used to store data through an SDMX50 Multiplexer and Campbell Scientific TDR100 wave generator. Matric suction was measured by means of purpose-made mini tensiometers that were fitted with 25 mm-long porous ceramic-cups (15 mm exposed) with an outer diameter of 6 mm (see Figure 3). The high-air-entry ceramic cup was joined to a rigid non-corrosive fiberglass tube (100 mm long, 6 mm outer ø, 3 mm inside ø). The other end was connected to a 1 bar Honeywell differential pressure transducer. The entire instrument was carefully filled with deaired water using a syringe, before insertion into the soil column. This was done to ensure equilibrium with the soil moisture content (Salas-Garcia et al., 2017). Once equilibrium was reached, the water in the mini-tensiometer was therefore also under negative pressure, similar to the porewater in the soil medium.

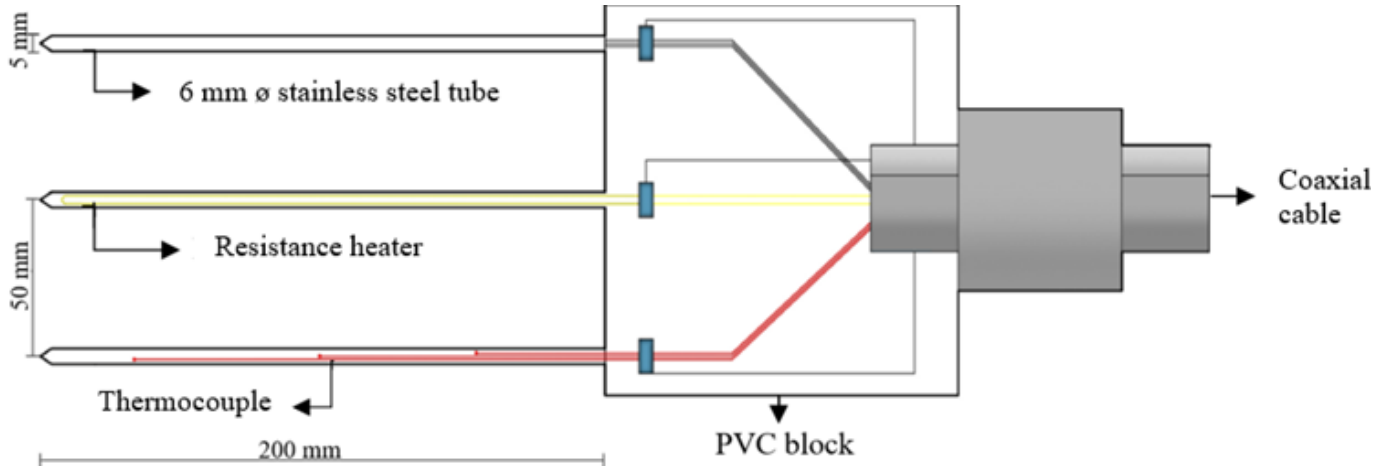

Figure 2: Custom-made TDR used to measure volumetric water content

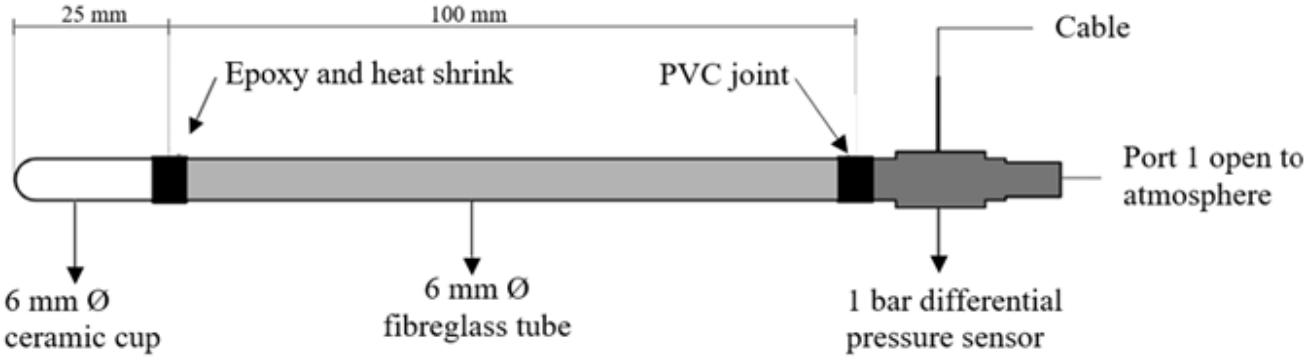

Figure 3: Custom-made mini tensiometer

Pore air pressure probes (PAPP) were used to measure pore air pressure. See Figure 4.

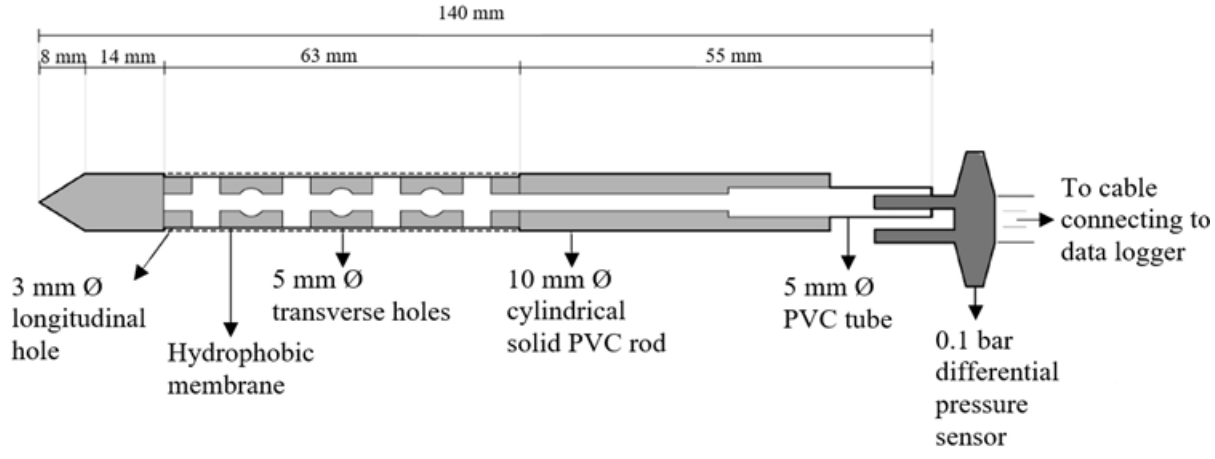

Figure 4: Custom made pore air pressure probe (modified from Waswa, 2013)

Experimental procedure

In order to draw comparisons with results obtained by Waswa (2013), a similar experimental procedure was followed. The sample was packed in a tall soil column in layers of 300 mm. Each layer was compacted at uniform bulk density to replicate that of tailings (Theron and Lorentz, 2023). Instrumentation was inserted through openings into the soil and sealed to prevent leakage and influence from external factors. After completion of the entire setup, water was introduced from the bottom of the column via the inlet valve, to avoid the entrapment of pore air (Waswa, 2013). Every care was taken to establish a constant water level at about 400 mm above the base where it remained constant, as indicated by the piezometer, for approximately 4 hours preceding each experiment. From the recorded data, the CF extended to about 200 to 300 mm above the water table. It was however not possible to determine the exact position of the water table, likely due to the soils' fineness and resulting high capillarity resulting in exaggerated levels of matric suction. Waswa (2013) also noted this concern and ascribed it to the fact that the zero-pressure line could rise above the CF.

The installation was left to reach equilibrium before application of three artificial rainfall events, each representing different return periods. Storm events 1:200, 1:100, and 1:50 years were selected to represent high intensity rainfall events that are likely to increase under future climate change conditions. Table 1 shows the calculation of ponding depth based on design storm data provided by Smithers and Schulze (2002). The setup allowed for continuous recording of data in 20-second intervals, allowing for the detailed analysis of both instantaneous and delayed responses.

Table 1: Description of incremental addition of water to tall soil column (Theron, 2023)

Event	Return period	Rainfall depth/h	Volume/h	Addition of water to tall soil column
1	1:200	84.1 mm	24 *l*	9 *l* over 30 min, 14 *l* over 15 min, 1 *l* over last 15 min
2	1:100	74.9 mm	21.2 *l*	8 *l* over 15 min and 13.2 *l* over 45 min
3	1:50	66.1 mm	18.7 *l*	7 *l* over 15 min and 11.7 *l* over 45 min

Although similar to Waswa's 2013 design, some alterations were made. The solid 140 mm long PVC rod (10 mm ø) was manufactured with a 3 mm ø hole drilled in the longitudinal center, together with seven 5 mm crosswise holes, drilled over 50 mm across the length. The length of the probe along which crosswise holes were made, was recessed and covered in a hydrophobic membrane that only enabled moisture to pass a high pressure while the flow of air is at low pressure (Waswa, 2013). The PAPP was connected to a differential pressure transducer, by means of a PVC tube, which in turn was eventually connected to a CR1000 Campbell Scientific Data Logger through a SDMX50 multiplexer.

Physical soil properties

With the purpose of producing an artificial substitute of tailings, physical characteristics were reproduced through the analysis of previous laboratory tests conducted by MacRobert and Blight (2013). The experimental material consisted of a concise mix of silica sand and silica dust and the particles were uniform in shape, clean and free of organic matter. The material is classified as a silty loam. Soil hydraulic parameters, such as hydraulic conductivity and water retention characteristics, were determined in the laboratory and were found to be similar to a known platinum tailings (Theron, 2023).

Observations

Each of the three artificial rainfall events exceeded the soil's infiltration capacity, which resulted in ponding, preventing the escape of air. This resulted in several rapid responses being recorded, but there were also a number of delayed responses. Ponding event 1 resulted in somewhat insignificant instant increases in pore air pressure at the four deep probes and was evident after the first two applications of event 1. The third application consisted of only one liter of water, which did not register any response. This finding highlights the significance of the intensity of rainfall events. With the exception of MT5, some minor changes (not shown) in pore water pressure were recorded 45 minutes after the start of the experiment. Since these changes were not caused by the arrival of the wetting front, tensiometric pore water pressure is likely to have responded to compressed pore air pressure.

Approximately seventy-three hours after the start of the experiment, the shallow TDRs recorded a slight response (see Figure 5). At the same time the deep PAPPs also registered significant changes, indicating the potential increase in pore air pressure, likely due to infiltration. In response, a simultaneous response in pore water pressure was measured in the unsaturated zone above the phreatic surface. From these results, it could be concluded that the magnitude of compressed pore air pressure has a direct impact on the extent to which groundwater levels will respond.

Similar observations were made by Waswa (2013) after analyzing responses during and after a high intensity rainfall event, that included a peak intensity of 228 mm/h that lasted 60 seconds. It resulted in the rapid response of tensiometric pore water pressure probes at different soil depths and a disproportionate rise of groundwater by 10.395 kPa (106 cmH_2O), not related to the arrival of the saturated front. Both these studies found a connection between the extent of compressed pore air pressure and the total change in pressure potential near the phreatic surface. According to Waswa (2013) the occurrence of compressed air ahead of the wetting front is indicative of the LE. It is suggested that the response of pore water pressure to compressed pore pressure is indicative of the presence of a pressure wave (Theron, 2023).

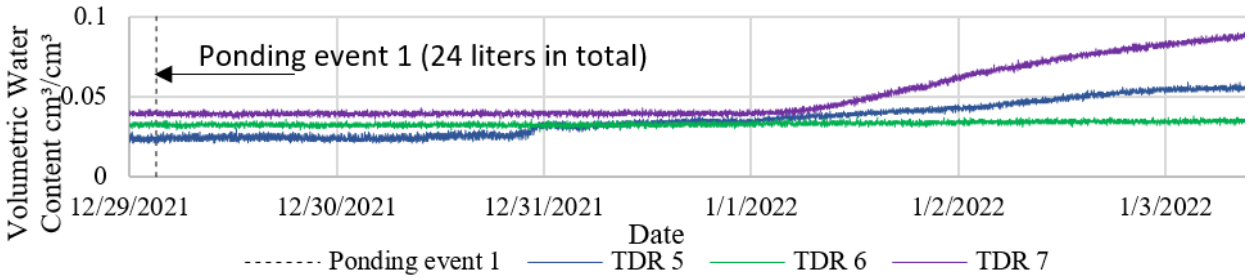

Figure 5: VWC observation before, during and after ponding event 1 (Theron, 2023)

The second infiltration test was carried out in the tall soil column after about nine weeks. The piezometric water level during the pre-simulation period of event 2 was again observed at about 400 to 500 mm from the base. The deepest TDRs indicated near saturated conditions, while TDR 4 was situated in the upper boundary of the capillary zone. After application of the second ponding event, there was an immediate change recorded at the three shallow probes. Responses at the four deep probes were measured shortly after but at less magnitude. Figure 6 shows the behavior before and after application with constant higher levels after application, resulting in VWC values that are substantially above the residual value.

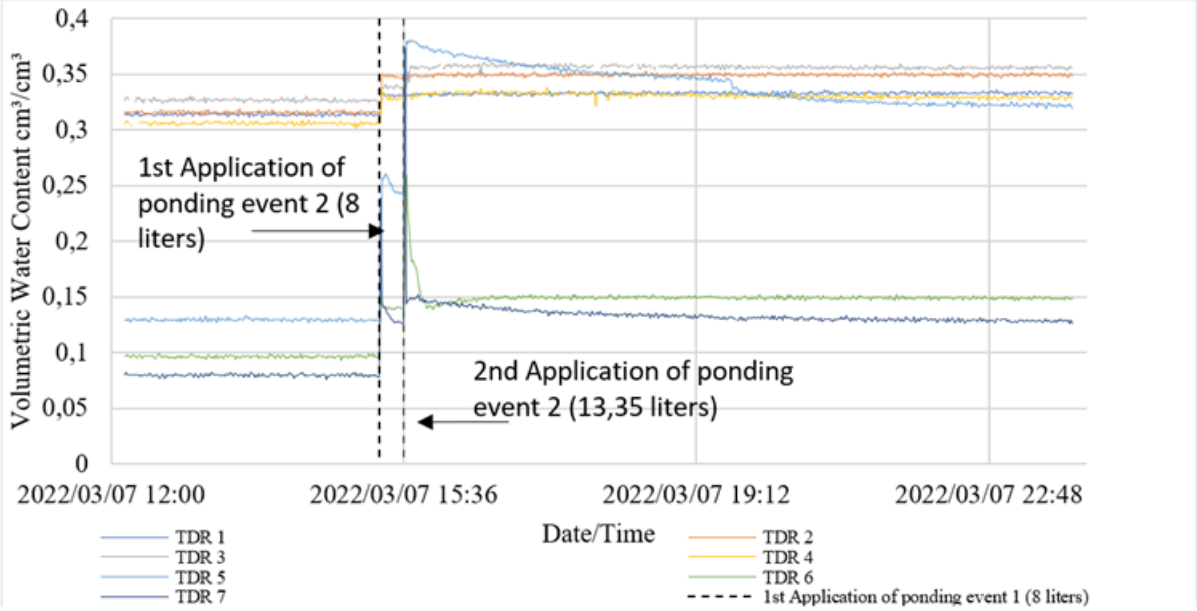

Figure 6: VWC observation before, during and after 1st and 2nd application of artificial rainfall event 2 (Theron, 2023)

Immediately following each application of ponding event 2, pore air pressure increased in relation to ponding depth. Application 1 of event 2 resulted in less ponding and pore air pressure increases at a maximum of 1.8 kPa. This is similar to Waswa's (2013) study that observed a 1.961 kPa change in pressure potential in fine soil within ten minutes of infiltration at the soil surface. The second application of 13.2 liters resulted in pore air pressure increasing instantly to a maximum of 10 kPa. In response, deep pore

water pressure sensors recorded several rapid as well as gradual declines. MT1 for instance showed an inverted spike at application 2 resulting in a 0.5 kPa change in tensiometric water pressure. MT4 also decreased rapidly from 70 kPa to 60 kPa. Both MT2 and MT3 declined gradually between 10 to 50 kPa.

Ponding event 3 consisted of the lowest simulated rainfall intensity. Even though there were no significant pressure changes observed in the unsaturated zone (therefore results are not shown), the three shallow TDRs showed similar results to event 2.

Interpretation of results

Shortly after the artificial rainfall event was administered to the soil surface, the majority of PAPPs, MTs, and TDRs responded. During event 1, the initial rapid response of pore air pressure probes is likely due to loading conditions after applications 1 and 2 (Theron, 2023). Although this resulted in small variations in pore water pressure, changes were insignificant. Observations further indicate that the significant (delayed) responses of deep pore air pressure probes were met with similar responses in deep pore water pressure probes. It is therefore suggested that the response recorded in the tensiometric pore water pressure was due to the change in compressed pore air pressure, as the saturation front advanced downwards into the soil profile. From the observations it was also evident that, as infiltration advanced, the magnitude of change in compressed pore air pressure also increased. This change transferred directly to the magnitude of change in pore water pressure. This is similar to the observed results interpreted by Waswa (2013), in which corresponding changes in pore water pressure were relative to compressed pore air pressure. The initial slow infiltration rates are attributed to the fine nature of the soil (not previously wetted) and the fact that eventual responses in pore water pressure were brought about by the advancing wetting front, compressed air pressure and the subsequent generation of transient pressure waves (Theron, 2023).

Both application 1 and 2 of ponding event 2 yielded rapid responses from most sensors. Of particular interest is the instantaneous increase in deep TDRs, indicating the rapid mobilization of pre-event water. Although Waswa (2013) confirmed VWC at the shallowest sensor to respond before arrival of the wetting front, this was only after 44 minutes from the start of the experiment, and therefore in contrast to the current study's findings. It should however be reiterated that these two studies have conducted analysis on different scales, which may have an influence on measured responses. Results do however coincide with infiltration tests conducted by Salas-Garcia et al. (2017), which found a sharp increase in water content at the shallow sensors within a few minutes after application. Similarly to the current study, VWC also decreased shortly after ponded infiltration stopped. Both studies found deep sensors to respond slower than top sensors and these responses were also at a lesser magnitude than changes recorded at shallow probes.

The magnitude of pore air pressure responses differed considerably between application 1 and 2 of ponding event 2. PAPP 2 for instance increased by almost 2 kPa after the application of 8 liters of water to

the soil surface, whereas the same sensor recorded an increase of almost 10 kPa after application of 13.3 liters. This illustrates the sensitivity of induced pressure head to rainfall intensity. Similarly to event 1, pore water responses at deep probes responded to the induction of compressed pore air pressure.

The last ponding event had the lowest rainfall intensity. It resulted in disparate yet insignificant fluctuations in pressure responses. Even though all TDRs recorded an instant increase, these were more rapid and of far greater magnitude at the shallow TDRs. Based on this, it is assumed that some degree of transient pressure wave generation caused responses at the deep probes, but that ponding depth was insufficient to trigger stable responses. These insignificant results in themselves support the premise of this study, i.e., that lower intensity rainfall events have less of an impact on the compression of pore air in the region of the CF, and thus are less inclined to impose pressure that results the diffusion of the injected energy through soil water.

Discussion

Although the wetting front did not reach the deep sensors, its downward approach brought about pressurized pore air in the unsaturated zone, which in turn resulted in a change in pore water pressure. It is recognized that the dynamic load applied to the soil surface could result in the tailings porous medium contracting, thereby generating excessive pore pressure. However, the delayed response of ponding event 1, demonstrated before arrival of the wetting front, suggests that transient air pressure waves contribute significantly to the generation of pore air propagation and a subsequent change in pore water pressure. It is therefore postulated that the gradual rise in pore air pressure at the deep probes is an indication of entrapped air and, as the wetting front approached, it compressed. The corresponding change in tensiometric pore water pressure, measured at the three deepest sensors, may be indicative of the formation of a distinct CF and rising phreatic surface, fed by groundwater and not due to infiltration. It is suggested that this may point towards the formation of an upward water pressure wave causing the water table to rise in response to a downward air pressure wave brought about by the descending wetting front.

It was also interesting to note that the magnitude of groundwater level responses showed a strong relationship with the magnitude of the compressed pore air pressure. In turn, it was found that the extent of pore air propagation was determined by the intensity of the rainfall event and points to the significance of energy injected into the tension saturation zone as the downward air pressure wave propagates towards the water table (WT). As it reached the WT, groundwater started to ascend as an upward water pressure wave. In contrast to Waswa (2013), and since the laboratory set up did not allow for the extension of the CF throughout the tall soil column, a continuous pore water phase was not found to be a prerequisite for GWR to occur. According to Waswa (2013), GWR is more likely to occur due to the energy of the rainfall event, whereas the LE is more likely to occur due to compressed pore air. It is suggested that responses observed

in the above laboratory experiments provide sufficient indicators pointing towards the presence of both these mechanisms.

Conclusion

The most noteworthy observation of the analysis is the change in pore water pressure above the water table brought about by the release of water held in tension to the phreatic surface. Since it occurs before arrival of the wetting front, this study has demonstrated the rapid mobilization of groundwater after the advancing wetting front compresses pore air in the vicinity of the CF, thereby increasing pressure between the wetting front and the phreatic surface. This finding is consistent with Waswa (2013), who showed these responses to manifest themselves in the form of either GWR or the LE.

Based on the results of laboratory analysis, it is suggested that transient pressure waves are generated by the intensity of a rainfall event as well as by the advancement of an approaching wetting front after infiltration. These pressure diffusion mechanisms cause an increase in the WT that changes groundwater pressure heads and matric suction, thereby reducing slope stability in partially saturated conditions. Waswa (2013) described comparable findings and suggested that pore air propagation and transient pressure wave generation contribute to slope instability in natural hillslopes. As a consequence, it is therefore probable that high intensity rainfall events also contribute to slope instability in tailings dams.

Abstract

A geochemical investigation was performed to support the development of a Groundwater Compliance Action Plan and the selection of a groundwater remedy for the United States Department of Energy Moab Uranium Mill Tailings Remedial Action (UMTRA) Project Site (Site). The objectives of the investigation were to identify sources of ammonia and uranium to groundwater and associated biogeochemical processes that contribute to natural attenuation of these contaminants. The investigation included soil and groundwater sampling and analysis, geochemical modeling, and laboratory column and batch reactor testing.

Groundwater redox conditions across the Site were found to be heterogenous and ranged from oxidizing to strongly reducing, resulting in attenuation of uranium via adsorption, association with iron and manganese (oxy)hydroxides, and precipitation of reduced mineral phases. Batch reactors provided evidence of biological ammonia oxidation (nitrification), rates of which are likely variable across the ammonia plume. A batch pore flushing model was used to estimate the time to achieve groundwater standards using column test data. Batch pore flushing model results indicated that the concentration target for the ammonia plume may be reached within one hundred years of natural flushing, while the uranium plume may require greater than one hundred years to reach concentration targets. Results of this investigation will support the development of a three-dimensional numerical groundwater fate and transport model that accounts for these geochemical processes and will improve the accuracy of remedial timeframe estimates.

Introduction

The Moab Uranium Mill Tailings Remedial Action (UMTRA) Project Site (Site), located in Moab, Utah, is a former uranium-ore processing facility where production ended in 1984. The United States Department of Energy Office of Environmental Management (DOE-EM) is responsible for remediating the site to meet 40 Code of Federal Regulations (CFR) 192 standards promulgated by the United States Environmental Protection Agency under the authority of the Nuclear Regulatory Commission (NRC). Tailings from the former mill were stored in an unlined impoundment (tailings pile), totaling 16 million tons of waste material. Surface cleanup has been ongoing since 2009 and consists of removal and transport of tailings via rail to an off-site disposal facility, with an estimated completion date around 2029.

Gravity-driven migration of tailings fluids and recharge through the tailings pile and former on-site ore storage areas in the northeastern part of the site led to contamination of site soil and groundwater. The primary contaminants of concern are ammonia, which was present in fluids used in the milling process (DOE, 2003), and uranium. An interim groundwater remedy is currently in place that utilizes a system of extraction and injection wells to prevent discharge of contaminated groundwater into the nearby Colorado River. Once surface cleanup concludes and the tailings pile is removed, a formal groundwater remedy must be selected and documented in a Groundwater Compliance Action Plan (GCAP). Under Title 1 of the Uranium Mill Tailings Radiation Control Act, natural flushing (i.e., monitored natural attenuation), may be selected as the groundwater remedy if it can be demonstrated that the remedy will achieve groundwater standards within one hundred years. The 40 CFR 192 groundwater standard for uranium is 44 micrograms per liter (µg/L), and the target groundwater concentration of ammonia based on adverse effects on local fish species is 3 milligrams per liter (mg/L).

A collaboration with Geosyntec Consultants, Inc. (Geosyntec), the Moab UMTRA Project team, the DOE Office of Legacy Management, the DOE-EM, and the Network of National Laboratories for Environmental Management and Stewardship was held in 2022 with the goal of generating actionable recommendations to develop a GCAP for the Site. The primary recommendation was development of a groundwater fate and transport model to predict the remedial timeframe under various groundwater remedies. This paper presents the results of soil and groundwater sampling, geochemical modeling, and laboratory column and batch reactor testing that will be used to parameterize a numerical model for estimating the remedial timeframe under various scenarios, including natural flushing.

Soil and groundwater collection

Soil and groundwater samples were collected from six temporary boreholes that were advanced using a track-mounted sonic rig. Borehole locations were identified based on existing data to target areas with

variable uranium and ammonia concentrations (Figure 1). Freshwater in the unconfined alluvial aquifer is underlain by a brine zone that varies seasonally in elevation but is often encountered at approximately 55 feet below ground surface (bgs) (DOE, 2003). Soil and groundwater collection targeted the vadose and freshwater saturated zones. At the Site, total dissolved solids (TDS) concentrations below 35,000 mg/L are considered to be in the freshwater zone.

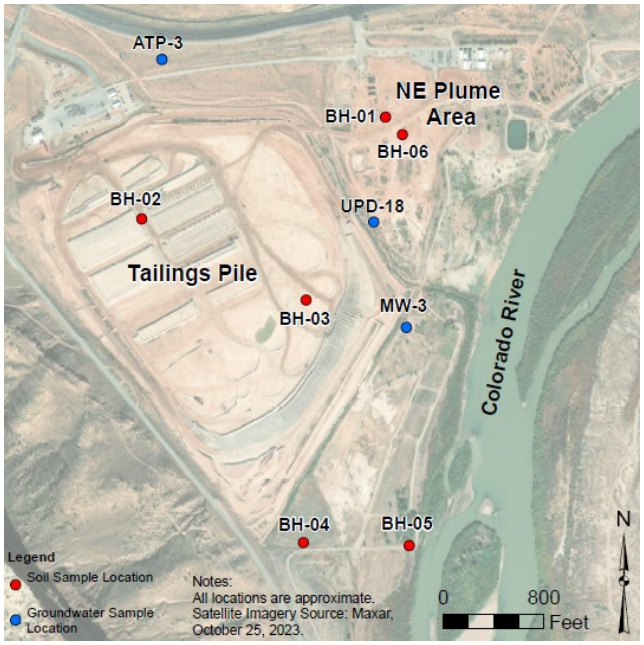

Figure 1: Site layout and soil and groundwater sampling locations

Soil collection and analysis

Soil was inspected, logged, and sampled as boreholes were advanced to a maximum of 60 feet bgs. Soil samples were collected at four depths within each boring to target the top and bottom of the vadose and freshwater saturated zones. Soil samples were shipped to GEL Laboratories of Charleston, South Carolina, for analytical characterization and Hazen Research of Golden, Colorado, for solid-phase extraction analysis and column testing.

Solid-phase extractions were performed on vadose and saturated zone soil samples to quantify the fraction of solid-phase uranium that has the potential to mobilize to groundwater. The solid-phase extractions consisted of sequentially exposing soil samples to four extraction solutions, each of which targeted a specific fraction of solid-associated uranium. The four-step sequential extraction procedure was based on the Tessier extraction method for trace metals (Tessier et al., 1979) and modified to target solid-associated uranium species based on the geochemical behavior of uranium (Salome et al., 2017). Step 1 targeted weakly sorbed/exchanged uranium; Step 2 targeted strongly sorbed/weak acid extractable uranium associated with carbonate minerals; Step 3 targeted uranium associated with iron and manganese

(oxy)hydroxide minerals; and Step 4 targeted uranium phosphate minerals and recalcitrant fractions. Reduced uranium minerals were likely extracted during Step 1 because the solution was oxic.

Groundwater collection and analysis

One grab groundwater sample was collected from the upper freshwater saturated zone at each borehole for analytical characterization. Additional bulk groundwater samples were collected from three existing monitoring wells for column and batch reactor testing (Figure 1). Bulk groundwater collected from ATP-3, located upgradient of the tailings pile, was used as influent for the column tests. Bulk groundwater samples from UPD-18 and MW-3, located downgradient of the tailings pile, were used for batch reactor testing. Groundwater samples were collected using a bladder pump or disposable bailer and shipped to GEL Laboratories of Charleston, South Carolina, for analytical characterization and Hazen Research of Golden, Colorado, for batch reactor testing.

Soil analytical results

Soil uranium concentrations ranged from 0.580 milligrams per kilogram (mg/kg) to 9.80 mg/kg and were moderately to strongly correlated with iron and manganese at some locations (r^2=0.57 to 0.93 and 0.52 to 0.79, respectively) when soil results were analyzed at individual borings, consistent with sequestration of uranium via adsorption to, or co-precipitation within, iron and manganese (oxy)hydroxide minerals. Uranium concentrations in soil samples were also strongly correlated to soil phosphorus concentrations at some borings (r^2=0.66 to 0.98). Geochemical modeling results indicate that uranyl phosphate minerals are undersaturated in Site groundwater (discussed below), and therefore, strong correlations between uranium and phosphorus are more likely to reflect the affinity of the phosphate and uranyl ions for adsorption onto iron (oxy)hydroxide minerals rather than evidence of precipitation of uranyl phosphate minerals.

Solid-phase sequential extraction results indicate that approximately 30% of solid-phase uranium was weakly adsorbed or reduced (Step 1); 30% of uranium was strongly adsorbed (Step 2); 25% of uranium was associated with iron and manganese (oxy)hydroxides (Step 3); and 15% of uranium was recalcitrant (Step 4). The percentage of uranium in the adsorbed fraction (approximately 60% in Steps 1 and 2 combined) was similar between the vadose and saturated zones. This fraction of uranium could mobilize via desorption during recharge through the vadose zone or inflow of background groundwater through the saturated zone. Iron- and manganese-associated uranium (Step 3) is less likely to mobilize to groundwater than adsorbed uranium because it would require dissolution of iron and manganese (oxy)hydroxides, which typically occurs under reducing conditions. Uranium is typically less mobile under reducing conditions because it tends to precipitate as insoluble reduced uranium minerals, such as uraninite. The fraction of uranium extracted during Step 4 (recalcitrant) is unlikely to mobilize to groundwater under current and

future site conditions. The average percentage of potentially mobile uranium (Steps 1 through 3) across all samples was 86%, with averages for individual boreholes ranging from 44% to 100%.

Soil ammonia concentrations at the Site ranged from approximately 1 mg/kg to 300 mg/kg. On average, the highest soil ammonia concentrations were beneath and downgradient of the tailings pile (BH-03, -04, and -05), consistent with the tailings pile as the primary source of ammonia to soil and groundwater.

Groundwater analytical results

TDS concentrations of groundwater samples ranged from approximately 1,000 to 31,200 mg/L and were less than 35,000 mg/L, confirming that samples were collected from the freshwater zone. Sodium and chloride were the most abundant cation and anion, respectively. Groundwater pH was circumneutral, ranging from 7.03 to 7.96. Dissolved oxygen (DO), oxidation-reduction potential (ORP), and redox indicator species, including nitrate/nitrite, dissolved iron, dissolved manganese, and sulfate, indicated that redox conditions varied across the Site from oxidizing to strongly reducing. Oxidizing conditions were observed at BH-04, ATP-3, UPD-18, and MW-3. Reducing conditions were observed in the northeastern plume area of the Site (BH-01 and BH-06) and at BH-03 and BH-05. Low concentrations of dissolved iron and sulfate at BH-01 and BH-06, combined with the other indicators of reducing conditions, suggest that sulfate reduction and formation of iron sulfide minerals were likely occurring at these locations.

Phosphate was measured in groundwater samples due to its importance for sequestering uranium as uranium-phosphate minerals. Phosphate concentrations were not detected in groundwater samples above the reporting limits (0.400 to 10.0 mg/L). Total organic carbon concentrations ranged from 1.85 to 17.9 mg/L, suggesting that sufficient organic carbon is available to support microbial transformations of uranium and ammonia (e.g., nitrification of ammonia, bioreduction of uranium) where redox conditions are suitable for those processes to occur. Groundwater uranium concentrations ranged from 3.57 to 3,480 µg/L and were not proportional to soil uranium concentrations, consistent with results of past site investigations (DOE, 2012) and indicating that geochemical processes besides adsorption are likely contributing to uranium sequestration in soil. Boring locations with the highest groundwater uranium concentrations also had the most oxidizing conditions. In contrast, borings with the lowest groundwater uranium concentrations had the most reducing geochemical conditions.

Precipitation of uranium and ammonia minerals

The Geochemist's Workbench® (GWB®) software package with the Minteq thermodynamic database (thermo_minteq.dat) was used to evaluate the likelihood of uranium and ammonia mineral precipitation in the freshwater saturated zone. Uranium and ammonia minerals were undersaturated in the groundwater samples, suggesting their formation is unlikely. To further evaluate the precipitation of uranium and

ammonia minerals, solubility diagrams were generated in GWB®. Groundwater uranium concentrations were less than the solubility of rutherfordine, UO_2OH_2 (beta), and schoepite, the least soluble uranyl minerals under Site conditions, indicating that formation of these phases is unlikely. The high ionic strength of Site groundwater increases mineral solubility and likely prevents precipitation of these phases. Although phosphate was not detected above the laboratory reporting limit in the groundwater samples, the impact of phosphate on uranium mineral saturation was evaluated. Groundwater uranium concentrations were less than the solubility of uramphite, Na-autunite, and K-autunite, the most insoluble uranyl phosphate minerals under site conditions, when phosphate concentrations were equal to the laboratory reporting limits (0.4 to 10 mg/L), indicating the formation of these phases in Site soil is unlikely.

Groundwater samples were plotted on a Pourbaix diagram (redox potential versus pH) of uranium speciation generated in GWB® using the groundwater composition at BH-02 to evaluate the potential for precipitation of reduced uranium minerals (Figure 2). Locations with strongly reducing conditions (BH-01, BH-03, BH-05, and BH-06) plotted within or near the stability field of uraninite, indicating that geochemical conditions at these locations are sufficiently reducing to support uraninite formation.

Column testing setup and results

The primary objectives of column testing were to (1) estimate the number of pore volumes of groundwater to be flushed through Site soil to reach target groundwater concentrations of uranium and ammonia and (2)

quantify cation exchange/absorption processes for uranium and ammonia for use in a future groundwater fate and transport model. The column test included operation of 12 columns—one column for each saturated zone soil sample collected from each boring. The columns were constructed from polyvinylchloride (PVC) with dimensions of 3 inches in diameter and 20 inches in length. PVC endcaps held the soil in place within the column. Tubing was connected to each end of the column through a hole drilled in each end cap. Tubing delivered influent to the bottom of the column and collected effluent from the top end of the column.

Saturated zone soil collected from the Site served as the media within the columns. Bulk saturated soil samples were homogenized prior to loading the columns with soil. Approximately one inch of clean sand was emplaced below and above the soil within the column to ensure even distribution of the influent across the diameter of the column and to prevent soil particles from exiting the column. Columns were tapped and swirled during loading to minimize formation of void spaces and preferential pathways.

The columns were operated for at least 28 days, representing approximately 165 years of groundwater flow through the Site based on the groundwater flow rate (approximately 0.17 pore volumes per year) and the flow rate through the columns (approximately 1 pore volume per day [PV/day]). Background groundwater from ATP-3 with a low uranium concentration (3.57 µg/L uranium) served as the column influent. Influent was pumped through each column in an up-flow direction with an average flow rate of 1.4 PV/day. Column influent and effluent were periodically sampled during the column test and analyzed for pH, DO, ORP, conductivity, and dissolved (0.45 µm filtered) uranium, ammonia, and alkalinity. For five days during the test, column influent was amended with bromide (41 mg/L), and bromide was measured in the column effluent. Bromide breakthrough curves were fitted with the Domenico analytical model (Domenico 1987) to calculate the flow rate and effective pore volume of each column. Effluent from each column was collected for the duration of the column test, weighed to determine the volume, and analyzed for uranium and ammonia to calculate the mass of each that was leached from column soil.

The column influent composition remained stable throughout the duration of the column tests and was representative of background Site groundwater. Column influent pH was circumneutral, with values ranging from 7.76 to 7.94. Influent groundwater was oxidizing, indicated by high ORP (>200 mV) and DO concentrations (>9 mg/L).

Effluent pH generally ranged from 7.6 to 8.6, and effluent DO concentrations were lower than the influent concentration. Effluent ORP values were initially lower than the influent value, then increased to the influent value over the course of the column test. These results indicate that the soil within the columns is more reducing than the influent groundwater, consistent with reducing conditions observed in some areas of Site groundwater. Effluent uranium concentrations exceeded the influent concentrations at all 12 columns, consistent with leaching of solid-phase uranium from Site soil as background groundwater flushes through uranium-impacted soil. Maximum uranium effluent concentrations ranged from 13 to 340 µg/L

and were strongly correlated with concentrations of total uranium ($r^2 = 0.84$) and adsorbed (sum of Steps 1 and 2 of the sequential extraction, $r^2 = 0.73$) uranium in column soil.

Maximum effluent uranium concentrations for each column were often measured in the second or third effluent sample, suggesting the rate of uranium desorption from Site soil is kinetically limited or other geochemical processes besides desorption are involved in uranium mobilization. Column effluent uranium concentrations were less than recent groundwater uranium concentrations measured at the site (up to 7 mg/L, DOE 2023), indicating that solid-associated uranium is not the only source of uranium to groundwater. Additional sources of uranium to groundwater include tailing fluids and solid-associated uranium in the vadose zone that can mobilize during groundwater table fluctuations or precipitation events. Once the maximum effluent uranium concentration was achieved, concentrations generally declined to a steady state or below the reporting limit (1 µg/L), consistent with an initial flushing of uranium from the column soil and attenuation of uranium over time. Effluent uranium concentrations did not exceed the groundwater standard at the deeper BH-01, BH-03, and BH-06 columns and the shallow BH-04 column. Effluent uranium concentrations exceeded the 40 CFR 192 groundwater standard of 44 µg/L in the remaining 8, and effluent concentrations in 7 of those columns were below the groundwater standard by the end of the test. The effluent uranium concentration of the shallow BH-05 column remained below the groundwater standard until 21.1 pore volumes, when it increased in the final effluent sample. The delayed increase in uranium coincided with a gradual increase of ORP in the column. The number of pore volumes pumped through the columns to achieve the groundwater standard ranged from 6.3 to 34.5.

The percentage of total uranium leached from the soil within each column ranged from 4.6% to 51%, and the percentage of adsorbed uranium leached from the soil within each column (sum of Steps 1 and 2 of the sequential extraction test), ranged from 7.6% to 71%. These results are consistent with the solid-phase extraction results which demonstrated that some solid-phase uranium is unlikely to mobilize to groundwater during flushing of background groundwater through the saturated zone.

Effluent ammonia concentrations were relatively stable during the column test; however, the majority of effluent ammonia concentrations were not detected above the laboratory reporting limit (1 to 10 mg/L). Column effluent ammonia concentrations were far below recent concentrations in Site groundwater (up to around 450 mg/L, DOE 2023), indicating that tailing fluids likely contribute to elevated ammonia concentrations recently observed in Site groundwater.

Batch reactor testing setup and results

The primary objective of batch reactor testing was to evaluate whether biological degradation of ammonia (nitrification) is occurring in groundwater at the Site. The batch reactor test used groundwater collected from two monitoring wells (MW-3 and UPD-18) and included operating duplicate live reactors and one

control reactor per location. Glass bottles served as the batch reactors, and Site groundwater served as the batch reactor medium. Batch reactors were periodically sparged with air during operation so the reactors remained oxic, a requirement for nitrification. Prior to beginning the batch test, the control reactors were sterilized in a 90 °C hot water bath for 2 hours. The reactors operated for 3 weeks and were agitated throughout the test using a shaker table. Batch reactors were sampled weekly and analyzed for pH, ORP, DO, conductivity, ammonia, nitrate, and nitrite.

Strong evidence of nitrification was observed in the UPD-18 live reactors. Over the course of the test, ammonia concentrations decreased, while nitrate concentrations simultaneously increased (Figure 3). Concentrations of nitrite, a transient nitrification intermediate, fluctuated and ultimately decreased by the end of the test. Ammonia concentrations in the control reactors remained relatively stable at the initial concentration. Changes in the average nitrogen species concentrations over the course of the test confirmed stoichiometric consumption of ammonia and nitrite and production of nitrate, indicative of nitrification. Evidence of nitrification was not observed in the MW-3 live reactors; ammonia concentrations decreased slightly during the test, but nitrate concentrations remained relatively constant at the initial concentration.

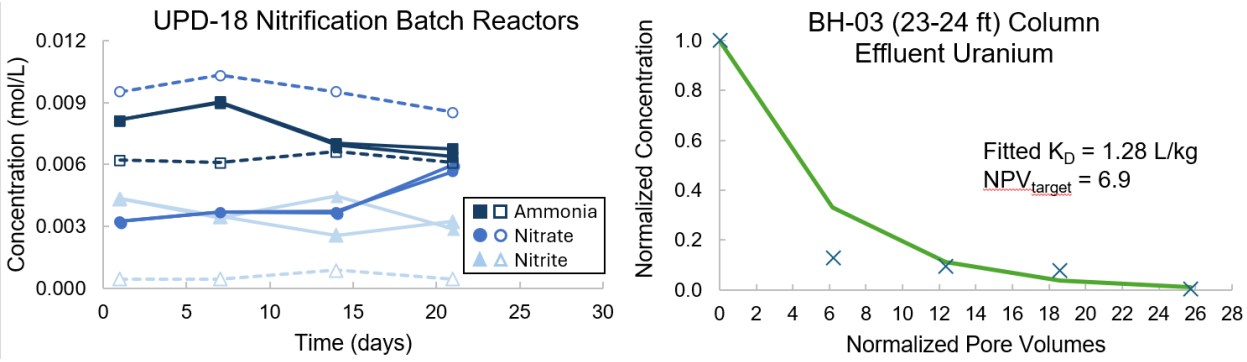

Figure 3: Left: time series of nitrogen species in duplicate live reactors (solid lines) and abiotic control reactors (dashed lines) containing groundwater from UPD-18. Right: time series of normalized effluent uranium concentrations in the BH-03 (23-24 feet bgs) column. The batch pore flushing model (green line) was fitted to the data by adjusting the value of K_d in Equation 1

Results of the batch reactor test are consistent with higher concentrations of oxidized nitrogen species (nitrate and nitrite) in the groundwater sample collected at UPD-18 (57.5 mg/L) compared to MW-3 (21.5 mg/L). These results also indicate that the degree of nitrification may vary across the ammonia plume. Although groundwater at UPD-18 and MW-3 is geochemically oxidizing with circumneutral pH and detectable concentrations of DO, nitrification was only observed at UPD-18 during the batch reactor test. Variable rates of nitrification across the Site could be due to the distribution of nitrifying bacteria in groundwater, which was not evaluated in this study.

Batch pore flushing modeling

The batch pore flushing model is an analytical model used to estimate the remediation timeframe for flushing clean water through a defined volume (Antelmi et al., 2020). Contaminant transport is assumed to be dominated by advection and linear sorption processes with negligible dispersion. For this analysis, the batch pore flushing model was first fit to the column test effluent uranium data to estimate the soil partitioning coefficient (K_d) and to calculate the number of pore volumes flushed to reach the 40 CFR 192 groundwater standard of 44 µg/L (Figure 3). Insufficient detections of ammonia in the column effluent data prevented calculation of K_d for ammonia. Next, a plume-scale batch pore flushing model was used with the average K_d for uranium derived from the column tests and a previous estimate of the K_d for ammonia (0.5 L/kg, DOE 2003) to estimate the remediation timeframe for natural flushing of uranium and ammonia.

The batch pore flushing model concentrations were calculated using Equation 1, where C is contaminant concentration at time, t; C_0 is the initial concentration, NPV is the number of pore volumes at time, t; R is the retardation factor; Q is the flowrate through the column; PV is the pore volume of column, derived from bromide tracer test; ρ_b is the bulk density of soil in column, calculated as the dry mass of soil divided by the volume of soil in the column; n_e is the effective porosity, derived from bromide tracer test; and K_d is the soil partitioning coefficient.

$$\frac{C}{C_0} = e^{\frac{-NPV}{R}} = e^{\frac{-Q*t/PV}{1+(\rho_b \times K_d/n_e)}} \quad \text{(Equation 1)}$$

C, C_0, Q, and ρ_b were measured for each column, and n_e and PV were derived from the bromide tracer test for each column. K_d is the only unknown and was varied to fit the model to the normalized measured effluent concentration data. The Excel solver tool was used to minimize the sum of the squared residuals between the measured and calculated normalized uranium concentrations by varying the values for K_d.

For columns with effluent concentrations exceeding the 40 CFR 192 groundwater uranium standard of 44 µg/L, the number of pore volumes flushed to reach the groundwater standard (NPV_{target}) was calculated using Equation 2, where R is the retardation factor, $R = 1 + \frac{\rho_b + K_d}{n_e}$, C_f is the target concentration, and C_0 is the initial concentration.

$$NPV_{target} = -R \times ln\left(\frac{C_f}{C_0}\right) \quad \text{(Equation 2)}$$

The fitted K_d values for each column ranged from 0.99 to 7.45 liters per kilogram (L/kg), with an average of 3.62 L/kg. The range for the six columns with effluent concentrations greater than the uranium groundwater standard is from 0.99 to 2.75 L/kg, with an average K_d of 1.71 L/kg. The average K_d for the columns with lower effluent concentrations is 6.14 L/kg. This suggests that sorption is nonlinear over the entire concentration range at the Site, and at lower concentrations (below the 40 CFR 192 groundwater standard) uranium may be more tightly sorbed to solids. This observation also indicates that the estimated

K_d of 1.71 L/kg may be representative of the low concentration plume area (average concentration of 0.29 mg/L), but the column test results may not be representative of the sorption coefficient for the high concentration plume area (average concentration of 1.8 mg/L). Based on the batch pore flushing model, the calculated number of pore volumes to achieve the 40 CFR 192 groundwater standard in each column ranged from 5.2 to 19.8 with an average of 14.3 pore volumes.

The plume-scale batch pore flushing model used the same equations as described above, but the parameters were based on the groundwater plume. For example, one pore volume is defined by the plume extent, and the flow rate is the estimated natural flushing rate through the plume (Antelmi et al., 2020). The plume-scale model results using parameters derived from the column tests show that proposed groundwater standards may be reached under natural flushing conditions within one hundred years for the ammonia plume, but longer than one hundred years may be required for the uranium plume. The plume-scale model indicates the proposed groundwater standard of 3 mg/L for ammonia may be reached in 50 years for expected natural flushing flow rates (140 gallons per minute [gpm]) and 58 years for the lowest estimated natural flushing flow rate (70 gpm). These estimates assume that ammonia biodegradation is occurring uniformly across the plume at a consistent average rate. The plume-scale batch pore flushing model indicates that achieving the target cleanup concentration for uranium may require more than one hundred years under natural flushing conditions. For expected natural flushing flow rates (190 gpm) through the high concentration portion of the plume, the estimated predicted remediation timeframe is 180 years. The estimated predicted remediation timeframe for the low concentration portion of the plume is at least 110 years. However, because of the complex processes associated with uranium transport, there is high uncertainty in the plume-scale batch pore flushing model estimates for uranium. The batch pore flushing model does not account for other relevant geochemical processes that have been identified in this investigation, including variable redox conditions, mineral precipitation, and nonlinear sorption. The model also does not account for heterogeneous hydrogeological conditions at the Site.

Conclusion

Groundwater redox conditions across the Site were heterogenous and ranged from oxidizing to strongly reducing. The primary mechanism of uranium sequestration at sampling locations with oxidizing geochemical conditions was adsorption to iron and manganese (oxy)hydroxides. Co-precipitation of uranium with metal (oxy)hydroxides was a secondary mechanism of sequestration. Precipitation of oxidized uranium minerals (e.g., uranyl phosphates) at the sampling locations is unlikely due to the high ionic strength and low phosphate concentrations of Site groundwater. At sampling locations with reducing geochemical conditions, the dominant mechanisms of uranium sequestration included adsorption of uranium to iron and manganese (oxy)hydroxides, co-precipitation of uranium with metal (oxy)hydroxides,

and precipitation of reduced uranium minerals (e.g., uraninite). On average, 63% of solid-phase uranium was adsorbed or reduced, 23% of solid-phase uranium was associated with iron and manganese (oxy)hydroxides, and 14% of solid-phase uranium was recalcitrant and unlikely to mobilize to groundwater under naturally occurring geochemical conditions. The primary mechanism of ammonia sequestration at sampling locations with oxidizing and reducing geochemical conditions was adsorption/cation exchange. Evidence of nitrification was observed in one reactor, and therefore, nitrification may be contributing to attenuation of ammonia in groundwater, but at variable rates within the groundwater ammonia plume.

Based on the batch pore flushing model fits of the column testing results, the calculated number of pore volumes to achieve the groundwater uranium standard was between 5 and 20 pore volumes (with an average of 14 pore volumes). The updated plume-scale batch pore flushing model results show that groundwater standards may be achieved under natural flushing conditions within one hundred years for the ammonia plume, but longer than one hundred years may be needed for the uranium plume. The plume-scale batch pore flushing model does not account for the complex uranium geochemical processes identified during this investigation or for heterogeneous hydrogeological conditions. Results of this investigation support development of a three-dimensional numerical groundwater fate and transport model that accounts for these geochemical processes in order to improve the accuracy of remedial timeframe estimates.

Critical Seepage Analyses for Stability of Tailings Dams

Dobroslav Znidarcic, University of Colorado, USA
Gordan Gjerapic, University of Colorado, USA
David Rees Gillette, Independent Consultant, USA

Abstract

The instability and catastrophic failures of tailings dams are caused by the presence of water, irrespective of the triggering mechanism. The most significant sources of water in tailings impoundments are water inflows brought into the impoundment during the deposition process and precipitation inflows (rain and snowmelt). Other sources of water such as inflows from different mine facilities, run-on, and potential inflows from antecedent seeps are typically less significant during standard operating conditions but may play a significant role during extreme events. Upon deposition, the pore water seeps through the impoundment and the tailings dam under the hydraulic gradients induced by gravity and any additional loading. While seepage analyses are often conducted for the purpose of calculating water balance, especially during filling operations, the seepage impact on the stability of tailings dams is frequently evaluated using only simplified methods, and without paying adequate attention to details of the underlying flow mechanisms.

This paper explores the effects of anisotropy and the presence of unsaturated zones on the stability of a tailings dam. It demonstrates that the commonly employed assumption of a linear piezometric line may lead to underestimated pore pressures on critical failure surfaces, especially in the zone near the downstream slope of the dam, which is essential for maintaining dam stability. In addition to the steady state analyses, the transient process of pore water infiltration into the previously unsaturated ("dry") regions of the tailings dam is modeled to evaluate the time required for the seepage from the pool area of the impoundment to reach the downstream slope of the dam.

The results highlight the need for realistic, problem-specific seepage analyses to be carried out throughout different stages of the impoundment life, including deposition, and closure and post-closure, to provide a realistic estimate of the tailings dam performance.

Introduction

Catastrophic failures of tailings dams are almost always facilitated or caused by the presence of water within

the tailings. The water is brought to the impoundment during deposition, with rainfall and snowmelt, and from run-on and any seeps existing in and around the impoundment. The recent paper by Reid and Fourie (2024) summarizes the results of a tailings slope stability comparative design ("round robin") exercise that focused on changes in the slope stability as the linear phreatic surface moves from its initial location (with the gradient/inclination of 9.2H:1V) to the ultimate inclination of 3H:1V parallel to the downstream slope. For simplicity, the "phreatic line" and the "piezometric line" are used synonymously in this paper. In geotechnical literature, it is customary to use the "phreatic line" as a "top" flow line and/or boundary between saturated and unsaturated zones, while the "piezometric line" is commonly used to denote the pressure head on the failure surface. The focus of the round robin exercise by Reid and Fourie (2024) was the selection of shear strength parameters for the tailings and the method of stability analysis. The selected linear piezometric lines in the exercise were consistent with the commonly employed approach in engineering practice; however, this linearization approach often fails to capture impacts of various seepage scenarios that are critical for the stability of tailings dams (see for example Gjerapic and Znidarcic, 2020 and Gjerapic et al., 2022). Hence, the focus of this paper is to demonstrate the importance of seepage analyses and the associated hydraulic conditions in evaluating critical scenarios for the stability of tailings dams.

Tailings densities and strength parameters used in this paper were selected based on the range reported by Reid and Fourie (2024) in their round robin stability exercise, while considering tailings properties reported for the recent failures of tailings storage facilities, see Morgenstern et al. (2016), Jefferies et al. (2019) and Robertson et al. (2019). The hypothetical tailings dam geometry from Reid and Fourie (2024) and the adopted parameters were chosen to correspond to the factor of safety (FoS) of 1.5 for the initial conditions in Figure 1. In addition to this baseline scenario, a set of seepage scenarios was chosen to demonstrate that the risks to tailings stability need to be evaluated by considering both geomechanical and hydraulic conditions, while bearing in mind that a careful consideration of seepage conditions may prove to be sufficient to indicate potential instability of the tailings dam, sometimes even without the need to conduct the corresponding stability analyses.

Figure 1 presents the selected hypothetical geometry for the analyses with three potential failure surfaces that are selected in this paper to evaluate the change in the FoS as the seepage conditions change. The deep-seated failure surface S1 in Figure 1 is the critical failure surface for the initial piezometric line when the shear strength below the piezometric line is given by $s_u/\sigma'_v=0.25$ and the shear strength above the line is given by $\phi'=36°$. The FoS of 1.5 for these baseline conditions indicates that the tailings dam is considered stable based on standards in current engineering practice. The other two shallower failure surfaces are selected to evaluate seepage effects on the general stability of the tailings dam (S2) and the toe stability (S3) as the seepage approaches the downstream slope of the dam.

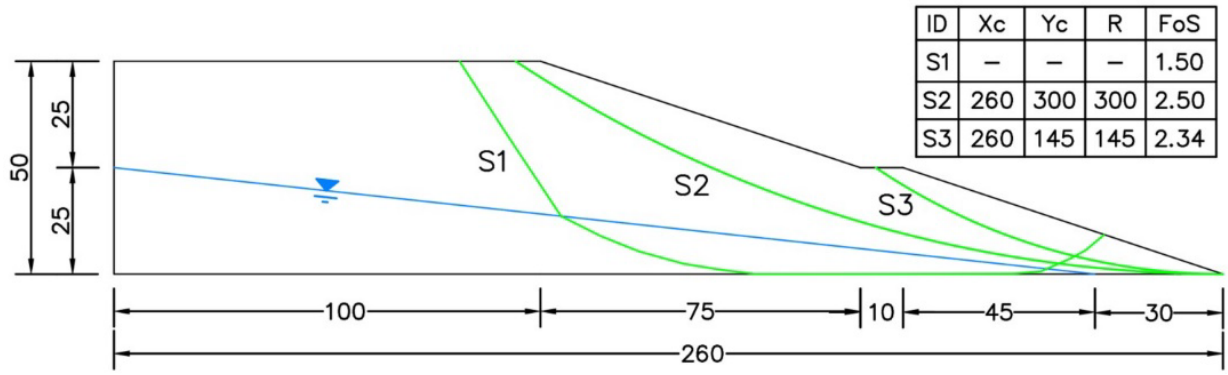

Figure 1: Geometry selected for the analyses with the initial linear piezometric line and the potential failure surfaces (based on Reid and Fourie, 2024)

A selected set of seepage scenarios in this paper was chosen to demonstrate flow conditions that could lead to compromised stability of tailings dams while neglecting a variety of other factors (e.g., the effects of earthquakes or depositional loading). The selected seepage scenarios explore stability impacts of the hydraulic conductivity anisotropy and the effects of re-saturation of tailings material along the wetting path under transient flow conditions. The effects of external seeps (e.g., perennial or seasonal inflows from antecedent sources) and rainwater/snow melt infiltration are not considered explicitly; however, these effects always warrant careful consideration when evaluating the stability of tailings dams.

Seepage scenarios

The seepage analyses in this paper were conducted using Slide2 (Rocscience, 2024) software because its groundwater module allows for the treatment of both saturated and unsaturated conditions, as well as the treatment of steady state and transient flow (e.g., the finite element groundwater module in Slide 2 can be used to model infiltration into initially unsaturated tailings zones). For all seepage analyses, it is assumed that the hypothetical tailings dam is resting on an impervious base, with the exception of the last 30 m at the downstream toe where a drainage layer is assumed, and that the pressure head is set to zero along that part of the bottom boundary (see Figure 1). On the left-hand side, 260 m behind the toe, a constant head boundary is assumed with two water levels and the hydrostatic pressure head distributions below the water levels. The top and downstream slope are assumed to be impervious (no water infiltration) except when the phreatic line reaches the boundaries, a zero-pressure head is imposed to allow for the seeping water to exit the domain.

Figures 2 presents the total head distributions and the associated phreatic surface for isotropic conditions (K_h=K_v) assuming the maximum water elevation of 25 m at the left-hand boundary.

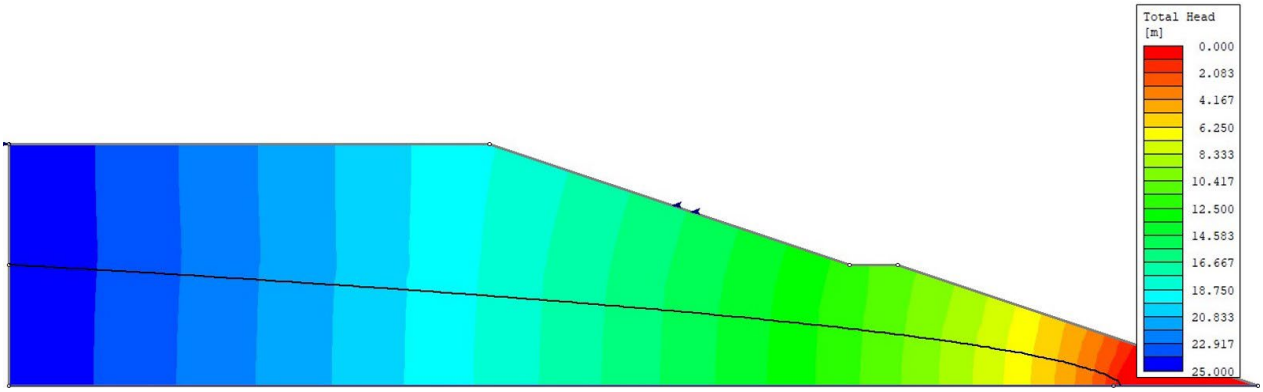

Figure 2: Total head distribution for isotropic conditions and maximum water elevation of 25 m at left boundary (base of tailings at elevation of 0.0 m)

It is noted that the phreatic lines (top flow line) in Figure 2 are substantially higher than the assumed liner piezometric line shown in Figure 1 at locations towards the embankment toe. For the upstream water level at 50 m shown in Figure 3, the seeping water reaches the downstream slope at an elevation of 25 m. This condition is considered critical in terms of factors of safety and the associated stability of the tailings dam.

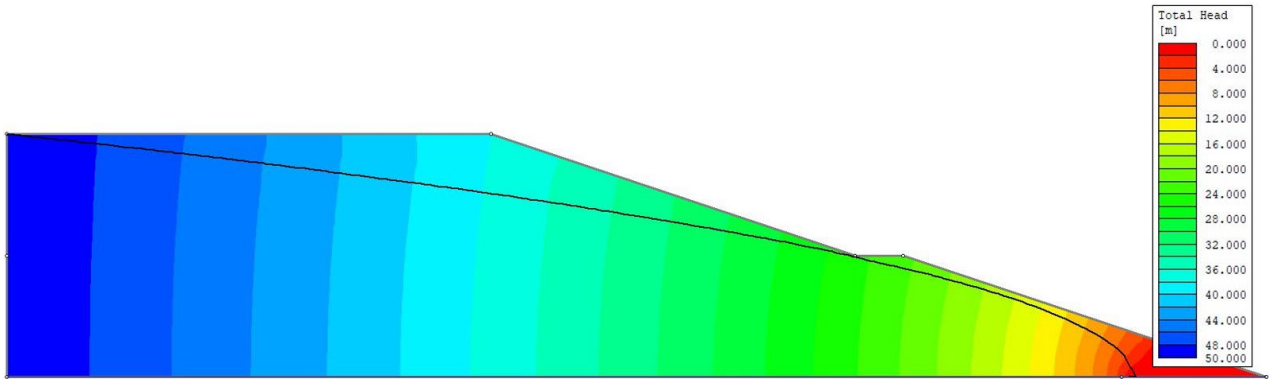

Figure 3: Total head distribution for isotropic conditions and maximum water elevation of 50 m at left boundary (base of tailings at elevation of 0.0 m)

Figures 4 and 5 present the results for the analyses where the hydraulic conductivity anisotropy ratio is considered (i.e., K_h/K_v denotes the ratio between horizonal and vertical hydraulic conductivities). Three cases are considered: 1) isotropic conditions with $K_h/K_v = 1$; 2) $K_h/K_v = 10$; and 3) $K_h/K_v = 100$. Note that the adopted anisotropy ratios do not necessarily represent the inherent anisotropy for a given tailings material (at a scale of millimeters or centimeters), but reflect the possible layering in the system due to segregation and other effects of material sorting during deposition (at a scale of meters).

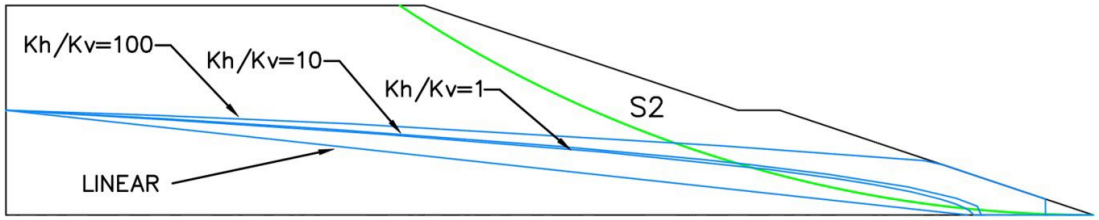

Figure 4: Comparison of steady-state phreatic lines for Kh/Kv = 1, 10 and 100 and maximum water elevation (total head) of 25 m at left boundary

For clarity, only the phreatic lines determined in these analyses are presented in Figure 4 and 5. Each of these lines is then used as a piezometric line for the FoS calculations. Figures 4 and 5 demonstrate that the tailings field-scale anisotropy may lead to increased elevation of the phreatic line, cause the seepage to saturate downstream zone of the dam, and eventually exit the toe of the dam. Any uncontrolled seepage out of the slope at the toe of the dam compromises its stability and may be an indicator of an imminent (large-scale) catastrophic failure, or may lead to gradual deterioration of stability conditions, e.g., a progressive failure due to washing out of the material caused by the high exit gradients.

Results in Figure 4 and Figure 5 indicate that, as the anisotropy ratio increases from 1 (isotropic) to 100, the seepage pattern becomes dominated by the horizontal flow. In such cases the presence of any horizontal drainage layers may become ineffective because these layers cannot protect the downstream slope from destabilizing effects of the seeping water exiting the slope. In such cases a positive vertical cutoff, in the form of a chimney drain or a massive, drained buttress at the down-stream slope, could prevent the seepage induced failure of a dam.

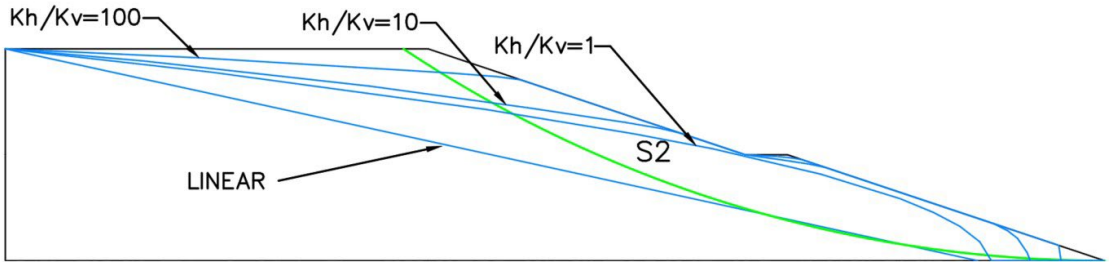

Figure 5: Comparison of steady-state phreatic lines for Kh/Kv = 1, 10 and 100 and maximum water elevation (total head) of 50 m at left boundary

Figure 6 presents the results of transient infiltration analysis, assuming an increase in the water levels at the upstream (left-hand) boundary from 25 to 50 m (the tailings base elevation is 0.0 m). In this analysis, we assumed that a steady state seepage condition has been established for the maximum water level at 25 m and then the water level is rapidly increased to a new elevation of 50 m. Initially, the area above the phreatic line at 25 m is unsaturated with pore pressures corresponding to suctions consistent with the initial steady state conditions.

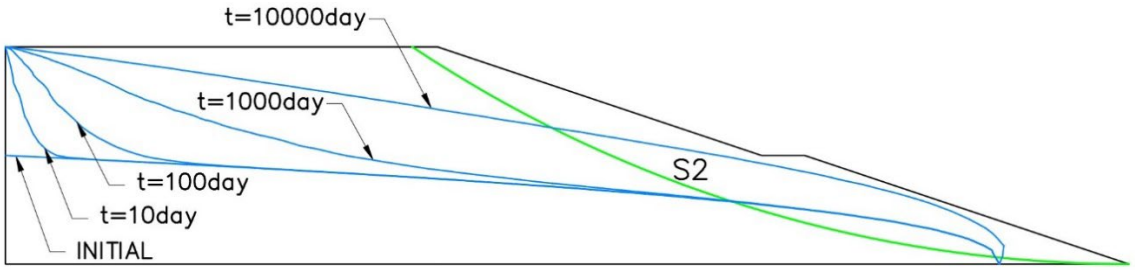

Figure 6: Transient seepage for the total head change from 25 to 50 m at left boundary

The governing unsaturated flow relationships used for the transient flow calculations are presented in Figures 7 and 8. These relationships from Hwang (1999) are typical for the fine-grained non-plastic or low plasticity soils with a clay content of less than about 15 percent. The soil water characteristic curves (SWCCs) for both drying and wetting conditions are displayed in Figure 7.

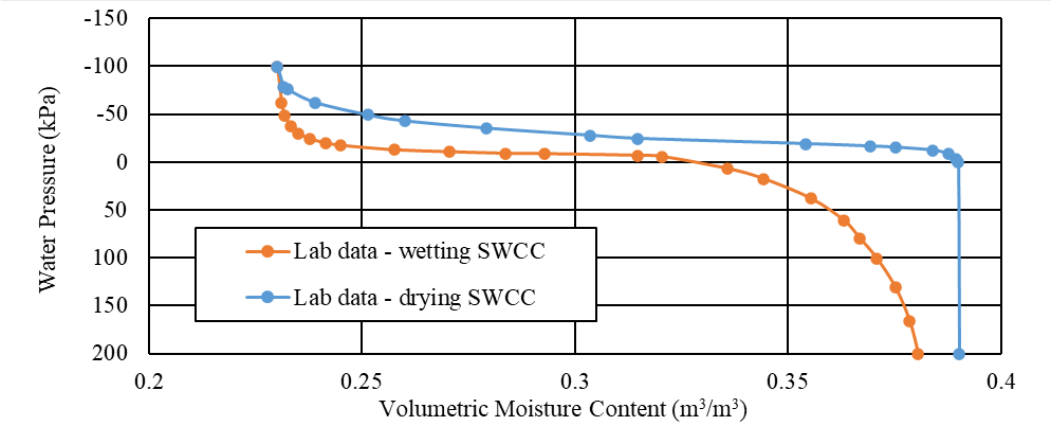

Figure 7: SWCC assumed for seepage analyses (after Hwang, 1999)

The unsaturated hydraulic conductivity relationships are shown in Figure 8.

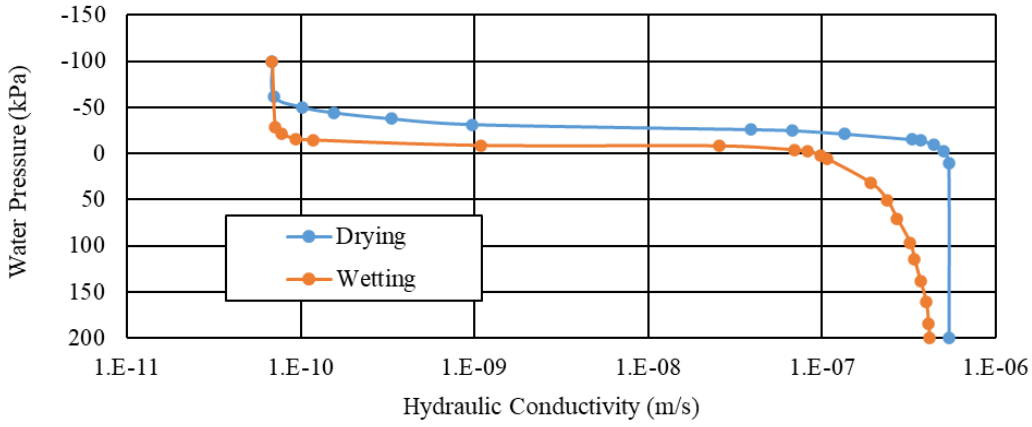

Figure 8: Unsaturated hydraulic conductivity for transient seepage analyses (after Hwang, 1999)

The results in Figure 6 illustrate the migration of the phreatic line towards the downstream slope which, initially, does not affect the tailings dam stability. However, as time progresses, the infiltrating front reaches the potential failure surface, reducing the dam stability to critical levels. The results in Figure 6 were determined for the wetting conditions with the hydraulic properties presented in Figures 7 and 8, that is, assuming that the tailings are initially dry. The actual propagation of the infiltration front, however, depends on the antecedent moisture conditions. If the pre-existing conditions are characterized by moisture contents higher than the initially dry state for the wetting curves, the hydraulic properties for the transient simulations may be in between the wetting and the drying relationships presented in Figures 7 and 8. In order to approximately account for the varying initial conditions, the transient analysis is repeated using the drying relationships presented in Figures 7 and 8. Thus, the two sets of properties will bracket the possible solutions and give a better sense of how quickly the saturation front might reach the downstream slope of the dam.

In addition, a change in water management practices or climate conditions is also likely to affect the migration of the infiltration front towards the downstream slope. Figure 9 presents the results for the same conditions as in Figure 6, but assuming that the top boundary is inundated from rain infiltration from the left boundary (x=0) to the crest of downstream slope (x=100 m). Substantially shorter saturation time is noted by comparing the phreatic lines at equal times in Figures 6 and 9.

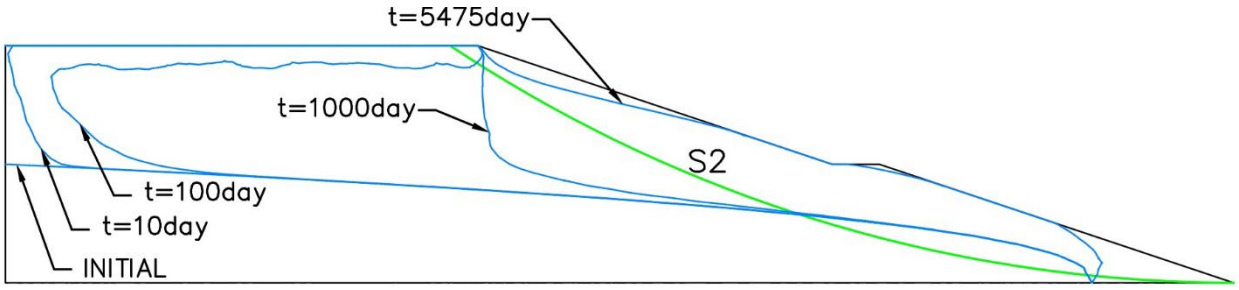

Figure 9: Transient seepage for the total head change from 25 to 50 m at left boundary and water infiltration on the top boundary from x=0 to x=100 m

The time for the infiltration front to reach the downstream slope, i.e., the time to initiate TSF failure, was determined for a subset of seepage calculations, with the results summarized in Table 1. These calculations were conducted to investigate the effects of initial moisture conditions and potential stability impacts due to changes in climate conditions or water management practices. Conducted seepage analyses utilize “Unknown” boundaries, where Slide2 seeks the elevation of the phreatic surface (location of zero pore-water pressure), and are referred to as “Open Head” boundaries or “Review Nodes” in some other programs (these nodes are subjected to seepage face condition where the total head is not able to exceed the elevation head). For case scenarios 12.1 and 12.2, the entire length of the surface boundary is defined

in this way. For case scenarios 12.3 and 12.4, only the portion between x=100 and x=260 m is defined that way, with zero pressure imposed at the top of the tailings from x=0 to x=100 m.

Table 1: Transient scenarios and estimated time to initiate TSF failure

Case ID	Surface boundary	Hydraulic parameters	Time to initiate TSF failure (year)
12.1	Unknown/seepage face (x=0-260)	Wetting	27
12.2	Unknown/seepage face (x=0-260)	Drying	12
12.3	Zero pressure (x=0-100), unknown (x=100-260)	Wetting	15
12.4	Zero pressure (x=0-100), unknown (x=100-260)	Drying	1.6

The results in Table 1 indicate that the scenarios exhibiting higher initial moisture contents and larger infiltration along surface boundaries will exhibit less favorable seepage conditions and shorter times before triggering failure conditions. For Cases 12.3 and 12.4, wetting by rainfall is assumed to result in zero pore-water pressures at the top of the TSF, resulting in the loss of suction with depth. For these scenarios, the upper parts of the TSF, which were previously characterized by negative pore pressures and low permeabilities, are now more permeable and are increasing the rate of infiltration towards the embankment toe. Therefore, depending on the antecedent moisture and boundary conditions, the TSF failure may be triggered after less than a couple of years (Case 12.4) or after several decades (Case 12.1) assuming that similar changes in the seepage conditions are imposed.

It should be noted that all steady-state (non-transient) seepage scenarios assume no external source of water, such as rainfall or snow melt, along the surface (top) boundaries. The presence of such external sources of water will lead to further increase in pore water pressure and will further compromise the dam stability. In any seepage and stability analyses for an actual project, such effects must be included based on the site-specific conditions.

Slope stability analyses

The change in the factor of safety for the various seepage scenarios and for the two selected potential failure surfaces (the first one considering a large-scale/global failure and the second one considering the toe stability) is evaluated by two strength approaches. The first approach, often referred to as the total stress or undrained shear strength analysis, assumes that the material below the phreatic lines is saturated and the shear strength for this material is given by $s_u/\sigma'_v=0.25$. In the second approach, often referred to as the effective stress analysis, the effective friction angle of 36 degrees is assigned to both saturated and unsaturated tailings. The porewater pressures are calculated along the failure surface by multiplying the vertical distance to the phreatic line by the unit weight of water. It should be noted that the piezometric line

for each potential failure surface is different, and strictly speaking it should be obtained from the flow net by calculating the pressure head at each point along the potential failure surface. The approximation of using the phreatic line as the piezometric line for all potential failure surfaces is acceptable as long as the seepage pattern is primarily horizontal, and the equipotential lines can be approximated with vertical lines. The assumed geotechnical properties for limiting equilibrium analyses are summarized in Table 2.

Table 2: Geotechnical properties for stability analyses

Peak undrained strength ratio, s_u/σ'_v	Effective friction angle, ϕ'	Unit weight above phreatic surface	Unit weight below phreatic surface
0.25	36°	18 kN/m^3	20 kN/m^3

The two strength approaches in this study differ depending on which sources of water pressures are considered for the stability analyses. For the undrained shear strength analyses it is assumed that the developed shear induced pore pressures are consistent with stresses and deformations at or before reaching the assumed peak undrained strength conditions, i.e., the residual (steady-state) undrained strengths and the potential effects of brittleness were not considered. In the effective stress analyses any shear induced pore pressures are neglected and the calculated pore pressures along the potential failure surfaces are calculated from seepage analyses only, i.e., without considering pressures induced by the deformation of tailings. Such an approach could be justified only for cases where tailings exhibit dilative behavior and/or tailings deformations cannot result in the development of positive pore pressures.

Table 3 summarizes the results of slope stability analyses for two selected potential failure surfaces, S2 and S3 in Figure 1, using both the undrained shear strength and effective stress approaches. As expected, the undrained shear strength approach yields lower factors of safety than the effective stress approach for all analyzed scenarios because it assumes that the additional pore pressures are generated due to either anticipated or actual deformation of tailings. These shear (strain) induced pressures are added to pore pressures resulting from the existing/undeformed seepage conditions. Considering that the focus of this study is a realistic portrayal of seepage conditions, it should be noted that both approaches lead to a significant reduction in the factor of safety as the water level increases from the initial value of 25 m to 50 m and/or when taking into account the effects of anisotropy.

For general stability (S2) and the undrained shear strength analysis approach, the factor of safety reduces from the initial value of 2.5 to 1.08 as the water level increases to 50 m and the piezometric lines are assumed linear. When a more realistic seepage pattern is assumed, even under isotropic conditions, the factor of safety is reduced to FoS=1.79 for the 25 m level and to FoS=0.87 for the 50 m level. The anisotropy ratio of 100 further reduces these values to FoS=1.27 at the 25 m level and FoS=0.52 at the 50 m level. For

the same failure surface (S2), the effective stress analysis (drained) approach results in significantly higher FoS values, however, these values are dramatically reduced from the initial value of FoS=2.5 for the initial conditions, with the linear phreatic line to FoS=1.11 for the elevated water level of 50 m at the left-hand boundary and the anisotropy ratio of 100.

Table 3: Calculated factors of safety for various seepage scenarios

Case ID	Description	General Stability Failure Surface S2		Toe Stability Failure Surface S3	
		s_u/σ'_v= 0.25	ϕ'=36°	s_u/σ'_v= 0.25	ϕ'=36°
1	Linear piezo-line, hmax=25 m	2.5	2.51	2.34	2.34
2	Linear piezo-line, hmax=50 m	1.08	2.13	2.34	2.34
3	FEM phreatic line, hmax=25 m, Kh/Kv=1	1.79	2.42	2.34	2.34
4	FEM phreatic line, hmax=25 m, Kh/Kv=10	1.7	2.38	2.1	2.34
5	FEM phreatic line, hmax=25 m, Kh/Kv=100	1.27	1.97	0.84	1.5
6	FEM phreatic line, hmax=50 m, Kh/Kv=1	0.87	1.59	1.08	1.67
7	FEM phreatic line, hmax=50 m, Kh/Kv=10	0.66	1.32	0.72	1.19
8	FEM phreatic line, hmax=50 m, Kh/Kv=100	0.52	1.11	0.52	1.02
9.1	FEM phreatic line, hmax=50 m, t=10 days	1.79	2.42	2.34	2.34
10.1	FEM phreatic line, hmax=50 m, t=100 days	1.79	2.42	2.34	2.34
11.1	FEM phreatic line, hmax=50 m, t=1000 days	1.79	2.42	2.34	2.34
12.1	FEM phreatic line, hmax=50 m, t=10000 days	0.87	1.59	1.08	1.67

Similar trends are seen for the transient infiltration analysis as the water level increases from 25 m to 50 m. For the initial 1,000 days of infiltration, there is no change in the FoS for S2 or S3 failure surface because the infiltrating front has not yet reached either of the failure surface locations nor caused changes in the initial pore pressures. However, when the wetting front reaches the global failure surface (S2) the factor of safety is reduced to 0.87 for the undrained shear strength approach and to 1.59 for the effective stress approach. Had this infiltration analysis been combined with the assumed anisotropy, the FoS reductions would have been more drastic, and the changes would have happened in a much shorter period of time.

For the toe stability potential failure surface (S3), similar trends in the FoS reduction are observed. The FoS is reduced from the initial value of 2.34 (no seepage effect at all) to the low value of 0.52 when considering the undrained shear strength approach and to 1.02 for the effective stress approach. Such a low value of FoS for the effective stress approach clearly indicates a high likelihood for the embankment toe to

become unstable when the seepage reaches the downstream slope and indicates a high likelihood of global or progressive failure being triggered in an undrained fashion.

Conclusion

The presented seepage and stability analyses demonstrate that the stability of a tailings dam can be compromised by internal seepage even in the absence of any other external triggers, such as earthquake or static loading, infiltration from rainfall or snow melt, increased antecedent flows, and other natural or man-induced triggers. Unless a substantial downstream zone of the dam can be protected from saturation by a properly designed drain or a toe buttress made of highly permeable material, the uncontrolled seepage at the downstream face of the dam will almost certainly result in tailing dam instability.

The commonly employed assumption of a linear piezometric line can significantly underestimate the pore pressures on the potential failure surfaces. When the results of properly executed seepage analyses are compared to the linear piezometric line, the factor of safety reduces by 25%, 30%, or even 50%. Accounting for the inevitable presence of tailings anisotropy may result in a further reduction in the FoS to 50% or even 20% of the original value.

For the vast majority of TSFs, conducting slope stability analyses using the undrained shear strength will lead to more conservative FoS values than using effective stress analyses or drained conditions. This is not surprising because the undrained shear strength approach accounts for the shear (deformation) induced pore pressures, while the effective stress approach accounts only for the pore pressures calculated in the seepage analysis (assuming dilative tailings and/or conditions that are not conducive to generation of positive pore water pressures). Hence, effective stress analyses would be justified only for cases where all tailings exhibit dilative behavior ("But who could guarantee that for a conventional tailings deposition?"), or where tailings are at a low level of saturation throughout the life of the impoundment so that any generated pore pressures during loading are negligible ("And who could guarantee that either?").

The presented transient seepage analyses demonstrate that, even when a portion of the tailings dam is initially unsaturated, the presence of water in the upstream body of the impoundment may inevitably lead to saturation of the downstream slope and reach the toe of the dam, unless adequate drainage and groundwater control measures are implemented in the design to manage these flows. The time required for triggering of these unstable downstream conditions depends on the material characteristics, climate, and general water management conditions, but it is expected to vary from several decades to several years (e.g., the Feijão dam failure) or even less.

The analyses in this study were conducted for a hypothetical tailings dam, but they illustrate the need for similar analyses to be conducted for any tailings dam design where the material properties and long-term changes in seepage conditions present a stability concern. In particular, the range of in-situ anisotropy,

unsaturated soil properties, time-dependency of material parameters, and any sources of water (e.g., rainfall, snowmelt, existing seeps, surface streams, and potential inflows due to water management at the mine site) must be considered. The absence of these critical seepage analyses is one of the factors that leads to underestimation of the severity of potential failure modes and, more importantly, the increased likelihood of catastrophic failures.

Abstract

The generation of contaminated neutral drainage (CND) is an important environmental issue for the mining industry, especially from filtered tailings whose reactivity may be enhanced. The gold mining industry is particularly challenged by the co-occurrence of Au and As-bearing minerals, including arsenopyrite and loellingite, leading to the generation of As-CND. Surface treatments using inorganic and organometallic passivation layers are increasingly recognized as promising strategies to limit oxygen access and the generation of As-CND. This study aims to evaluate and compare the performances of silicate- and catecholate-based coatings to limit As mobilization from low sulfide filtered tailings (0.07% As, 0.05% S). Four treatment solutions were studied: 1) Si/H_2O_2, 2) Si/Fe, 3) Si/catechol, and 4) Fe/catechol. The effect of reagents concentration (10 – 100 mM), drying time (1 – 5 days) and pre-washing cycles was investigated using batch tests. The mobility of As from reprocessed tailings was evaluated through static leaching tests. Results showed that the use of Si in inorganic and organometallic coatings had a negative effect, as it induced twice as much As mobilization (up to 1.5 mg/L vs. 0.6 ± 0.2 mg/L for untreated tailings), highlighting the prevalent role of anionic competitiveness on passivation mechanisms. On the contrary, the use of Fe in inorganic and organometallic coatings was beneficial. It enhanced the immobilization of As, which increased at greater concentrations of reagents (up to 95% of immobilization) and allowed the tailings to reach Canadian federal legislative limits (<0.3 mg/L) in final post-treatment effluents and leachates. The drying time had a moderate influence on As mobilization from reprocessed tailings, suggesting that environmental conditions of the management of low sulfide filtered tailings will impact treatment efficiencies. Further studies are required to evaluate the long-term performances of the surface treatments in oxidative and reductive conditions.

Introduction

Contaminated neutral drainage (CND) occurs through the oxidation of mine wastes in which neutralizing minerals are in abundance compared to acidifying minerals (i.e., sulfides), as in the case of low sulfide tailings. Although desulfurization was proved to be efficient as an integrated management option for mine drainage prevention, recent studies have shown that desulfurized tailings can still induce CND (Barago et al., 2023; Rey et al., 2020). CND has become a major environmental issue for the mining industry, but its treatment is challenged by the low contents of contaminants, the low stability of treatment residues, and the need for chemical reagents, energy, and infrastructure (Prepilková et al., 2022). These challenges, associated with stricter regulations (e.g., Metal and Diamond Mining Effluent Regulations – MDMER), has led to an interest in prevention strategies, especially for filtered tailings whose reactivity is enhanced by their low degree of saturation (Lara et al., 2013; Davies, 2011).

Prevention strategies for CND include, among others, surface treatments. Several coating agents are available for the surface treatment of mine tailings, such as oxide layers (Tabelin et al., 2016), organic or inorganic compounds (e.g., calcite, silicates, silanes) (Feng et al., 2023; Fan et al., 2021; Roy et al., 2020), organometallic complexes (Park et al., 2021), and even biological coatings (He et al., 2022; Gerson et al., 2022). They control the type of coating mechanisms at stake: i) organic or inorganic passivation, ii) carrier-microencapsulation (CME), iii) biocalcification or iv) biopassivation, respectively. Biological surface treatment will not be discussed in further detail in this paper.

Immobilization mechanisms and, therefore, the physicochemical properties of coating layers are strongly dependent on the nature of the coating agent used. Inorganic coating reagents generally create sorption sites through Fe-nonmetal-O bonds (Fan et al., 2017). Phosphates, silicates, and carbonates are all options for the surface treatment of main sulfides (Roy et al., 2020; Kollias et al., 2019), but the competitive effects of As and similar anions regarding Fe affinity could represent a challenge for As-rich tailings (Kollias et al., 2022; Cheng et al., 2009). Catechol is an isomeric benzenediol ($C_6H_6O_2$) capable of forming mono-, bis-, or tris- coordination complex with diverse metals and anions. Catecholate-based coatings are increasingly studied as viable organometallic complexes for surface treatment. They can be synthetized using different metals (e.g., Fe, Al), as well as different anions (e.g., PO_4^{3-}, SiO_4^{3-}) (Li et al., 2021; Park et al., 2020). The decrease of sulfide oxidation by CME is based on three different mechanisms: i) the degradation of catechol at the surface of the minerals, ii) the production and adsorption of intermediates catecholate, and iii) the liberation of metals or anions that can precipitate and form a protective layer at the surface of the sulfide minerals (Satur et al., 2007).

Previous studies on surface treatments carried out in the mining context mainly targeted the oxidation of pyrite, and to a lesser extent arsenopyrite, but did not cover their effect on non-sulfidic As-bearing minerals (i.e., loellingite) that can be found in low sulfide tailings (Lagae Capelle et al., 2024) and present

divergent chemical behaviors due to different bulk structures and electronegativity (Harmer and Nesbitt, 2004). For example, lower yields of natural coatings formation through oxidation dissolution were observed on loellingite vs. arsenopyrite (Stolze et al., 2022). Besides, the efficiency of such treatments depends on many operating conditions, such as tailings mineralogy and particle size, the nature of the coating agent and its concentration, as well as drying time (Tu et al., 2022). Temperature, pH, and reaction time also play an essential role in the formation of coating layers (Kollias et al., 2022; Li et al., 2021).

In this context, the main objective of this study was to assess and compare the efficiency of different surface treatments, including Si-based inorganic passivation, Fe- and Si-bearing catecholates (CME), to decrease the mobility of As from low sulfide filtered tailings. Immobilization mechanisms were investigated to understand the challenges associated with the use of inorganic silicates. The influence of the nature of coating agents and their concentrations as well as the drying time on the immobilization of As was evaluated using a static leaching test on untreated vs. reprocessed tailings.

Materials and methods

Physico-chemical and mineralogical characterization of tailings

Low sulfide filtered tailings were sampled at the Éléonore mine site, an active gold mine located in the James Bay region (Quebec, Canada) in 2021. They were stored in 500 L barrels, sampled through drilling, dried, and homogenized using the 80-stroke technique prior to physico-chemical and mineralogical characterization as well as surface treatment experiments. Initial characterization included water content, particle size distribution, and chemical and mineralogical composition. Water content was estimated by drying samples at 60°C for 48 hours (ASTM, 2010). Particle size distribution was determined using a laser diffraction grain size analyzer (Malvern Mastersizer S). The chemical composition was reconciled using: i) inductively coupled plasma-atomic emission spectroscopy (ICP-AES – Perkin Elmer Optima 3100-RL) after 4-acid standard digestion (HNO_3/HBr/HF/HCl); ii) whole rock analysis; and iii) X-ray fluorescence spectroscopy (XRF – Bruker S2 Ranger) on homogeneous and deagglomerated samples. Sulfur and carbon contents were determined using an induction furnace at 1,360°C (ELTRA CS-20) equipped with an infrared analyzer. Main gangue, sulfides, and As-bearing minerals were identified using an X-ray diffractometer (XRD) (Bruker A.S. Advance D8) and a scanning electron microscope (SEM) (Zeiss Sigma 300 VP) equipped with an energy-dispersive X-ray spectrometer (EDS) (Oxford Instrument, Ultim-Max 170 mm^2).

Preparation of surface treatment solutions

Surface treatment solutions included two inorganic solutions (Si/H_2O_2 – I-Si, $Si/Fe/H_2O_2$ – I-Fe-Si) and two organometallic solutions, also referred to as CME solutions (Fe/catechol – CME-Fe and Si/catechol – CME-Si). Inorganic solutions were produced by mixing a source of silicate ions (5-25 mM Na_2SiO_3, Alfa

Aesar) with an oxidizing agent (2% H_2O_2, Anachemia VWR), with (I-Fe-Si) or without (I-Si) a source of Fe ions (5-25 mM $FeSO_4$, Sigma Aldrich) during 5 minutes at 200 rpm and room temperature. The choice of reagent concentrations was based on previous work performed on a Ni-rich waste rock (Roy et al., 2020). CME solutions were synthesized according to experimental procedures described by Li et al. (2021) for CME-Fe and Yuniati et al. (2015) for CME-Si, using a source of catechol (2-15 mM pyrocatechol 99%, ThermoScientific) and either a source of Fe (4-20 mM $FeNO_3$, Anachemia VWR) or Si (10-100 mM Na_2SiO_3, Alfa Aesar). Their synthesis was realized by titration to reach pH 7-8, using NaOH (0.1 M, Mat Laboratory) or H_2SO_4 (95-98%, VWR Chemicals), to produce bis-catecholate that is chemically stable in the targeted pH range (Park et al., 2018).

Surface treatment

Surface treatments were carried out on 10 g of tailings in 100 mL Erlenmeyer flasks. Inorganic and CME solutions were added to tailings to reach a solid/liquid ratio of 1/10 (v/v) and the slurry was mixed for 4 hours at 200 rpm and room temperature. Post-treatment effluents were recovered by Buchner filtration (0.45 µm porosity) and analyzed for metallic and anionic contents using ICP-AES and ionic chromatography (IC, Methrom 940 Professional IC Vario), respectively. The final content of catechol after CME treatments was quantified using UV-vis spectroscopy (Ultrospec 2100 Pro). Solids, referred to as reprocessed tailings, were recovered, and dried at 60°C for 1 to 5 days. The mobility of As and S in initial and reprocessed tailings was assessed using modified Field Leaching Tests (FLT – Hageman, 2007). The bulk chemical composition of reprocessed tailings was determined by XRF.

Evaluation of contaminants mobilization: field leaching tests

The mobility of As and S from tailings (untreated vs. reprocessed with inorganic and CME solutions) was estimated using a FLT based on the method developed by Hageman (2007). Samples were mixed with deionized water at 250 rpm and room temperature, using a solid/liquid ratio of 1/20 (w/w), for 5 minutes. Leachates were recovered after a Buchner filtration (0.45 µm porosity) and analyzed for metallic, anionic, and organic contents using ICP-AES, IC, and UV-vis spectroscopy, respectively. The results were used to evaluate the surface treatment efficiency for limiting the mobilization of As.

The efficiency calculation (E_{tr} – Equation 1) was based on the comparison of the amounts of contaminants released during FLT performed on reprocessed tailings ($Q_{FLT\text{-}tr}$ – Equation 2) and on initial tailings ($Q_{FLT\text{-}ini}$ – Equation 3). Negative E_{tr} values indicate that the mobility of the contaminant of interest increased after passivation treatment, while positive values indicate a diminution of the mobility of the targeted contaminant after the passivation treatment.

$$E_{tr}\ (\%) = (Q_{FLT\text{-}ini} - Q_{FLT\text{-}tr}) / Q_{FLT\text{-}ini} \times 100 \qquad \text{(Equation 1)}$$

$$Q_{FLT\text{-}tr}\ (mg_{As}) = (C_{FLT\text{-}tr}.V_{FLT})/(C_{ini}.m_{ini} - C_{leached}.V_{leached}) \quad \text{(Equation 2)}$$

$$Q_{FLT\text{-}ini}\ (mg_{As}) = (C_{FLT\text{-}ini}.V_{FLT})/(C_{ini}.m_{ini}) \quad \text{(Equation 3)}$$

Where $C_{FLT\text{-}tr}$ and $C_{FLT\text{-}ini}$ are the concentrations of contaminants released during FLT carried out on reprocessed and untreated tailings (mg/L), respectively, V_{FLT} is the volume of FLT solution (L), C_{ini} is the concentration of contaminants initially present in the tailings (mg/kg), m_{ini} is the mass of tailings used for FLT (0.01 kg), $C_{leached}$ and $V_{leached}$ are the concentrations of contaminants leached (mg/L) and the volume (L) of the solution used during the passivation treatment, respectively.

Results and discussion

Physico-chemical and mineralogical characterization of tailings

Low sulfide filtered tailings were uniformly graded (Cu < 3) and fine-grained (D_{10}: 3.5 µm, D_{60}: 41.7 µm and D_{80}: 77.0 µm) materials with a low water content (15.8% – v/v). They were mainly composed of Si (30%), followed by Fe (2.5%), Al (2.5%), and Mg (2.1%). The concentrations of As and S were low (848 and 1,216 mg/kg, respectively), which is consistent with previous studies (Rakotonimaro et al., 2021). Main gangue minerals were quartz (38%), plagioclase (20%), biotite (12%), and K-feldspar (9.0%), while identified sulfides and As-bearing minerals were loellingite (0.04%), pyrrhotite (0.006%), and arsenopyrite (0.004%).

The concentration of As and Fe in the leachates obtained from FLT on untreated tailings were 0.62 ± 0.14 mg/L and 0.12 ± 0.04 mg/L, respectively. These values were used to compare the mobility of contaminants from untreated and reprocessed tailings and therefore to quantify the efficiency of the different surface treatments tested.

Influence of the nature and concentration of reagents

Evolution of As and Fe concentration in final post-treatment effluents

The effect of the nature and the concentration of different inorganic (I-Si, I-Fe-Si) and organometallic (CME-Fe, CME-Si) coating agents on the passivation of As-bearing minerals to limit the mobilization of As from tailings was assessed. Figure 1 presents, for each tested initial concentration of reagents (x), the final concentration of As and Fe in the post-treatment effluents (y_1) (i.e., the concentration of As leached [$C_{leached}$, Eq. 2] during the surface treatment), as well as the content of coating agent immobilized onto the tailings surface (y_2) (i.e., the difference between final and initial concentrations of coating indicators).

For I-Si and CME-Si, high contents of As, generally above legislative limits in Canada (0.3 mg/L – MDMER, Minister of Environment and Climate Change), were leached during the treatment step, indicating that post-treatment effluents will require further appropriate treatment before their discharge due

to their low quality. Increasing the initial concentration of Si improved the immobilization rate of Si, which reached above 80% for both I-Si and CME-Si, but it did not impact (for I-Si) and even increased (for CME-Si) the leaching of As during the treatment step (Figures 1a, 1c). However, for I-Fe-Si, higher immobilization rates of Si at higher initial Si concentrations (> 90% at [Si] > 15mM) were combined with an immobilization rate of Fe near 100%, inducing 10 to 50 times less As leaching than I-Si and CME-Si respectively. The results suggest the formation of Fe-Si complexes or Si-doped Fe-(hydr)oxides (Fan et al., 2017) onto the tailings surface when Fe ions were added to the coating solution. Concentrations of As leached during I-Fe-Si treatment were below 0.1 mg/L and were not influenced by initial [Si] and [Fe], which indicates that ferrosilites can limit tailings oxidation and As mobilization despite the possible competitive effects between Si and As anions that were previously reported (Kollias et al., 2022).

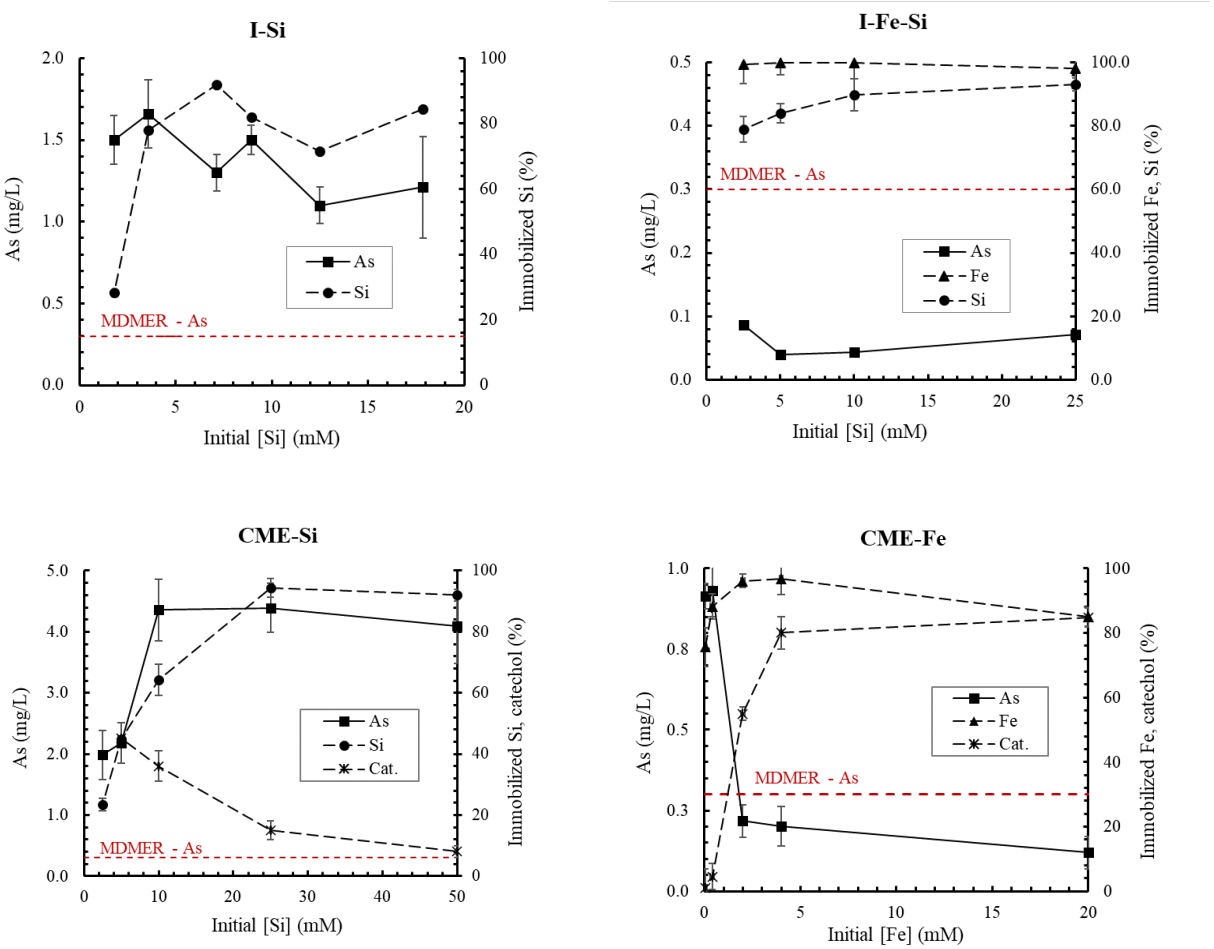

Figure 1: Influence of initial concentration of Si for I-Si, I-Fe-Si, CME-Si, and Fe for CME-Fe on the concentration of As (square) leached during the treatment step and the immobilization of coating indicators (dotted line) like Si (circle), Fe (delta), and catechol (cross) (treatment time: 4 h, drying time: 24 h)

The levels of As leached during treatment are higher for CME-Si than I-Si (up to 5.6 mg/L for CME-Si vs. up to 1.7 mg/L for I-Si) despite relatively similar Si immobilization rates, indicating that the use of an oxidizing agent (H_2O_2) during I-Si treatment may have enhanced the formation of Fe-(hydr)oxides at the tailings surface, a natural coating layer (Tabelin et al., 2016), which was more concluding than catechol immobilized at rates below 40%. The comparison of CME treatments showed that the concentrations of As released during CME-Fe treatment were much lower than during CME-Si for the same initial [catechol] of 2 to 3 mM (0.21 ± 0.09 mg/L for CME-Fe vs. 3.2 ± 0.44 mg/L for CME-Si) (Figures 1b, 1d). The decrease in As mobility during CME-Fe can be associated with the simultaneous immobilization of Fe and catechol at rates above 80%.

I-Fe-Si and CME-Fe would present higher efficiency for limiting As mobilization from reprocessed tailings, confirming the important role played by Fe ions in the immobilization of As (Park et al., 2021; Cheng et al., 2009).

Efficiency of prevention: mobilization of As and Fe from reprocessed tailings

The mobility of As (and Fe for I-Si and CME-Si) from reprocessed tailings was compared to their mobility from untreated tailings to evaluate the efficiency of the surface treatment presented in Figure 2. Negative efficiencies represent As and Fe levels in FLT leachates from reprocessed tailings higher than in untreated tailings (i.e., 0.62 mg/L of As and 0.12 mg/L of Fe). They indicate that the surface treatments were not only inefficient but increased the mobility of As and/or Fe from tailings. The remobilization of coating indicators (i.e., Si, Fe, catechol) is also presented in Figure 2 to correlate As mobility to the stability of coating layers.

Despite low remobilization rates of Si (and catechol) (0-15%), negative efficiencies for As mobilization were calculated for I-Si regardless of the initial Si concentration and for CME-Si at more than 25 mM of Si (Figures 2a, 2c). Whereas the mobility of Fe was decreased by 60-100% in both cases. Results are consistent with previous work on sulfurized tailings and confirm the low effectiveness of Si-based tailings for As-rich tailings (Kollias et al., 2022). The use of catechol in CME-Si treatment improved efficiency (E_{tr} of -30% for I-Si vs. +30% for CME-Si at 10 mM of Si), possibly because of the higher stability of Si-based coating layers (<2% of remobilization for CME-Si vs. up to 5% for I-Si) as well as the occurrence of a low catecholate layer.

The efficiencies of I-Fe-Si and CME-Fe treatments were positive regardless of the initial Si and Fe contents, reaching up to 95% of As immobilization (Figures 2b, 2d), decreasing the concentration of As in FLT leachates below legislative limits (0.3 mg/L) for [Si] > 2.5 mM and [Fe] > 4 mM, respectively. The results showed the positive influence of using Fe ions as part of a coating agent for the retreatment of As-rich tailings. For instance, the use of I-Fe-Si (vs. I-Si) increased the passivation efficiency from -33%

to 89% at an initial [Si] of 10 mM, while the use of CME-Fe (vs. CME-Si) increased it from 33 to 55% for As at an initial [catechol] of 3 mM. A slight improvement of As immobilization in I-Fe-Si reprocessed tailings was observed at greater initial Si concentrations, which can be associated with lower Si and Fe remobilization rates (Figure 2b). For CME-Fe, the passivation efficiency went up from 55% to 95% and can also be associated with lower catechol and Fe remobilization (Figure 2d). Increasing the initial content of coating agents was beneficial for producing more stable passivation layers.

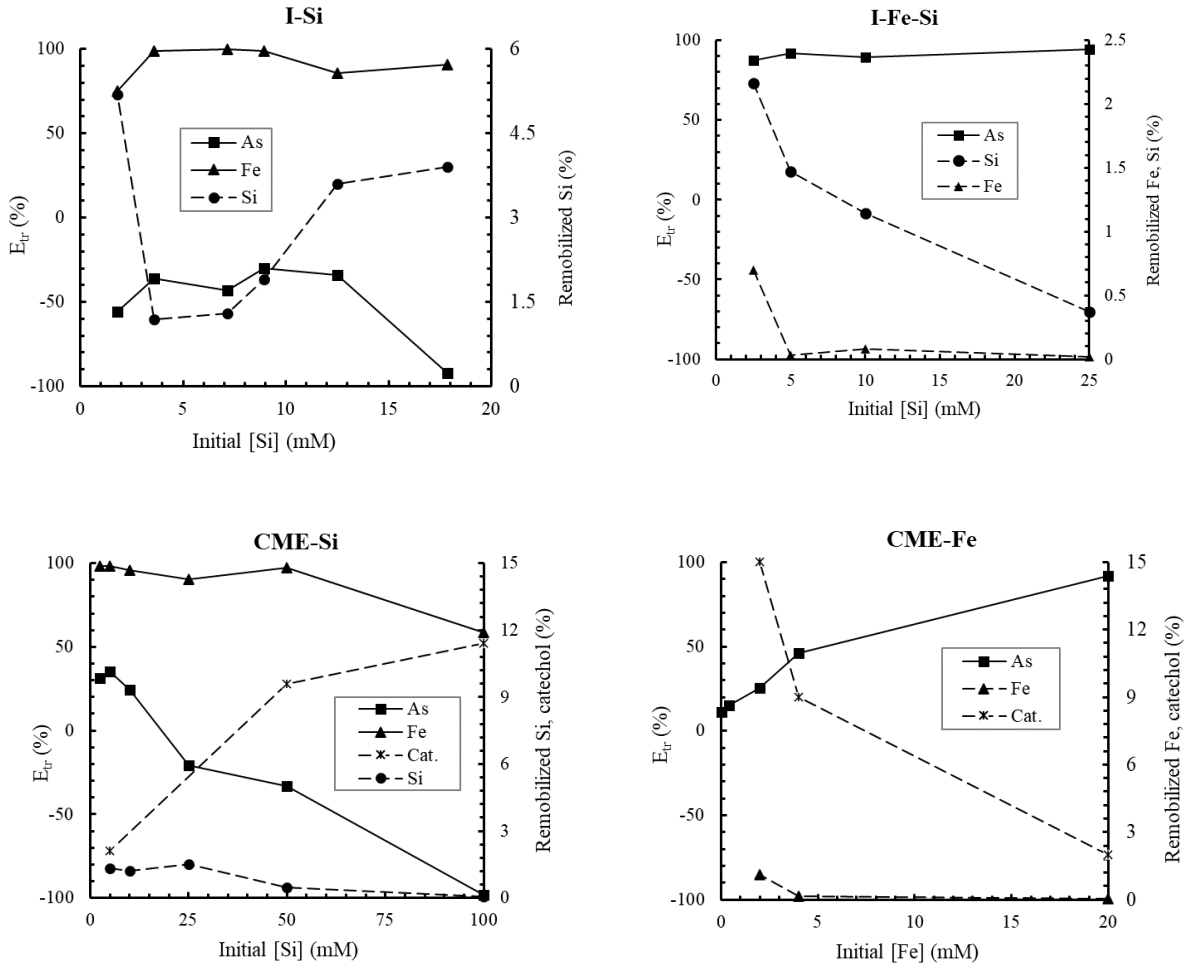

Figure 2: Influence of initial concentration of Si for I-Si, I-Fe-Si, and CME-Si, and Fe for CME-Fe, on the treatment efficiency to limit the mobility of As (square), Fe (delta), and the remobilization (dotted line) of Si (circle) and catechol (cross) (treatment time: 4 h, drying time: 24 h)

Influence of drying time

The influence of drying time (time between passivation treatment and FLT) on the performances of surface treatments applied to mine wastes or sulfide minerals is not well documented. Additional experiments have been carried out to evaluate the effect of drying time on inorganic and organometallic passivation efficiency

regarding As mobilization. Based on the results of the FLT performed on untreated vs. reprocessed tailings that are shown in Figure 3, the drying process had a strong (R^2: 0.953, R^2: 0.922, R^2: 0.855 for CME-Fe, I-FeSi, CME-Si, respectively) and positive influence on the efficiency of CME-Fe, I-Fe-Si and CME-Si treatments. According to the linear correlation identified between As passivation efficiency and drying time, the immobilization of As increased by 6.8, 7.9, and 7.5 point of percentage per day of drying respectively for CME-Fe, I-Fe-Si, and CME-Si. While, for I-Si, the results showed no significant effect of the drying time on the efficiency of the coating layers. These preliminary results suggest that the drying process influences the stability of catecholate layers, as well as of ferrosilite complexes. On site, the drying process of filtered tailings is controlled by environmental conditions of disposal. Further work is required to evaluate the influence of drying temperature, a factor that is especially important for mining activities in Nordic climates.

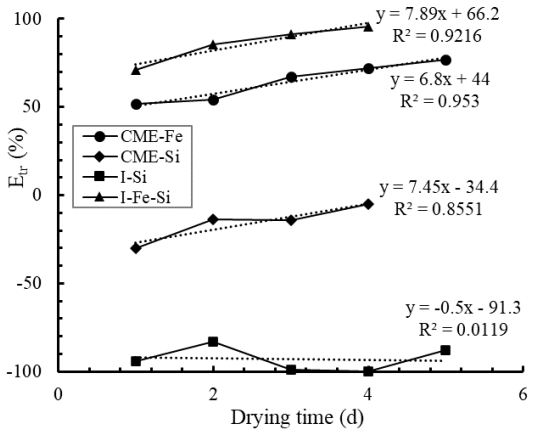

Figure 3: Influence of drying time () on the immobilization of As for CME-Fe (circle), CME-Si (diamond), I-Si (square) and I-Fe-Si (delta) treatments (respective initial concentrations: [Fe]: 4 mM, [Si]: 50 mM, [Si]: 18 mM, treatment time: 4 h)

Conclusion

The oxidation of As-rich low sulfide filtered tailings plays a role in the major environmental challenges faced by the Au mining industry. This study investigated the efficiency of surface treatment to limit loellingite and arsenopyrite oxidation and reduce As mobility using inorganic or organometallic agents: Si/H_2O_2, Si/Fe/H_2O_2, Si/catechol, Fe/catechol. Among the four types of surface treatment, I-Fe-Si (i.e., Si/Fe/H_2O_2) and CME-Fe (i.e., Fe/catechol) seemed to be the best options. They both induced lower As solubilization during the treatment step, while producing stable coating layers that limited up to 90% of As mobility during leaching tests. The concentration of As in post-treatment effluents and FLT leachates for CME-Fe and I-Fe-Si were generally below the Canadian federal regulations (0.3 mg/L – MDMER).

The influence of the operating conditions was inconsistent from one coating agent to another. Increasing Fe and catechol initial contents allowed the improvement of the passivation efficiency and decreased As solubilization during the treatment step, whereas increasing Si initial content had a negative impact on the treatment, indicating the prevalence of anionic competition onto the coating mechanisms. The drying process was observed to be influent on the passivation efficiency of catecholate-based treatments (i.e., CME-Fe and CME-Si), possibly because of the production of more stable organic coating, and of the production of more stable ferrosilite complexes for I-Fe-Si, while having no effect on I-Si treatment. The findings of this study suggest that the use of silicates, without the addition of Fe ions, is not appropriate for the surface treatment of As-rich low sulfide tailings due to their high anionic competition. The use of Fe ions, in combination with silicates or catecholates, is a promising option to reduce As-CND.

Ongoing and upcoming work includes:

1. the estimation of optimal operating conditions for CME-Fe and I-Fe-Si using a Box-Benhken experimental design,
2. the investigation of biological coatings,
3. the evaluation of the long-term stability of reprocessed tailings in oxidative and reductive conditions (both found in filtered tailings storage facilities).

The Internal and Interface Shear Strength of Geosynthetic Clay Liners for Mining Application

Andrew Jung, Western GeoSystems, USA
Reza Gorakhki, CETCO, USA

Abstract

Geosynthetic clay liners (GCLs) have been used widely as an alternative for compacted clay liners and covers in mine waste applications. The high swelling of bentonite particles in the GCL creates a uniform barrier layer that results in low permeability of water and mine waste leachate. GCLs must provide sufficient internal and interface shear strength stability, especially if GCLs are used in steep slopes under high normal loads. Peel strength is a common parameter that is typically correlated to internal shear strength properties of GCLs. The relationship between internal shear strength and peel strength of GCL at normal stresses of 287, 575, 862, and 1,724 kPa is evaluated in this study. The data in this study was compared with the peel strength-internal shear strength relationships found in the literature. The interface shear strength of GCL and two textured geomembranes under normal stresses ranging from 240 kPa to 2,310 kPa is presented in this study. The study concludes that the relationship between peel strength and internal shear strength is unique based on manufacturing, needle-punching density and the method with and without heat treatment of the geotextile end fiber bundles. Additionally, in a composite liner system with a separate geomembrane above the GCL, the high peel strength GCL can force the failure mechanism from internal GCL failure to the interface between the GCL and the geomembrane.

Introduction

Geosynthetic clay liners (GCLs) are widely used as a hydraulic barrier in mine waste containment systems due to their superior hydraulic performance, self-healing properties, ease of installation, economic advantages, and easier quality control process (Robbins et al., 1995; Babu et al., 2001, Guyonnet et al., 2009; Fox and Stark, 2015; Rowe et al., 2019; Rowe, 2020). GCLs consist of a low permeability layer encapsulated between two geotextile layers. The low permeability layer typically contains natural sodium or a mixture of bentonite and polymer that primarily controls the hydraulic properties of the GCL. Many studies have evaluated the hydraulic properties, advantages, and limitations of the low permeability layer in GCLs (Meer and Benson 2007; Scalia and Benson, 2011; Bradshaw et al., 2013; Chen et al., 2019).

Internal and interface shear strength of GCLs and adjacent layers are typically measured via displacement-controlled direct shear testing. Internal and interface shear strength of GCLs is primarily controlled by the geotextile types, the method used to bond the geotextile and low permeability layer together (e.g., needle punching, heat treating after needle punching, stich bonding), bentonite extrusion, and the properties of adjacent material (geomembrane or soil). In the side slope and bottom liner applications, GCLs should provide appropriate internal and interface shear strength (Ghazizadeh and Bareither, 2021). In most heap leach pad applications, a high normal stress ranging between 1,000 to 2,000 kPa is applied on the liner system. The liner not only should have a high enough peak shear strength, but also the failure mechanism (i.e., interface failure or internal GCL shear strength failure) is also important since it governs the long displacement shear strength. The GCL should have high enough internal shear strength that it forces the failure to the interface layer between GCL and geomembrane.

Bareither and Ghazizadeh (2021) evaluated the failure mechanism of GCLs and textured geomembrane in normal stress ranging between 100 kPa to 2,000 kPa. They reported that as normal stress or geomembrane texture intensity (i.e., asperity height or spike density) increases, the failure mechanism moves from the interface between the GCL and the geomembrane to the GCL internal failure mode. GCL internal failure in design is undesirable since the long displacement shear strength of GCL is equivalent to the shear strength of unreinforced bentonite.

To evaluate the needle-punching extent on GCLs, industry uses a parameter known as peel strength. Peel strength is defined as the tensile force per specimen width that is required to separate the top and bottom geotextile (ASTM, 2015; Ghazizadeh and Bareither, 2018). Zornberg et al. (2005) evaluated the relationship between GCL peel strength and internal shear strength in normal stress of 35, 138, and 310 kPa and showed that a relationship between the GCL peel strength and internal shear strength appeared at the 310 kPa normal stress, but not at the lower normal stress of 35 and 138 kPa (Zornberg et al., 2005). Athanassopoulos and Yuan (2011) evaluated the GCL peel strength-shear strength relationship at normal stresses of 240 kPa, 479 kPa, and 718 kPa and suggested the following relationships for peel strength ranging between 740 to 2,666 N/m:

$$\tau_p=9.73\cdot(Ps)\text{^}0.4101 \quad \sigma_n=240 \text{ kPa} \qquad \text{(Equation 1)}$$

$$\tau_p=24.55\cdot(Ps)\text{^}0.3463 \quad \sigma_n=479 \text{ kPa} \qquad \text{(Equation 2)}$$

$$\tau_p=33.16\cdot(Ps)\text{^}0.3364 \quad \sigma_n=718 \text{ kPa} \qquad \text{(Equation 3)}$$

where τ_p is peak internal shear strength of GCL, Ps is the peel strength, and σ_n is normal stress applied during shear test.

Ghazizadeh and Bareither (2021) evaluated Equation 2 for Ps ranging between 740 to 2,180 N/m for heat and non-heat treated GCLs. They confirmed the general trend suggested in Athanassopoulos and Yuan (2011); however, they found disparities in shear strength results between products with relatively similar peel strength values.

The objective of this study was to: (i) evaluate the Athanassopoulos and Yuan (2011) relationship for higher Ps ranges up to 4,500 N/m; (ii) evaluate the effect of the needle-punching method (i.e., heat treated versus non-heat treated) on the internal shear strength of GCL; and (iii) evaluate the interface shear strength between GCL and geomembrane in high normal stress for heap leach pad applications.

Methods and materials

Characteristics of the eight GCLs used in this study are listed in Table 1. The materials were all commercially available needle-punched GCLs in North America. GCLs in this study were varied between geotextile mass per unit area, peel strength, and needle-punching methods. Two interface shear strength tests between soil and GCL were conducted as part of this study. The soil used in this study was a silty sand compacted to approximately 95% of maximum dry density at optimum moisture content according to standard compaction effort. The maximum dry unit weight of soil was 15.4 kN/m^2 and optimum water content was 20%. Two geomembranes were used in this study to perform the interface shear strength between GCL and geomembrane. Both geomembranes were HDPE and commonly used for heap leach pad application, one geomembrane had a thickness of 60 and the other had a thickness of 80 mm.

Table 1: Characteristics of the geosynthetic clay liners

Characteristic	GCL1	GCL2	GCL3	GCL4	GCL5	GCL6	GCL7	GCL8
Peel Strength , P_s (N/m)	1,874	2,417	2,539	2,434	3,275	3,362	4,448	4,203
Needle Punching Method	NHT[1]	NHT	NHT	HT[2]	HT	NHT	NHT	NHT
Carrier geotextile mass/area (g/m^2)	200	200	200	200	200	200	200	200
Cover geotextile mass/area (g/m^2)	200	200	200	200	200	300	300	300

[1]NHT = non heat treated needle-punching method, [2]HT = heat treated needle-punching method

The laboratory study includes: (i) 21 GCL internal shear strength tests under normal stresses of 287 kPa, 575 kPa, 862 kPa, and 1,724 kPa; (ii) 2 interface shear strength tests between GCL7 and silty sand soil under normal stress of 862 kPa and 1,724 kPa; and (iii) 7 GCL and geomembrane interface shear strength tests. The testing was performed according to ASTM D 6243.

GCL samples were prepared in 300 mm by 300 mm specimens for normal loads up to 861 kPa. Specimens with 150 mm by 150 mm dimensions were prepared for normal stress higher than 861 kPa. Prior to testing, GCLs were hydrated in deionized water for 24 hours under low normal stress of 9.6 kPa. Hydration was followed by a consolidation stage and increased load on top of GCL was doubled every 2 hours until the target normal load was achieved. Then the GCL was consolidated under the target normal load for 24 hours prior to shearing. Shearing was performed using a displacement-controlled method at a shear rate of 1 mm/min.

Results

GCL internal shear strength

A summary of the GCL internal shear tests is listed in Table 2. Data in Table 2 includes normal stress, peak and residual shear strength, secant and peak shear strength, and failure mode. Two general trends were observed for the internal shear strength of GCLs. The peak internal secant friction angle of a given GCL decreased with an increase in normal stress. Additionally, the internal shear strength of GCL increased as peel strength increased for a given normal load. Both of these trends agree with previous findings in the literature (Athanassopoulos and Yuan, 2011; Ghazizadeh and Bareither, 2021).

None of the GCL samples failed internally at a normal load of 287 kPa. The internal shear strength of GCL at a normal load of 287 kPa was higher than the interface strength between GCL's geotextiles and the steel grip of direct shear machine. The same behavior was recorded for high peel GCLs at higher normal stresses. GCL2 did not fail internally at normal stress of 575 kPa and GCL7 did not fail internally at a normal stress of 862 kPa.

A summary of the peak secant friction angle against GCL peel strength for a normal load of 575 kPa is shown in Figure 1. Figure 1 also shows the Athanassopoulos and Yuan (2011) model for a normal load of 718 kPa as well as the maximum peel strength that they used to establish Equations 1 to 3 (peel strength < 2,666 N/m). The secant peak friction angle of non-heat treated GCLs matched with the Athanassopoulos and Yuan (2011) model.

The secant friction angle of non-heat treated GCL was higher than the secant friction angle of heat treated GCL at comparable peel strength. This could be due to the difference in failure mechanism in the peel strength test and direct shear strength test. The secant friction angle of GCL4 was approximately 4.00 lower than GCL 2 despite having very close peel strength (peel strength for GCL2 and GCL4 were 2,417 N/m and 2,434 N/m, respectively). GCL2 and GCL3 resulted in approximately similar peak secant friction angle as GCL5 despite having a lower peel strength. The peel strength of GCL2 and GCL3 were 2,417 and 2,539 N/m, respectively, and GCL5 had a peel strength of 3,275 N/m. This result suggests that the

correlation curves suggested by Athanassopoulos and Yuan (2011) are not applicable for different needle-punching methods. This behavior suggests that the correlation between shear strength and peel strength is different for heat treated compared to non-heat treated GCLs. The higher secant friction angles are achievable with both methods; however, the non-heat treated GCLs can achieve the target shear strength at lower peel strength values.

Table 2: Summary of internal direct shear tests on 150-mm and 300-mm GCL specimens

Product	Normal Load (kPa)	Peak Shear Strength (kPa)	Secant Peak Friction Angle (°)	Long displacement Shear Strength (kPa)	Long displacement Friction Angle (°)	Failure Mode
GCL1	287	276	43	125	23	No Internal
	575	344	31	74	7	Internal
	862	399	25	89	6	Internal
	1,724	646	21	106	4	Internal
GCL2	287	216	37	124	23	No Internal
	575	366	32	184	18	No Internal
	862	477	29	95	6	Internal
GCL3	287	322	48.2	103	19.7	No Internal
	575	370.2	32.8	63	6.3	Internal
	862	469.7	28.6	86	5.7	Internal
GCL4	287	279	44	60	12	No Internal
	575	311	28	63	6	Internal
	862	402	25	82	5	Internal
	1,724	569	18	106	4	Internal
GCL5	287	317	48	96	18.5	No Internal
	575	361	32	60	6	Internal
	862	475	29	77	5.1	Internal
GCL6	862	503	30	79	5	Internal
	1,724	811	25	154	5	Internal
GCL7	862	573	34	572	32	No Internal
	1,724	944	29	159	5	Internal

A summary of the peak internal secant friction angle and peel strength of GCL for normal stress of 861 kPa is shown in Figure 2. The Athanassopoulos and Yuan (2011) model was not plotted for this normal stress since the normal stress of 861 kPa was larger than the normal stress range used in Athanassopoulos and Yuan (2011) study.

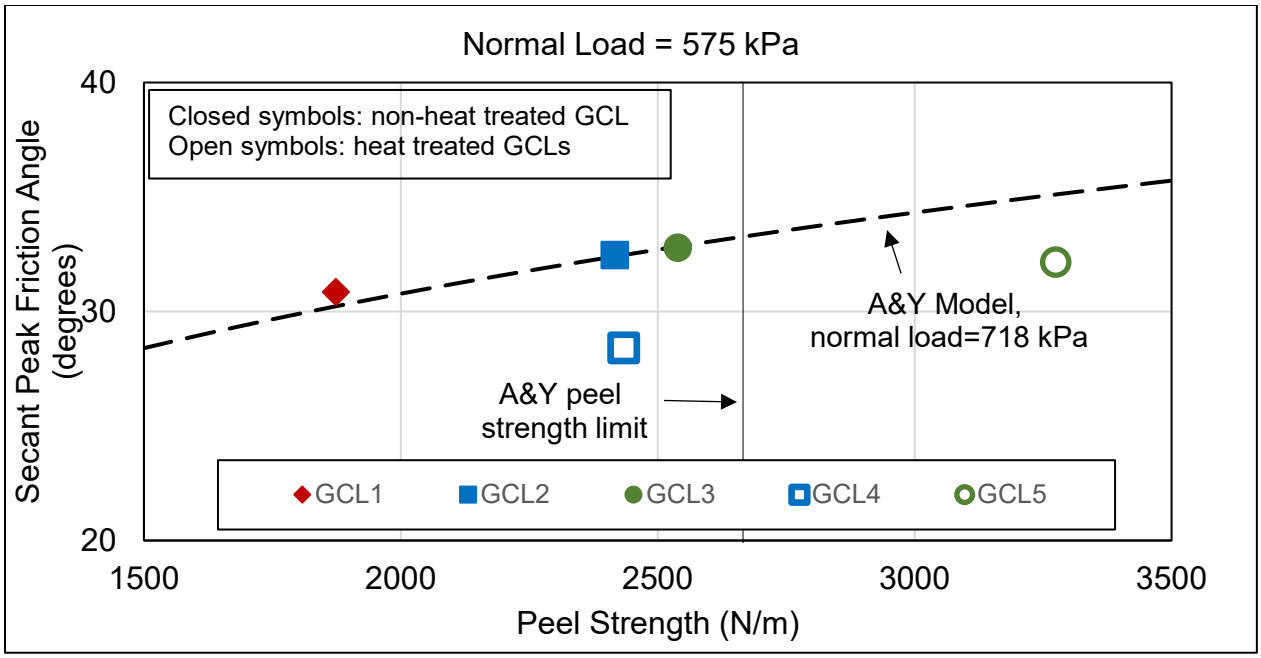

Figure 1: Relationship between internal peak secant friction angle with peel strength of GCL at normal stress of 575 kPa

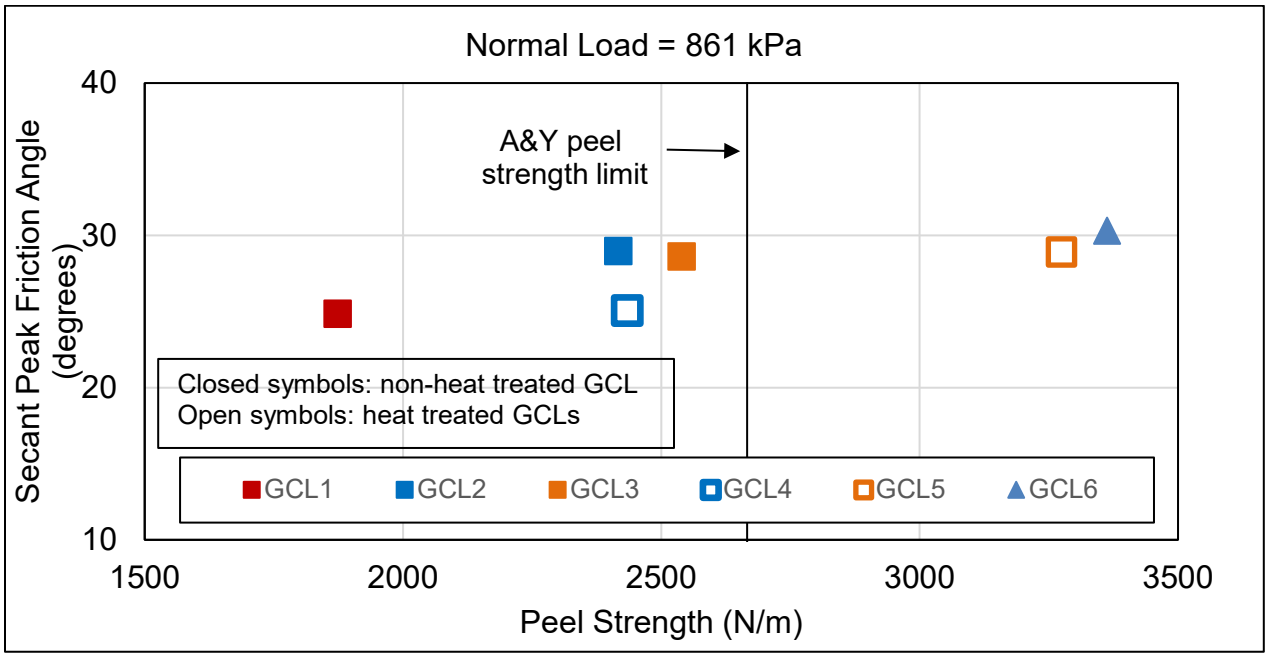

Figure 2: Relationship between internal peak secant friction angle with peel strength of GCL at normal stress of 861 kPa

In general, the secant friction angle increased with an increase in peel strength of GCL when data was evaluated independently (GCL4 and GCL5 as heat treated and GCL1, GCL2, GCL3, and GCL6 as non-heat treated).

Similarly to lower normal stress, the peak secant friction angle of the non-heat treated GCLs were higher than the heat treated GCLs with similar peel strength. Comparison of GCL2 and GCL3 with GCL4 suggests that the secant peak friction angle of non-heat treated GCL is approximately 3.7° higher than the heat treated GCL. Similarly, GCL6 had approximately 1.4° higher peak secant friction angle than GCL5 at approximately similar peel strength. This behavior suggests that high internal shear strength of GCL is achievable with both methods; however, peel strength and needle-punching methods should be considered in combination to evaluate the internal shear strength of a GCL.

A summary of internal peak friction angle of GCLs at a normal load of 1,724 kPa on 150 mm by 150 mm specimens is shown in Figure 3. Similarly, secant friction of GCL increased via an increase in peel strength of GCL in non-heat treated specimens. No conclusion can be drawn for heat-treated GCL since only one heat treated GCL specimen was tested for this normal stress.

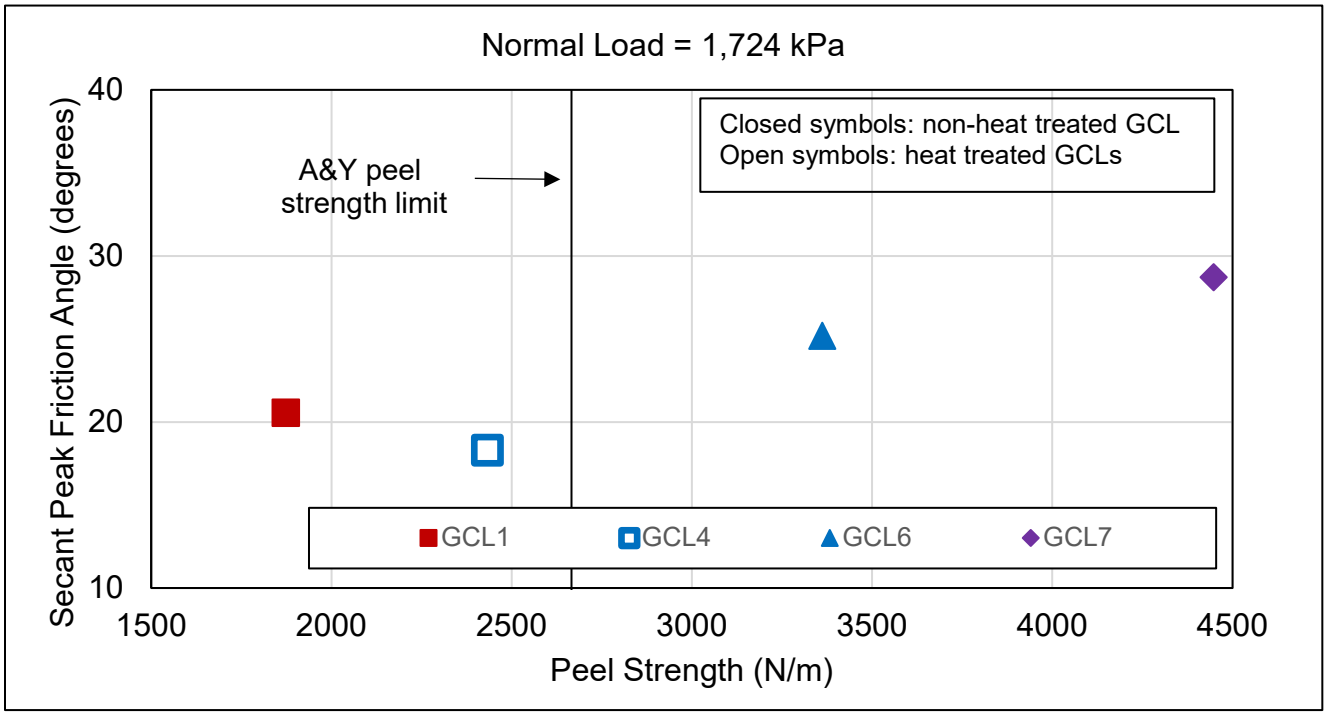

Figure 3: Relationship between internal peak secant friction angle with peel strength of GCL at normal stress of 1,724 kPa

Compacted soil and GCL interface shear strength

Two interface tests were performed between GCL and a compacted silty sand at 95% of maximum dry unit weight at optimum moisture content (dry unit weight = 15.4 kN/m^2 and water content = 20%) to further investigate the shear behavior of the GCL with the highest peel strength (i.e., GCL7). A summary of results is shown in Table 3. GCL7 did not fail internally in normal loads of 862 kPa and 1,724 kPa. The secant

friction angle of interface between silty sand and GCL was 27° and 25°. The long displacement friction angle of 24° and 23° confirms that the failure mechanism did not involve the internal GCL failure.

Table 3: Summary of interface shear strength between GCL7 (peel strength = 4,448 N/m) and compacted silty sand

Normal Load (kPa)	Peak Shear Strength (kPa)	Secant Peak Friction Angle (°)	Long-displacement Shear Strength (kPa)	Long displacement Friction Angle (°)	Failure Mode
862	443	27	377	24	Interface
1,724	817	25	741	23	Interface

Geomembrane and GCL interface shear strength

The results of interface shear strength between GCL8 and two geomembranes are shown in Table 4. Similarly to the observations of Bareither and Ghazizadeh (2021), the peak shear strength and residual shear strength decreased with an increase in normal stress.

Table 4: Summary of interface shear strength between GCL8 and two textured geomembranes

GM thickness (mm)	Normal Load (kPa)	Peak Shear Strength (kPa)	Secant Peak Friction Angle (°)	Long-displacement Shear Strength (kPa)	Long displacement Friction Angle (°)	Failure Mode
60	239	119	26	76	18	Interface
60	718	320	24	195	15	Interface
60	1,436	623	24	310	12	Interface
60	1,915	810	23	399	12	Interface
80	479	242	27	175	20	Interface
80	958	464	26	279	16	Interface
80	3,208	1,350	23	759	13	Interface/Partial GCL failure

However, the complete internal shear strength in GCL was not observed in any of the tests. This is due to the very high peel strength of GCL8, which provided enough internal shear strength to force failure mechanism to the interface between GCL and geomembrane. The only exception is the interface between GCL8 and the 80 mm geomembrane at 3,208 kPa normal stress, which resulted in partial GCL internal failure. This phenomenon happens when some of the GCL needle bonds fail but the two geotextiles do not completely get separated. As a result of the high peel strength of GCL8, the long displacement secant

friction angles range between 12 degrees (for very high normal stress) to 20 degrees (for medium normal stress).

Conclusion

The objectives of this study were to assess the internal and interface shear strength of high peel strength GCL for high normal loads in mining applications (e.g., heap leach pads) and understand the role of needle-punching method on the internal shear strength of GCL under high normal stress. The following conclusions have been drawn based on the results of this study:

- An increase in the peel strength of GCLs resulted in an increase in the internal shear strength of GCLs at a given normal stress, regardless of the needle-punching method (i.e., heat treated or non-heat treated). However, the relationship between peel strength and GCL internal shear strength was unique based on the needle-punching method.
- High secant friction angles were achieved in both heat treated and non-heat treated GCLs. However, the non-heat treated GCLs reached the target shear strength at a lower peel strength.
- Both the internal shear strength and interface shear strength of GCL decreased with an increase in normal stress.
- An increase in the peel strength of GCLs can change the failure mechanisms from the internal failure of the GCL (low long displacement shear strength) to geomembrane-GCL interface (high long displacement shear strength).

Acknowledgements

All of the peel strength and direct shear tests were performed at iSGI Testing Services, LLC. The authors would like to thank Dr Yuan for his useful input in this study.

Prediction of Pore Air and Water Pressure Propagation Induced by Extreme Rainfall in Tailings Dams

Simon A. Lorentz, SRK Consulting, South Africa
Charné Theron, Hanze University of Applied Sciences, Groningen, Netherlands

Abstract

The stability of upstream deposited tailings dams is dependent on maintaining a drawn down phreatic surface and unsaturated profile in its outer edge. However, it has been speculated that intense rainfall events could induce unexpected translation of pore air and water pressures into the tailings profile and thus compromise the effective stress in the unsaturated zone, or result in a sudden rise in the phreatic surface. This phenomenon, known as the Lisse effect, has been observed and studied in hydrological sciences to explain the rapid delivery of antecedent hillslope groundwater during storm events. However, the phenomenon has not been comprehensively applied to evaluating tailings dam slope stability. In this paper, the outcomes of controlled observations of the phenomenon in column and analytical experiments are assembled and evaluated in terms of the surface water application volumes and rate, the properties of the porous media, and the resultant nature of pore pressure and phreatic surface responses. In addition, application of applied theories to evaluate the rapid transmission of pore pressures through a profile in response to an advancing wetting front, leads to the development of a methodology that could be applied to tailings materials with a range of hydraulic conductivities and water retention characteristics. The theory is applied to a series of profiles of different tailings porous media, using varied water application rates. Resultant perturbations in phreatic surface elevation and changes to pore pressures in the unsaturated zone are used to evaluate changes in effective stress distribution in the unsaturated outer wedge and subsequent stability criteria. A possible evaluation algorithm for assessing stability criteria is suggested.

Introduction

The effects of pore air pressure increase due to advancing wetting fronts during extreme rainfall events have been the subject of considerable study (Guo et al., 2008; Sun et al., 2015; Waswa and Lorentz, 2019). Nevertheless, experimental observations are rare, particularly for soil materials of a range of textures. As a first attempt at observing pore air pressure, unsaturated water content, and suction dynamics during an advancing wetting front, tall columns (3 m) were filled with porous media and instrumented. Observations

were used to derive the dynamics of the transfer of pore air pressure to the capillary fringe (saturated porous media above the phreatic surface) and deductions were made on the effects on the effective stress.

These dynamics are illustrated for a sand, a tailings mix, and a platinum tailings material.

Methodology

Two columns that were 3,000 mm tall by 600 mm diameter were filled with porous media and instrumented with sensors to monitor the volumetric water content (TDR), pore water suction (tensiometers) and pore air pressure (especially constructed hollow probes [10 mm diameter] with breather holes and wrapped with a hydrophobic membrane). Pore air pressure was measured relative to atmospheric pressure using a differential pressure transducer attached to the hollow probe (Waswa, 2013). The column layout is illustrated in Figure 1.

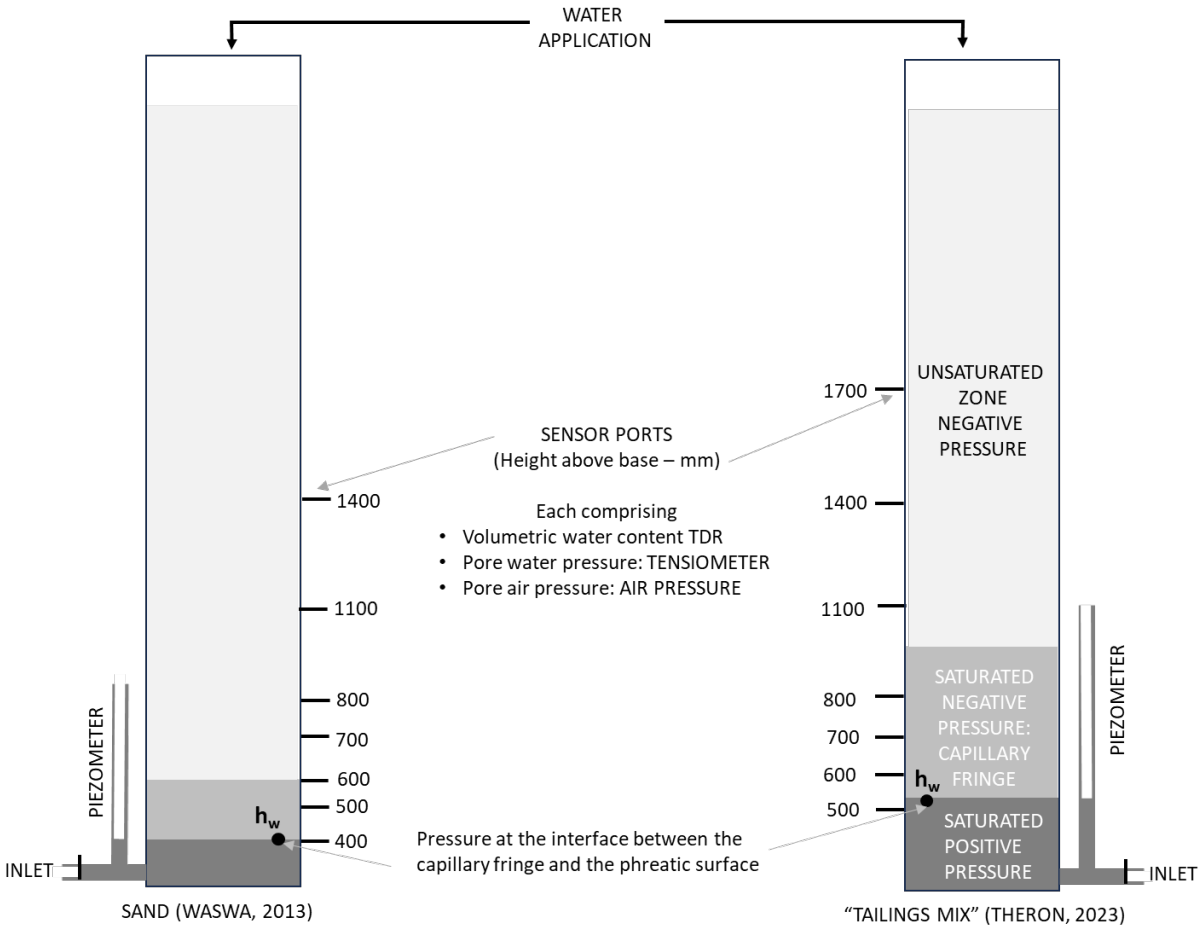

Figure 1: Column tests on sand (left) and tailings equivalent (right)

The first column (Waswa, 2013) was filled with a fine sand and the second with a "tailings mix," made up by combining two fine silica sands with two silica dust fractions so that the final texture was

similar to a known platinum tailings (Theron, 2023). The textural characteristics of the two materials are shown in Figure 2. The saturated hydraulic conductivity of the sand material was 8.7×10^{-5} m/s and that of the "tailings mix" was 7.5×10^{-8} m/s. Water retention characteristics of the materials were derived by air pressure desorption. The resultant van Genuchten parameters for these retention characteristics are listed in Table 1 and the curves are illustrated in Figure 3.

Table 1: van Genuchten hydraulic characteristics of the sand and "tailings mix"

	θ_s	θ_r	α (1/m)	n
Sand (Waswa, 2013)	0.36	0.05	3.15	2.54
Tailings Mix (Theron, 2023)	0.46	0.04	0.12	1.58

The instrumentation was inserted through the column walls and sealed. All the sensors were linked to a logger for recording at 20-second intervals. Water was introduced near the base of the column to establish a phreatic surface near the base (400 mm above the base in the sand and 500 mm above the base in the "tailings mix"). Once equilibrium was reached an extreme rainfall event was simulated by rapidly applying water to the top of the column.

Results

Although additional grades of sand were tested and multiple applications of simulated rain were made during the two experiments, the results of the first application for the fine sand and the "tailings mix" are used in an assessment of the dynamics.

Following Waswa (2013), a simple diffusion equation was used to simulate the transfer of pressure from air to water. The pore water pressure at the interface between the phreatic surface and the capillary fringe (h_w illustrated in Figure 1), was predicted using the diffusion equation solution as:

$$h_w = erfc\left(\frac{y_d}{\sqrt{4d_e t}}\right)$$

Where y_d is the depth of the capillary zone, d_e is an effective diffusion coefficient and t is the time. The diffusion coefficient was derived by fitting the equation to the observed pore water pressure data at the phreatic surface. The sand phreatic surface responded fully in 1 hour, with the applied pore air pressure completely transferred to the capillary fringe (h_w). The "tailings mix" however, took over 65 hours for the transfer of pressure to the capillary zone. These responses resulted in diffusion coefficients of 3.7×10^{-1} m^2/hour for the sand material and 3.0×10^{-2} m^2/hour for the "tailings mix." The responses are shown in Figure 4, together with a simulated response for a platinum tailings impoundment profile, which predicts a phreatic surface rise of almost 2 m.

Discussion

Although the column experiments are somewhat shallow, compared to a profile in a tailings impoundment, the results indicate a significant difference in responses between the sand and the tailings materials. The tailings material took 10 times as long as the sand to respond to the pore air pressure propagation in the capillary fringe. In addition, these responses are far more rapid than the response of a wetting front predicted by Darcy's law. At a unit hydraulic gradient, it is predicted by Darcy's law that a wetting front would take a year to move through 2.5 m, whereas the pore air pressure induced a positive pressure rise in the phreatic surface within 65 hours. Experimental and analytical assessment of the phenomenon have been attempted in hillslope hydrology (Zhao et al., 2017; Waswa, et al., 2013), but attempts to link these responses to slope stability seem to be lacking.

While the rapid rise of the phreatic surface in the capillary fringe has been easily deduced from these experiments, the significance to stability criteria of an increased pore air pressure in the unsaturated part of the profile is less obvious. Relationships have been derived between the suction stress and unsaturated porous media characteristics (Fredlund and Morgenstern, 1977; Sun et al., 2015). The effective stress, (σ') is defined as the difference between the total stress, (σ) and the pore water pressure (μ_w), and the pore water pressure has been defined as the difference between the wetting phase pressure and a suction stress (σ^s), (Sun et al., 2015), so:

$$\sigma' = \sigma - u_a - \sigma^s$$

Where the suction stress is defined in terms of the water retention characteristic parameters as:

$$\sigma^s = -\frac{S_e}{\alpha}\left(S_e^{\frac{n}{1-n}} - 1\right)^{\frac{1}{n}}$$

So, it is evident that an increase in air pressure, without immediate, complete transference to the water phase pressure, may well affect the effective stress in the unsaturated profile of a tailings impoundment and lead to unstable conditions.

Conclusion

Tall column experiments have demonstrated a rapid response to pore air pressure increasing ahead of a significant wetting front. The pore air pressure increase responds immediately to the top surface of the capillary fringe and results in a rise in the phreatic surface. These responses, whether in sandy soils or fine tailings materials, occur far more rapidly than the predicted arrival of the wetting front through Darcy flux. This sudden rise in the phreatic surface could result in unstable slope conditions.

Pore air pressure increases in the unsaturated zone of a tailings profile may also impact the effective stress. Further experimentation and in-situ observation are required to determine how the pore air pressure

increase would influence stability conditions in the unsaturated profile as well as the phreatic surface. It is also recommended that documented tailings slope failures are examined using hydraulic characteristics, initial conditions, and rainfall sequences (up to 21 days antecedent rain) in the light of the mechanisms described here. In-situ, or larger scale tests, using porous media with a range of textures and varying antecedent application rates, are also recommended.
