Asbestos tailings in the historical asbestos mines in Quebec were known to contain significant amounts of magnesium, nickel, iron, and silicon. The tailings sample used in the study contained 24.5% Mg, 0.268% Ni, 5.70% Fe, 17.4% Si. A two-part HCl-NaOH leach process was used to extract magnesium (Mg) from the tailings, while reducing the environmental footprints by valorization of the silicon (Si) content in the tailings to a sodium silicate solution, a precursor for amorphous silica production. The leaching of the asbestos tailings in a 10 M HCl solution at 60ºC for 60 minutes followed by the leaching of the acid leach residue in a 5 M NaOH solution at 60ºC for 60 minutes resulted in over 90% Mg extraction in the acid leachate, and nearly 90% Si extraction in the alkaline leachate. The overall mass reduction of the asbestos tailings was over 90%. The deportment results showed that 91.5% of the Mg was in the acid leachate, 1.03% was in the alkaline leachate and 7.44% was in the final residue. On the other hand, 3.43% of the Si was in the acid leachate, 85.7% in the alkaline leachate, and 10.9% in the final residue. Higher HCl strength (10 M) was found to be crucial not only to achieve high extraction yield for magnesium (> 90% Mg) in the acid leach, but also for higher silicon extraction (~ 90%) in the subsequent alkaline leach. Increasing the leaching time in the acid leach had little effect on the extraction yield of Mg, but undesirably more Si was dissolved in the acid leachate.

Introduction

The mining of chrysotile fibers (asbestos) began in the Eastern Townships of Quebec between 1877 and 1879 (BAPE, 2020). The annual production of asbestos reached its peak at 1.3 million tonnes in the 1980s, before restrictions of its use were in place in numerous countries (Vigneux and Roy, 2010). Asbestos tailings were generated after chrysotile was mined. At least 22 heaps of tailings and waste rocks are situated in three areas (Thetford Mines, East Broughton and Val des Sources, formerly Asbestos) with the total tonnage and area estimated to be over 2.0 Gt and 2240 ha, respectively (Beaudoin et al., 2008; Vigneux and Roy, 2010). According to mineralogical studies of the tailings samples obtained in the areas (Chen et al., 2000; Beaudoin

et al., 2008; Thibault, 2011), over 90% of the materials are serpentine, present mainly as lizardite, $Mg_3Si_2O_5(OH)_4$, with minor antigorite $(Mg,Fe)_3Si_2O_5(OH)_4$, but occasionally chrysotile free fibers are spotted ranging from less than 1% to 38% by volume. Minor amounts of brucite $Mg(OH)_2$, magnetite Fe_3O_4, and awaruite Ni_8Fe_3 are also present. The typical compositions of these asbestos tailings is as follows: 20 – 25% Mg, 0.2 – 0.3% Ni, 5 – 6% Fe and 18 – 20% Si (Ficara et al., 1998; Chen et al., 2000; Holcroft et al., 2018).

The most common remediation strategy for asbestos tailings is to leave them as they are in heaps, as the formation of hard cemented crust on the surface helps to limit the release of fibers into the air. However, other field remediation options, including revegetation and CO_2 sequestration by serpentine carbonation, have been tried (Lechat et al., 2016; Beaudoin et al., 2018). The shortfalls of these options are their inability to reduce the footprints of these tailings, as well as the permanent lock-up of valuable mineral resources present in them. Another well-developed strategy is to reprocess the asbestos tailings, because they are a vast potential magnesium resource, available at little or no cost (Celik et al., 1992; Ficara et al., 1998; Watson et al., 2000).

For over a decade, the Magnola project has directed research and development efforts towards resolving the technical issues in filtration and solution purification associated with the leaching of silicate minerals as well as iron and impurities controls. Technologies for extracting Mg from the asbestos tailings to produce ultra-pure $MgCl_2$ brine suitable for the electrolytic production of high-quality magnesium metal was commercialized and operationalized in Danville, Quebec, between 2000 and 2003. Unfortunately, the Magnola plant was shut down due to the significant drop in the magnesium price at the time (Burstow, 2002; Creber et al., 2011; Habashi, 2017). Nevertheless, the electrolytic production of Mg powered by hydroelectricity (as is the case in Quebec) is considered to produce lower GHG emissions (5 kg CO_2 per kg Mg produced) when compared to the thermal reduction process, the so-called Pidgeon Process (12 kg CO_2 per kg Mg produced), which currently produces around 85% of the world's primary magnesium (Ehrenberger, 2020). Another advantage of extracting Mg from serpentine tailings using concentrated HCl acid is its potential of valorization of the Si content in the tailings as silicates are converted to amorphous silica during the leaching process (Chen et al., 2000; Dutrizac et al., 2000):

$$Mg_3Si_2O_5(OH)_{4(s)} + 6HCl_{(aq)} \rightarrow 3\,MgCl_{2(aq)} + 2SiO_{2(amorphous)} + 5H_2O_{(l)} \qquad \text{Reaction 1}$$

The amorphous silica in the resulting acid leach residue can be dissolved in a concentrated NaOH solution, thus producing a concentrated sodium silicate solution:

$$SiO_{2(amorphous)} + 2NaOH_{(aq)} \rightarrow Na_2SiO_{3(aq)} + H_2O_{(l)} \qquad \text{Reaction 2}$$

The latter can be further purified and used as a feed stock to produce high-quality amorphous silica suitable for a wide range of commercial uses, for example in rubber and chemical sensor applications (Fedoročková et al., 2014 and 2015).

The present study examines the potential of reprocessing the asbestos tailings with a two-part HCl-NaOH leaching process. The objective is to reveal the operating conditions under which the extraction of Mg and Si from asbestos tailings can be optimized. Five series of two-part leaching experiments, involving the leaching of asbestos tailings sample in concentrated HCl solutions in part A, and the leaching of the resulting acid leach residue in concentrated NaOH solutions in part B, were conducted. The extraction yields of the elements of interest (Mg, Ni, Fe, and Si) in both the acid and alkaline leachates were determined based on the compositions of the feed and the product streams. The deportment of the elements, as a result of the two-part HCl-NaOH leaching, were partitioned into three fractions; that is, (i) in the acid leachate; (ii) in the alkaline leachate; and (iii) in the final leach residue. The mass reduction achieved in each leaching step and the overall mass reduction were also reported.

Methods

Materials

An asbestos tailings sample (ABT) was collected in a tailings storage facility in the historical Thetford Mines areas in Quebec. The tailings sample was sent to COALIA, a research laboratory specialized in the safe processing of asbestos materials, where sample preparation, characterization, and leaching experiments were conducted.

Procedure

Five series of two-part HCl-NaOH leach experiments were conducted. Each series of experiments consisted of part A (acid leach) and part B (alkaline leach). The experimental conditions included the initial concentrations of the leachates ($[HCl]_i$ and $[NaOH]_i$), the respective leaching temperatures, T_A and T_B, and retention times, τ_A and τ_B, for each series of experiments are given in Table 1. In part A, a pre-determined amount of tailings sample ABT (250.00 ± 0.12 g) was placed in a known volume of concentrated HCl solution such that the initial pulp density was kept at 45.0 wt.%, which was equivalent to a solid-to-liquid (S/L) ratio of about 2:5. At the end of each acid leach test, the final acid leachate and leach residue were separated and collected. The acid leach residue was washed with a copious amount of deionized water before drying in an oven at 60°C until there was no further change in weight. A portion of the acid leach residue was returned to be used as a feed to part B (alkaline leach tests). A fixed amount (100.00 ± 0.01 g) of the acid leach residue was placed in a known volume of concentrated NaOH solution such that the initial pulp density was kept at 17.0 wt.%, which was equivalent to a S/L ratio of 1:6. The final alkaline leachate

and leach residue were collected following the same procedure used in the acid leach tests. The dried solid and filtrate samples obtained in the leach tests were analyzed for the element of interests using XRF and ICP-OES, respectively. The calculations of the percent extraction and deportment of the elements of interest (Mg, Ni, Fe and Si) are given in the Appendix.

Table 1: Experimental conditions for the two-stage acid and alkaline leach experiments

	Part A (Acid Leach)			Part B (Alkaline Leach)		
Series	$[HCl]_i$ (M)	T_A (°C)	τ_A (min)	$[NaOH]_i$ (M)	T_B (°C)	τ_B (min)
1	5.0.	60.	60.	5.0	60.	60.
2	10.	60.	60.	5.0	60.	60.
3	10.	60.	300.	5.0	60.	60.
4	10.	60.	360.	5.0	60.	360.
5	10.	60.	360.	5.0	90.	360.

Results and discussion

The composition of the tailings sample ABT is given in Table 2. The tailings sample contained 24.5% Mg, 0.268% Ni, 5.70% Fe, and 17.4% Si, and had a LOI of 14.2%. The sample was well homogenized as indicated by the low standard deviations for the elements of interest. The X-ray diffraction pattern of the sample indicates lizardite $Mg_3(Si_2O_5)(OH)_4$ as the major serpentine phase and antigorite (Mg, $Fe)_3Si_2O_5(OH)_4$, as the minor serpentine phase, with a fair amount of magnesium and nickel presented as brucite $Mg(OH)_2$, and awaruite Ni_8Fe_3, respectively. Other iron phases such as magnetite Fe_3O_4 are also present. The mineralogy of the tailings sample ABT is comparable to those previously obtained in the Thetford Mines areas (Chen et al., 2000; Thibault, 2011). The tailings sample was ground and used in the two-part HCl-NaOH leach tests. The bulk particle size distribution (PSD) of the tailings sample is given in Figure 1, whereas the apparent particle size P_{80} was determined to be around 114 μm.

Table 2: Composition of the asbestos tailings samples used in the acid leach (stage A) experiments

sample	Mg (%)	Ni (%)	Fe (%)	Ca (%)	Al (%)	Si (%)	LOI (%)
ABT	24.5	0.268	5.70	0.289	0.807	17.4	14.2
$\sigma \times 10^1$	± 2.18	± 0.279	± 0.784	±0.0412	± 1.29	± 5.34	± 5.01
n	4	4	4	4	4	4	4

There were five series of two-part leaching experiments, involving the leaching of asbestos tailings sample (ABT) in concentrated HCl solutions in part A, followed by the leaching of the resulting acid leach

residue in concentrated NaOH solutions in part B. The compositions of the resulting leach residues and leachates obtained in part A and part B leach tests are shown in Tables A1 to A4 in the Appendix.

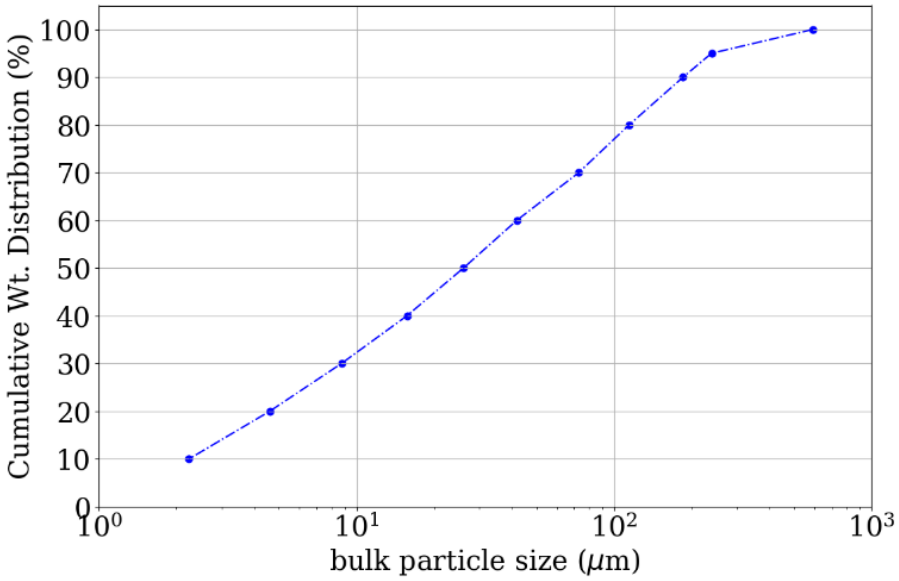

Figure 1: The bulk particle size of the asbestos tailings sample (ABT) with P_{80} of 114 µm

Effects of HCl strength

In Series 1 of the two-part HCl-NaOH leach experiments, the tailings sample was leached in a 5 M HCl solution at 60ºC for 60 minutes in part A, followed by part B, leaching of the leach residue obtained from part A in a 5 M NaOH solution at 60ºC for 60 min. The extraction yields of the elements of interest (Mg, Ni, Fe and Si) in each part are presented as a bar chart in Figure 2. The results of Series 1, denoted as (A1: 5M HCl) and (B1: 5 M NaOH), showed that over 90% of Ni but less than 60% of Mg and around 45% of Fe were extracted in the acid leachate, while around 50% of Si was extracted in the alkaline leachate. In Series 2, the HCl strength in part A (acid leach) was increased from 5 M to 10 M. As a result, both the extraction yields of Mg and Fe increased to over 90% (see bars denoted as A2: 10 M HCl). Importantly, the extraction yield of Si in the subsequent alkaline leach (B2: 5 M NaOH) increased significantly to almost 90% despite all conditions being identical to that used in Series 1, except for the increase in HCl strength. The HCl strength not only increased the extraction yield of Mg in the acid leach stage but also enhanced the dissolution of Si in the subsequent alkaline leach stage.

However, at a higher HCl strength, the co-extraction of Fe also increased from 45 to 90%. This suggested that at least one of the Mg- and Fe-bearing silicate minerals present in the tailings sample was leached only at higher HCl strength, resulting in more silicate minerals converted to amorphous silica as in Reaction 1. The use of higher HCl strength was necessary in the acid leach stage for a higher extraction

yield of Si in the subsequent alkaline leach stage. Higher HCl strength resulted in higher mass reduction in the acid leach step (Series 1: 31.7% vs. Series 2: 39.3%), and significantly higher mass reduction in the subsequent alkaline leach step (Series 1: 38.1% vs. Series 2: 85.2%), as shown in Figure 2.

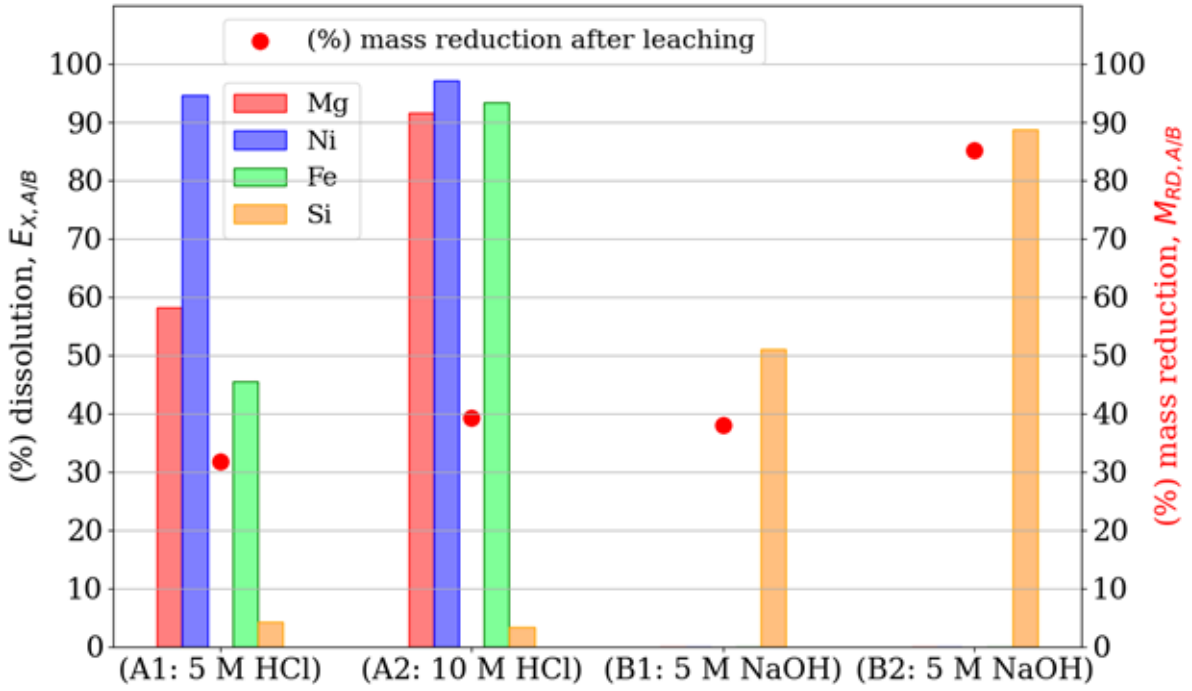

Figure 2: The comparison of the percent extraction, $\%E_{X,A/B}$, of the elements of interest (Mg, Ni, Fe and Si) and the percent mass reduction, $\%M_{RD,A/B}$, in the two-part (A) HCl - (B) NaOH leach process conducted with 5 M and 10 M HCl strength (Series 1 vs. Series 2)

Effects of retention time and temperature

The retention time of the acid leach (part A) was increased from 60 minutes in Series 2 to 300 minutes in Series 3. When comparing the results of Series 3 to Series 2, there was no considerable difference in terms of Mg, Ni and Fe extraction, except a higher Si extraction (6.15% vs. 3.43%) in the acid leach. The retention time of the acid leach (part A) was further increased to 360 minutes in Series 4. Again, no considerable difference was observed when the results of Series 4 were compared to those obtained in Series 2 and 3. However extended retention time in the acid leach resulted in more Si extracted in the acid leachate (i.e., 16.4% in Series 4), but it had little effect on the extraction of Si in the alkaline leachate. An increase in the temperature of the alkaline leach from 60 to 90°C in Series 5 also had little effect on the extraction of Si.

Deportments of Mg, Ni, Fe and Si

Based on the compositions of the acid and alkaline leachates as well as the final residues obtained in the five series of two-part HCl-NaOH leach tests (see Tables A1 to A4 in the Appendix), the deportments of the

elements of interest under various leaching conditions are mapped out in Figure 3. The deportment results showed that the leaching of the asbestos tailings in a 10 M HCl at 60°C, followed by the leaching of the acid leach residue in a 5 M NaOH solution, resulted in the maximum extractions of Mg, Ni, Fe and Si in the leachates (refer to Series 2). The amount of Mg, Ni, Fe, and Si remaining in the final residue obtained from Series 2 were 7.44%, 1.30%, 5.22%, and 10.9%, respectively. The deportments of Mg, Ni, and Si in the acid leachate were 91.5%, 97.1%, 93.4%, and 3.43%, respectively. The deportments of Mg, Ni, and Si in the alkaline leachate were 1.03%, 1.55%, 1.41%, and 85.7%, respectively. The overall mass reduction after the two-part HCl-NaOH leaching was around 90%.

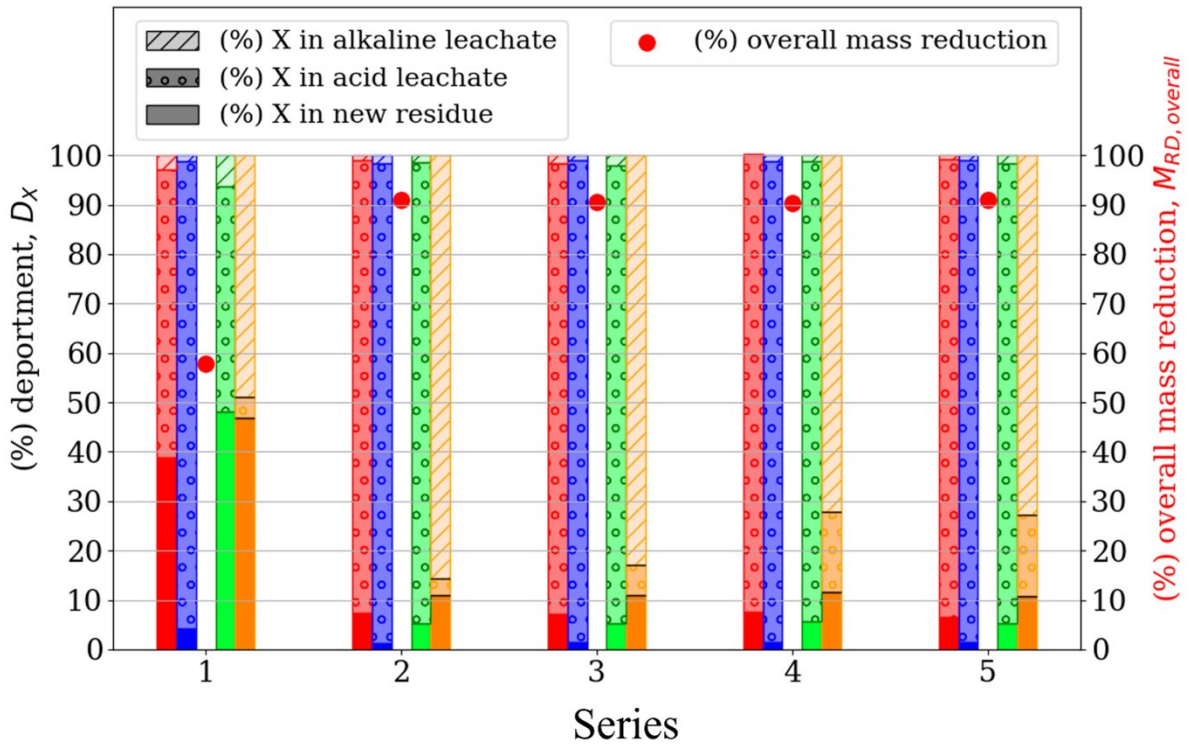

Figure 3: The deportments of the elements of interest, $\%D_X$, where X: Mg (red), Ni (blue), Fe (green) and Si (orange), and the percent overall mass reduction, $\%M_{RD, overall}$, in the five series of two-part HCl-NaOH leach process

Conclusion

1. The leaching of asbestos tailings sample ABT in a 10 M HCl solution at 60oC in 60 minutes, followed by the leaching of the resulting acid leach residue in a 5 M NaOH solution, resulted in over 90% extractions of Mg and Ni in the acid leachate and nearly 90% Si extraction in the alkaline leachate.
2. The use of higher HCl strength (10 M vs. 5 M) was found to be crucial not only in achieving higher Mg extraction in the acid leach but also in reaching higher Si extraction in the subsequent alkaline leach step.

3. The increase in the acid leach retention time had not improved the extraction of Mg and Ni but undesirably increased the dissolution of Si in the acid leachate.
4. The increase in the alkaline leach temperature and/retention time had not improved the extraction of Si in the alkaline leachate.

Appendix

Calculations

The percent extraction of the elements of interest (X: Mg, Ni, Fe, and Si) in part A (acid leach), $\%E_{X,A}$, and part B (alkaline leach), $\%E_{X,B}$, can be determined with this equation:

$$\%E_{X,A/B} = (1 - \frac{\%X_P \times m_P}{\%X_f \times m_f}) \times 100\% \quad \text{(A1)}$$

where m and $\%X$ are the mass and the percent content of element X in the solid sample. The subscripts, f and p, correspond to the terms for the feed and the leach residue, respectively. The deportments of the respective elements are partitioned into three fractions: those reported to (i) acid leachate, (ii) alkaline leachate and (iii) final leach residue. The percent deportment of element X in the acid leachate, $\%D_{X,A}$ is the amount of element X extracted from the tailings sample ABT in part A (acid leach) and can be equated as:

$$\%D_{X,A} = \%E_{X,A} \quad \text{(A2)}$$

The deportment of element X in the alkaline leachate, $\%D_{X,B}$ is the amount of element X extracted from the acid leach residue in part B (alkaline leach) and can be written as:

$$\%D_{X,B} = (100 - \%E_{X,A}) \times \%E_{X,B} \quad \text{(A3)}$$

Then, the deportment of element X in the final alkaline leach residue, $\%D_{X,S}$ is determined by differences; that is:

$$\%D_{X,S} = 100 - \%E_{X,A} - \%E_{X,B} \quad \text{(A4)}$$

The percent mass reduction, $\%M_{RD,A/B}$ as a result of acid leaching in part A or alkaline leaching in part B is determined by this equation:

$$\%M_{RD,A/B} = (1 - \frac{m_P}{m_f}) \times 100\% \quad \text{(A5)}$$

whereas the overall percent mass reduction, $\%M_{RD,overall}$ is equated as:

$$\%M_{RD,overall} = \%M_{RD,A} + \%M_{RD,B} - \frac{\%M_{RD,A} \times \%M_{RD,B}}{100} \quad \text{(A6)}$$

Evaluation of Best Available Technologies and Practices for Tailings Seepage Detection and Monitoring at Cobre Panamá

John H. Fortuna, FloSolutions, Ecuador
Carlos Hubner Torres, First Quantum Minerals, Cobre Panamá, Panamá

Abstract

The Cobre Panamá porphyry copper project is in the District of Donoso, Colon, 120 kilometers west of Panamá City. Mining is open pit; processing includes in-pit primary crushers, overland conveyors to secondary crushers, SAG mills, and ball mills. A flotation circuit produces copper sulfide concentrates, delivered by slurry pipeline to a filter plant co-located at a purpose-built port facility. Tailings are stored in a downstream-construction tailings management facility (TMF), and water is reclaimed for operations. Commercial production started in 2019.

At all TMFs, proper control of seepage and gradients in the tailings embankment and foundation is fundamental for successful facility performance, physical stability, and environmental protection. Cobre Panamá has methods in place to measure seepage from the embankments and foundation that reports to onsite collection systems, and a robust surface water and groundwater monitoring program. Given the tropical monsoon climate and the associated challenges of detecting dilute seepage, Cobre Panamá initiated a study to evaluate collection system efficiency and potential for seepage bypass. This study also sought to develop and comprehensively assess practical solutions to measure and estimate seepage rates, informed by field monitoring, best available technologies (BATs), and best available practices (BAPs). About 20 technologies and alternatives were assessed systematically and ranked in terms of capital and operational cost, time for implementation, complexity, accuracy, and precision of results. A process for technology identification, screening, scoring, and selection, including incorporation of site-specific selection and ranking criteria, is described. Selected technologies and best practices include instrumentation upgrades, new detection technologies, incorporation of telemetry and data management practices, and preparation of a mitigation action plan that describes the steps and actions that will be taken to evaluate and mitigate any seepage release.

Introduction

First Quantum Minerals Limited (FQM) is the 90% owner of Minera Panamá S.A. (MPSA), the Panamanian company that holds the Cobre Panamá concession, and is the operator of the Cobre Panamá Mine. This study was undertaken to evaluate alternatives to improve seepage monitoring from the tailings management facility (TMF) of the Cobre Panamá mining project.

At the time of this study (2022), Cobre Panamá had in place a robust TMF monitoring strategy, including a downgradient surface water and groundwater monitoring network, and was in full compliance with all regulatory requirements for environmental monitoring and reporting. However, Cobre Panamá was concerned that due to the high rainfall environment, there might still be a potential for dilute seepage to bypass collection and monitoring systems. This study was undertaken to assess if there were better ways to assess and monitor seepage, so as to prevent any release to the environment.

Background

The TMF is located next to the main pit and the process plant. The impoundment footprint is 20 square km, with sides roughly 4 km by 5 km. There are two large embankments of 4 and 3.5 kilometers at the east and north limits (East and North dams). The starter dams of both embankments were constructed up to a dam crest at 76 meters above sea level (masl). Their design included an adequate foundation, core, rockfill, and filters blanket and chimney. The continuous construction of the embankment uses cyclone sand obtained from tailings up to the ultimate dam crest elevation of 146 masl (Figure 1).

Figure 1: Cyclone sand embankment construction at Cobre Panamá

The TMF started to receive tailings in late February 2019. Two initial downstream lifts have been completed with a dam crest elevation of 85 masl, including a downstream buttress. Future lifts of the embankment may move to a modified centerline method.

Project objectives

The Mine is in a wet tropical environment on the Caribbean coast of Panama and receives up to 3.5 m of rain per year. The TMF construction method – hydraulic sand slurry discharged to the construction area – combined with the wet climate, lead to difficulty in isolating the seepage rate from other sources of water that mix with it and report to the same location.

At all TMFs, proper control of seepage and seepage gradients in the tailings embankment and foundation is fundamental for successful facility performance, physical stability, and protection against internal erosion (Byler and Morrison, 2022). At present, Cobre Panamá has methods in place to control and measure seepage from the embankments and foundation that reports to onsite collection systems. However, the potential for seepage to bypass collection systems has not been evaluated systematically.

This study was undertaken to identify and evaluate practical solutions to measure and estimate seepage rates, informed by field monitoring, best available technologies (BATs), and best available practices (BAPs).

Evaluation approach

Relevant guidance

Development and ranking of alternatives considered the framework of the GlobalTailingsReview.org / International Council on Mining and Metals (ICMM) "Global Industry Standard on Tailings Management" (ICMM, 2020). Topic III: "Design, Construction, Operation, and Monitoring of the Tailings Facility" and Topic IV "Management and Governance" contain key principles related to design and implementation of monitoring systems to manage risk at all phases of the facility lifecycle. This assessment also considers the integration of tailings and water management, including hydrology and hydrogeology data, into water management plans and practices as advocated by the ICMM "Tailings Management Good Practice Guide" (ICMM, 2021).

Consideration of site conceptual model

Assessments of seepage and collection system bypass must start with a robust understanding of the site conceptual model, degree of hydrogeologic complexity, natural hydraulic containment, expected interactions between the TMF and groundwater, and the potential for seepage risk. The level of certainty in the site characterization and site conceptual model must also be considered.

Engineered structures, including seepage collection and containment systems, can have unintended consequences on the tailings-groundwater system, with several examples documented at major copper TMFs globally (Fortuna et al., 2021). At Cobre Panamá, rockfill starter dams have a saprolitic core anchored in the foundation up to the design height of the crest (76 masl), with an additional 9 m of saprolitic face (76 to 85 masl) to mitigate seepage.

Review of best available technologies and practices

In general, BATs are technologies that help identify and assess risk, and BAPs are practices, strategies, and ideas that help manage risk or reduce the probability of occurrence (Boswell and Sobkowicz, 2015). A more detailed description of BATs and BAPs is available from the Mining Association of Canada (MAC) (MAC, 2021).

While there is a recent history of application of BATs/BAPs to TMFs (e.g., Boswell and Sobkowicz, 2015), studies on BATs and BAPs for control of seepage problems are lacking. Recent guidance documents that include BATs/BAPs assessments (MEND, 2017) are focused primarily on tailings storage type (e.g., conventional vs. filtered vs. paste) and do not consider seepage control and potential environmental impacts. MAC (2021) briefly discusses seepage management and control technologies, but only in terms of the original design and engineering elements emplaced during construction (i.e., use of liners, underdrains, and water retaining dams).

Screening of BATs against technology selection criteria should result in selection of the solution that most effectively reduces the physical, geochemical, ecological, social, and economic risks associated with seepage during the entire tailings storage life cycle. Upon selection, these technologies can be integrated more broadly into BAPs for seepage detection of monitoring. A schematic illustrating this overall process is shown in Figure 2.

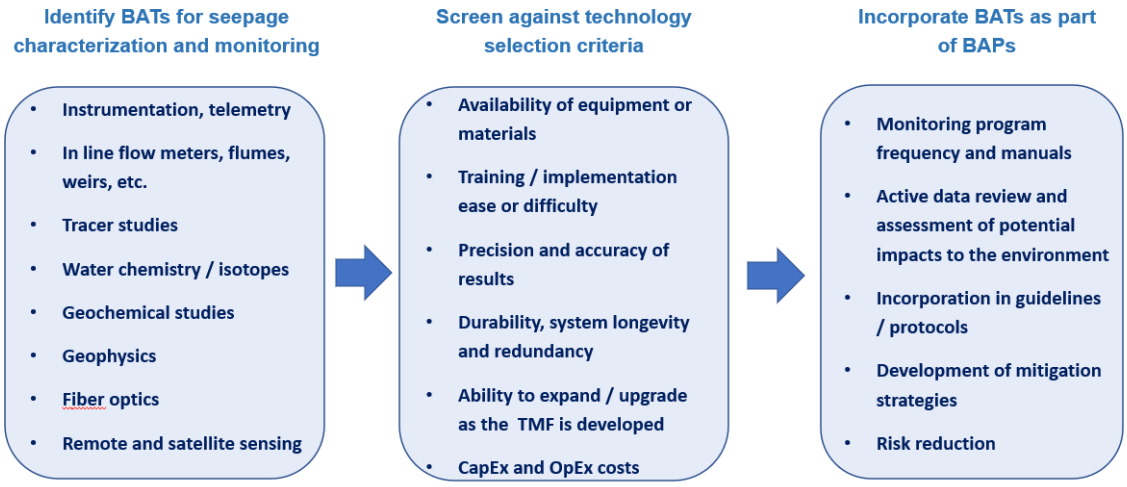

Figure 2: Schematic illustration of the application of BATs/BAPs to seepage characterization

There is often a heavy emphasis on technology selection and instrumentation at TMFs, but in our experience BAPs are equally if not more important in the monitoring of overall TMF performance. Development of appropriate management systems, monitoring plans, and operational procedures are fundamental to getting the most out of the selected technologies.

Technology identification and screening

Technology identification considers all readily available technologies that may be suitable for meeting project objectives, including new and emerging technologies. In addition to literature searches and reviews, we held numerous teleconferences to discuss applications and case studies with suppliers and vendors, including CGG SA, EWS Australia, SkyGeo, Silixa Ltd, and others. The process we used for identification and selection of technologies for incorporation into BAPs is illustrated graphically in Figure 3.

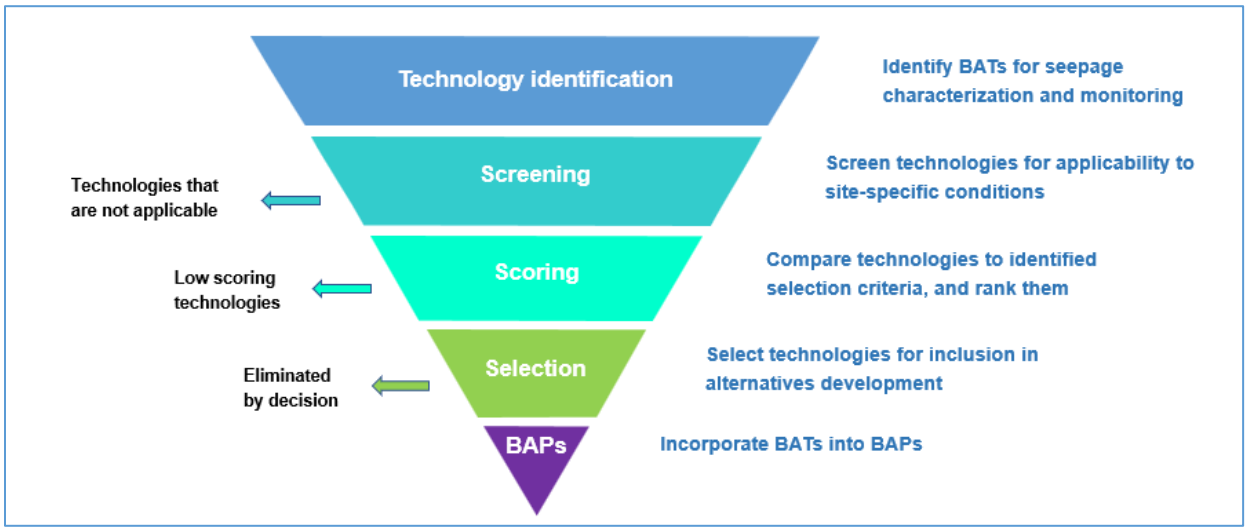

Figure 3: Technology identification and screening process

Technologies available for the monitoring of TMFs and seepage processes are constantly evolving and advancing. Monitoring systems generally fall into two categories of systems: i) terrestrial-based; and ii) remote systems (Hatton and Chapman, 2022). Monitoring frequency, data recovery, and data management practices need to be considered as part of monitoring systems. Automated data collection systems allow for enhancements in these areas. For example, use of electronic sensors linked to satellite-based telemetry systems combined with secure web-based data portals provide real-time access for viewing instrument measurements, data trends, and exceedances of water quality criteria.

The technology screening process considers the applicability of these different technologies to the site-specific conditions and project objectives at Cobre Panamá that may limit their use, or materially affect their potential performance. Technologies that do not meet project objectives are unlikely to function properly based on site conditions that have been eliminated during the screening process. All technologies

that pass to the technology screening phase are considered potentially able to meet project objectives and aid in compliance with the Environmental and Social Impact Assessment (ESIA) and permit conditions for seepage detection and monitoring.

Technology selection and scoring

The approach to technology selection uses a criteria-based decision matrix with criteria scoring. Key steps in this process are as follows:

1. Identify relevant user requirements or criteria.
2. Develop weights for each of the requirements.
3. Generate several viable technologies for a solution.
4. Select one of the technologies as a baseline to establish the current state.
5. Evaluate each alternative technology against the baseline, scoring it as positive, negative, or equal in meeting the criteria.
6. Total the values from each option, multiplying each value by its weight if the optional scoring mechanism was used.
7. Combine the best elements of each technology to create an optimal hybrid solution.

There are many potential criteria that can be used for technology selection, as illustrated graphically in Figure 4. Criteria may include commercial risk, technical feasibility, team skills and confidence, system redundancy, and other factors. Best practice dictates that a limited number of key criteria be used to streamline the ranking and selection process. Use of too many criteria may slow down the process or result in several technologies scoring within a narrow range, making selection more difficult.

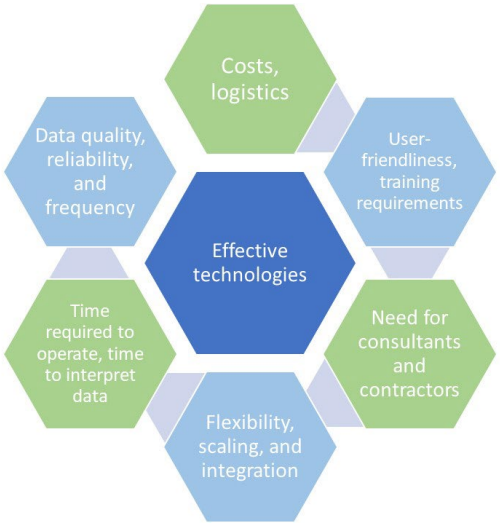

Figure 4: Example of technology screening criteria

Criteria should be selected from each of the general categories important to corporate approval and technology implementation: "technical," "people," "economic," and "operational" categories. This will ensure proper balance in scoring. Evaluation criteria are rarely of equal importance, and the selected criteria should be weighted based on how important they are to final technology selection. Numerical scales are used for criteria weighting (typically from 1 to 5 or 1 to 10), with input from the operational team on the relative importance of each criterion. The baseline for comparison is typically the "current state," in this case, the ongoing water level measurements and water quality monitoring program.

Alternatives development

Following the technology scoring and selection, we developed alternatives and recommendations to incorporate BATs into BAPs for the Cobre Panamá site. Each alternative is a combination of one or more technologies that follow a common implementation theme, e.g., installation of vibrating wire piezometers (VWPs) and groundwater wells with manual water level measurements – where the activities undertaken as part of the alternative are complimentary.

Based on experience at similar sites, seepage detection and monitoring technologies may be different for detection of embankment seepage than they are for downgradient seepage bypassing collection systems. We have developed alternatives with consideration of implementation difficulty, complexity, accuracy of measurements, training required to implement, expected monitoring frequency, capital and operational costs, and other site-specific factors.

Technology identification and screening

Technology identification describes all technologies considered as part of our assessment and preliminary screening to assess applicability to the project site. The screening includes both terrestrial and remote monitoring systems, as well as a variety of instrumentation, measurements, and study techniques.

Terrestrial monitoring systems and instrumentation

Piezometers and water level measurements

Piezometers and vibrating wire piezometers (VWPs) are important instruments at most TMFs. Measurement of changes in water levels and gradients are one of the primary ways to detect changes in TMF-groundwater system behavior, including changes related to seepage discharge.

Groundwater wells and water quality data

Groundwater wells allow for collection of water quality samples. Water quality parameters elevated in tailings pond water relative to groundwater can serve as natural tracers for seepage flow. Use of exploratory

data analyses and machine learning (EDA/ML) techniques applied to the entire water quality data set can be effective at identifying unique water signatures and seepage impacts (Ezzy and Fortuna, 2020).

At Cobre Panamá, primary and secondary seepage indicator parameters and levels have previously been identified. Water quality monitoring is highly effective for seepage detection at this site. Additional water quality parameters, such as stable isotopes of oxygen and hydrogen, may provide insights into surface water-groundwater interactions and flow pathways.

Drain flow monitoring

Flow monitoring in drain systems helps understand changing system dynamics in the TMF. Changes in drain flow may indicate changes to seepage rates from the TMF, or phreatic surface levels in the embankments. A complete monitoring system must include drain flow rates, drain water quality, and water levels in piezometers in embankments.

Seepage collection facility monitoring

There are 7 sand/seepage collection facilities (SCFs) distributed in the north (3 SCFs) and east dams (4 SCFs). The SCFs consist of seepage collection ponds and trenches linked to pumps, pumping stations, and piping to route water back to the TMF pond. The SCFs may be useful for monitoring or estimating seepage if the relative contributions from various water sources can be distinguished. Water collected at SCFs may include multiple sources, including water from slurry sand construction of embankments, rainfall runoff, seepage from the TMF, and shallow groundwater discharge to SCF trenches, where they intersect the water table. Discharge/pumping volumes in SCFs can be related to these various components using a water balance approach.

Tracer studies

To date applied tracer studies have seen little application to TMF sites, perhaps because travel times through tailings are excessively long and monitoring for “natural” tracers like elevated sulphate in TMF pond water serve almost the same purpose. Tracer testing applications at TMFs are typically concerned with travel times and flow pathways (British Geological Survey, 2007), but they have also been used for a variety of other purposes including quantification of tailings properties and characterization of fluid flow behavior (Divine et al., 2013).

Perimeter fiber optics

Great advances have been made in the development and application of distributed fiber-optic sensing systems over the last decade. There are two basic classes of these systems that can be employed at TMFs. Distributed acoustic/vibration sensing systems (DAS or DVS), and distributed temperature sensing systems

(DTS). DAS technologies detect vibrations and capture acoustic energy along optical fibers. Classification algorithms are used to detect and located acoustic "events" such as leaks, cable faults, or strain deformation (AP Sensing, 2022). DTS technologies function as linear temperature sensors, which can be used to generate a continuous temperature profile along the entire sensor cable.

Fiber optical sensing offers the advantage of cost-effective, high spatial monitoring coverage (Mondanos and Johansson, 2020). Seepage can be tracked through seasonal temperature variations common in surface water. Key advantages over traditional sensing systems include precision, durability, reliability, density of information, and economic aspects (Inaudi and Blin, 2016). In Sweden, more than 100 dams have been outfitted with fiber optic cables for detection of seepage using DTS (HydroResearch; Silixa; Sisprobe, 2020). Most installations are made by installing cables in the dam toe, upstream of the drainage system, or just downstream of the dam (Mondanos and Johansson, 2020). Recent study results show that temperature monitoring in the upstream filter gives information about seepage inflow areas, while measurements in the dam toe provide information about small leakage flows (HydroResearch; Silixa; Sisprobe, 2020

Ground geophysics

Various ground geophysics techniques have been explored for use in seepage detection monitoring over the last 20+ years. Combinations of self-potential (SP), direct current (DC) resistivity, induce polarization (IP) and transient electromagnetic (TEM) methods have been applied to mine sites to develop a clearer understanding of seepage problems (Buselli and Lu, 2001). Focused research into this topic have identified electrical resistivity (ERT) and SP as potentially applicable to seepage detection, but background changes to dam conditions (e.g., embankment raises) affect responses, and it takes a long time for equilibrium conditions to reestablish (Mainali, 2007).

Seepage paths have also been mapped using Electric-based technology, where a low voltage, low amperage alternating electrical current is used to energize water by electrodes placed in tailings and another in contact water below the tailings dam. Successful case studies have been published (Urlich and Garnder, 2017) demonstrating the use of this technology for mapping seepage pathways and increasing understanding of flow pathways between sources and discharge areas.

Seismic interferometry

Ambient seismic noise interferometry is a relatively new technique to identify subsurface changes associated with strain or saturation, potentially including seepage (Hatton and Chapman, 2022).

In one study, the authors recorded three weeks of continues data during a period of heavy rainfall using 10 short-period geophones at a tailings dam in Tasmania (Olivier et al., 2017). Although this study was not specific to seepage, the implication is clear: if seepage losses result in additional saturation (i.e., of

a previously unsaturated zone), then it could be detected using this method. Currently, this technology is being trialed at several other facilities; however, it may be more appropriate for monitoring seepage build-up in embankments rather than detecting seepage losses downstream.

Remote monitoring technologies

Remote monitoring includes aerial photography/unmanned aerial systems, and satellite-based systems. Remote monitoring systems may be passive – utilizing naturally occurring radiated or reflected energy screened based on discrete wavelength or spectrum, or active – where the sensor system emits energy such as laser or radio waves and measures the reflected condition (Hatton and Chapman, 2022).

UAV/drone surveys

The sheer size of most TMFs combined with the potential for environmental or stability risks inherently make appropriate surveying and monitoring costly and difficult. Surveys using unmanned aerial vehicles ("UAVs" or "drones") have gained widespread acceptance for tailings applications due to the low cost and potential to survey large areas quickly and easily. Drone surveys can provide a variety of different types of information depending on sensor configuration but are commonly used to survey topography and monitor changes in embankment deformation or displacement, tailings volumes/material placement, pond size, tailings subsidence and consolidation (Rauhala et al., 2017). In terms of seepage detection and monitoring at TMFs, at least one provider advocates for use of drone surveys with a thermal camera + HD imaging (Skymine AUV, 2022).

The ability of a UAV survey to detect seepage depends on two principal factors: 1) the expected change in the environment that the seepage will create and 2) the ability of the sensor to detect that change. A UAV survey may be useful in identifying any preferential flow pathways through embankments or the shallow subsurface – particularly in environments where the surface water (tailings pond) temperature is significantly different than groundwater temperature.

Satellite sensing

Early applications of satellite sensing for TMF seepage monitoring focused on vegetation health surrounding the facilities, as determined by satellite-based monitoring indices using combinations of surface reflectance at two or more wavelengths (Chetty, 2013). More recent "Earth Observation" ("EO") techniques include optical-based satellite data, Global Navigation Satellite System, Global Weather forecasting models and Interferometric Synthetic Aperture Radar (InSAR).

Recent research across a range of these techniques have concluded that while these technologies can be used to improve dam monitoring and reduce risk posed by failure, particularly in remote environments, they are not a substitute for onsite measurements (Lumbroso et al., 2021).

LiDAR

Advanced light detection and ranging (LiDAR) sensors are gaining widespread acceptance for monitoring of tailings facilities, principally for monitoring of dam highwalls to detect movement or deformation. LiDAR deployment by manned aviation is common, but often cost-prohibitive. In the past, the poor weight-bearing capacity of traditional drones has limited their ability to carry LiDAR technology. Larger modern multi-rotor drones and fixed wing unmanned aerial systems are suitable for this purpose (Rocket Mine, 2022), and can be more accurate than those due to the higher point density obtained by flying at lower altitudes (WingtraOne, 2022). A key advantage of LiDAR is the ability to sense in areas of moderate to dense forest canopy.

The applications of LiDAR to seepage detection and monitoring are limited. Although some providers claim they can detect zones of saturation with this technology, and by proxy changes to the elevation of the groundwater table, seepage detection use cases at TMFs are not well established.

InSAR

Interferometric Synthetic Aperture Radar (INSAR) is a remote, satellite-based technology for measurement of millimeter-scale displacement in the ground surface. INSAR relies on interferometry – the collection and interpretation of two SAR images acquired at different times over the same area. Interferometry and interpretation of these measurements are used to estimate displacement.

Due to the frequency with which potential displacements can be monitored, many mine sites are adapting this technology for routine TMF monitoring. The use case for seepage monitoring is less established; however, there are documented cases where visual signs of seepage have been correlated to localized horizontal displacement or "bulging" near the seepage location (personal communication with SkyGeo, 1 March 2022).

In February 2022, an "InSAR Feasibility Report" for monitoring of the TMF embankment was prepared by CGG for the Cobre Panama Mine. The report indicates some InSAR limitations at this site including dense vegetation, which SAR struggles to penetrate, and active mine operations which change the ground cover too rapidly to remain coherent. Based on the reported results during the trial, this technology is not considered sufficient for seepage detection and monitoring at this site.

SkyTEM

SkyTEM is an airborne electromagnetic method (AEM) originally developed at Aarhus University in Denmark. SkyTEM systems can map the near surface in high resolution concurrently with accurate high-resolution measurements to depths over 500 meters (Skytem, 2022). The technology has been effectively demonstrated for accurately mapping water levels and salinity in complex environments (Kirkegaard, et al., 2011).

SkyTEM has seen numerous applications to TMFs. Tailings are typically highly conductive due to the presence of high salt, acid, or base contents in dam waters. Typical objectives of these surveys are detection of conductive seepage plumes downstream of embankments, mapping of permeable geologic features like faults, mapping depth to bedrock, and assessment of groundwater interception systems (Reid, Christensen, and Godber, 2012). Substantial advances in the development of both hardware and inversion software since 2005 have resulted in data and results from an airborne (helicopter) platform from time domain methods that are comparable to ground-based geophysical systems (Auken et al., 2015).

Automated data collection and telemetry

In addition to instrumentation, monitoring frequency, data recovery, and data management practices need to be considered as part of monitoring systems. Automated systems allow for enhancements in these areas. Use of electronic data collection and satellite-based telemetry systems combined with secure web-based data portals provide real-time access for viewing instrument measurements, data trends, and exceedances of water quality criteria.

Telemetry systems

Automatic data acquisition of geotechnical and hydrogeologic instrumentation is usually done by connecting instruments via cabling or wirelessly to a central gateway or instrumentation housing. The gateway may transmit data by cellular signal, satellite modem, or directly using the mine Wi-Fi. There are also low power, stand-alone single instrument satellite transmitters that have been developed for remote sites, including for VWPs and "well caps" for groundwater monitoring wells (EWS Monitoring, 2022). Companies like Sensemetrics offer complete end-to-end solutions including sensors, connectivity, a cloud platform, and dashboards and analytics.

When combined with instrumentation, telemetry systems can provide data on water levels, secondary parameters like chloride (if ion-specific probes are deployed in wells), and temperature that may be useful in detecting seepage. At the time of this study (2022), Cobre Panamá was already undertaking installation of a telemetry system for existing instrumentation.

Data visualization and dashboards

Dashboards are data visualization tool that track, analyze, and display key information, metrics, and data points. A variety of tools are available for the building of dashboards, including PowerBI, Tableau, and others. Site-specific custom dashboards can be developed to provide easy review of relevant site parameters and set with "flags" or "alerts" when parameters exceed trigger levels or other criteria. At Cobre Panamá, a custom dashboard could be constructed with alerts when primary and secondary seepage indicator

parameters (from water quality monitoring data) exceed threshold or trigger values, or for temperature (for dataloggers or VWPS with telemetry or fiber optic data).

Analytical approaches

This category includes calculations and models that can be used to assess the potential for seepage discharge through embankments and the foundation and bypass of collection systems. This category is unique in that they can be used to make forward or future predictions, and for this reason have great utility for planning purposes. For example, models can be used to assess the impact of future embankment raises on seepage discharge patterns, and to plan for improvements in seepage detection and monitoring programs to accommodate these changes. Models can also be used to evaluate mitigation strategies when seepage is detected – such as increased pumping rates at SCFs to capture seepage bypass. The reliability of these approaches can be continually improved through recalibration to operational monitoring data.

Water balances

If a detailed TMF water balance exists, flow measurements from drains and seepage collection systems can be compared to expected discharge identified in the water balance to estimate the quantity of seepage being lost (bypassing the collection system). However, water balances may be circular, i.e., measured seepage rates from seepage collection structures are sometimes used as inputs to the water balance – and use of flow measurements may not work unless there are significant changes in observed rates reporting to the SCFs.

TMF water balances often start as estimates that are refined over time during the life of operations as additional data become available. Use of a water balance and flow estimates to estimate seepage losses at an early-stage TMF can be problematic. There is a site wide-water balance developed primarily as an operational support tool, with particular focus on the prediction of the discharge water quality compliance risks (Piteau Associates, 2022). However, this site-wide model is not specific to the TMF and does not appear to be calibrated to SCF drain flows.

Seepage modeling

Analytical and numerical models can be useful tools for evaluating hydrogeological risks associated with TMFs, including migration of seepage through the embankments and foundation. The value in these approaches is influenced by the amount of supporting data and the quality of the site conceptual hydrogeologic model. Modeling approaches are not direct tools for detecting and monitoring seepage but can provide estimates of expected seepage for use in water balances or for comparison to other site observations. Simple two-dimensional (2D) section models using software like SEEP/W (GeoStudio) are relatively easy to set up and run and can provide preliminary estimates of seepage quantities and travel times to downgradient monitoring points. However, due to geometric limitations, these models cannot

provide information on likely flow pathways and studies have shown that if the flow patterns internal to the TMF are 3-dimensional (e.g., flow into and out of the design section), there can be significantly different predictions of the phreatic surface and pore pressures in 2D models relative to 3-dimensional models (Rouncivell et al., 2020).

Groundwater modeling

A well-constructed, properly calibrated local-scale 3D numerical groundwater flow model can provide many advantages for an operational TMF. When sufficient information is available to build and calibrate this type of model, it can be used for a variety of predictive purposes including estimation of seepage from the impoundment to the foundation, prediction of seepage through embankments, evaluation of mounding in embankments and foundation pore pressures, and evaluation of seepage flow paths. In addition, this type of model can be used to evaluate expected changes in future seepage rates during embankment raises and TMF development, to design and assess monitoring systems, and to assess the effects of changes to seepage capture systems (i.e., pumping rates). There is no tool that is better or more useful for understanding the impact of TMF construction on interactions in the TMF-groundwater environment.

TMFs are inherently complex. TMG-groundwater models can also be complex, and care must be taken not to overcomplicate them, i.e. by including too fine of a mesh resolution around drainage structures or too much detail in tailings deposition time steps, or they become unwieldly.

Technology scoring and selection

Selection criteria

To define the selection criteria and appropriate weighting factors, FloSolutions and Cobre Panamá operational personnel participated in a technology selection criteria workshop. More than 20 possible criteria in three broad categories were considered: economic and logistics criteria, technical criteria, and people and operations criteria. During the workshop, a total of ten criteria were selected for the technology scoring process.

The reduction aimed to avoid an over-parameterization of criteria that could complicate the selection process. Too many criteria can overlap, causing some aspects to be double-valued and thus over-weighted in the final score. Alternatively, some criteria might have had the same score across all technologies to be evaluated and, therefore, would not have made any difference. The criteria reduction process considers the specific context of the mining operation under evaluation, which may differ if applied to another operation, resulting in a different set of criteria than those ultimately used in this study.

Technologies are assigned a qualitative score on a scale of 1 to 5 for each criterion, with 1 being least favorable and 5 being the most favorable. Each criterion was assigned a weighting factor ranging from 1-

3, with 1 being the least important and 3 being the most important. Selected criteria and weighting are summarized in Table 1.

Selection scoring matrix

For selection purposes, the "base case" is the current seepage detection and monitoring system at Cobre Panamá, which consists of a series of 7 SCFs and a network of perimeter monitoring bores and piezometers surrounding the TMF to the north and east sides. The technology scoring matrix is presented in Table 2. The matrix includes both nominal (raw) and weighted scores. There are ten evaluation criteria, resulting in maximum nominal and weighted scores of 50 and 95, respectively.

Table 1: Selection criteria descriptions and weighting

Criteria	Description	Weight
Economic and logistics criteria		
Capital expenditure (CapEx)	Includes the cost of procurement and deployment or installation	3
Operational expenditure (OpEx)	Ongoing (annual) system operations fees, upgrades, and replacement costs. This criterion considers that the TMF will be continually raised over time, and whether technology deployment will need continuous updates to accommodate these changes	1
Consultants and contractors	The need for onsite contractors and consultants to install instrumentation or program or deploy systems or train staff. Important due to the challenges of obtaining visas and other site logistics. Instrumentation that can be installed by local contractors receives high scores; when international and out-of-country contractors are required scores are low.	2
Technical criteria		
Data	Data reliability, quality, frequency, precision, accuracy, and spatial and temporal density	2
Flexibility	Technology flexibility, adaptability to different site conditions, and ease of scaling as the TMF is raised and developed	2
Integration	Ability to integrate with existing or future onsite monitoring technologies, such as slope stability monitoring systems. Includes "co-benefits" – technology for one purpose that provides benefits in another area	3
Time Lag	The time required to identify or detect seepage risks or impacts after they occur.	1
People and operations criteria		
Ease of use	User-friendliness of technology, including time required by onsite staff to use / monitor	1
Automation	Automation vs. need for inspection. For example, the need for manual review of laboratory analytical data vs. a dashboard that uploads data and instantly flags water quality exceedances.	2
Skills and training	The level of staff technical skills or training required to implement or operate technology or process and interpret data	2

Table 2: Technology scoring matrix

		Evaluation Criteria Scores										Total Score	
	Technology	CapEx	OpEx	Consultants/ contractors	Data	Flexibility	Integration	Time Lag	Ease of Use	Automation	Skills and Training	Nominal	Weighted
No.	*Weighting factor*	3	1	2	2	2	3	1	1	2	2		
0	Base case	5	3	1	2	3	2	1	5	1	5	28	54
1	Piezometers	2	3	4	4	5	5	1	5	1	5	35	68
2	Wells / Water quality	2	3	4	4	5	5	1	5	1	5	35	68

17	Seepage modeling	5	4	4	3	4	3	4	3	2	3	35	67
18	Groundwater modeling	3	3	4	5	5	4	5	3	4	2	38	72

Selected technologies

Detection and monitoring of seepage through embankments and foundation

In terms of instrumentation, continuous fiber optic systems may be an effective technology for identifying seepage releases. Perimeter fiber optics score highly due to their ability to provide continuous, real-time data of high precision and accuracy, integration with existing technologies, and flexibility as the dam configuration changes (only a basal perimeter system is required). As a co-benefit, modern systems include ULTRA HD quality distributed temperature, strain, and acoustic measurements in real-time using the same optical fiber cable (Silixa, 2022). They can be used to monitor slope stability, map seepage below the drainage system, and identify density changes in subsurface geology with distributed acoustic sensing using both passive and active seismic surveys (Mondanos and Johansson, 2020). This technology has high capital costs for deployment of a perimeter fiber optic cable over several kilometers, which reduces the weighted score.

Flow monitoring in drain systems helps understand changing system dynamics in the TMF and should be considered a critical part of a comprehensive seepage detection and monitoring program. A complete monitoring system should include drain flow rates, drain water quality, and water levels in piezometers in embankments. More information is needed on the drain configuration and available monitoring points at Cobre Panamá to provide specific recommendations for implementation of this technology.

SkyTEM has seen numerous successful applications to TMFs and should be considered for establishing baseline conditions at Cobre Panamá. The mapping of the foundation conditions prior to further tailings deposition, combined with mapping of depth to bedrock and conductive and permeable geologic features like faults in and around the TMF would establish a powerful baseline data set for use in seepage detection and monitoring, as well as for foundation parameterization during future predictive groundwater modeling.

Detection and monitoring of downstream seepage that bypasses the SCFs

Traditional monitoring techniques like piezometers, groundwater monitoring wells, and water quality data have moderate scores due to the need to collect manual measurements and samples and resulting data infrequency. Nevertheless, these systems are familiar, easy to use, do not require training, and are adaptable. Water quality sampling is the sole method to detect sulfate, the primary seepage indicator parameter, downstream of the SCFs. When these traditional systems are combined with automated instrumentation and telemetry (discussed below), scores increase significantly. For the foreseeable future, these systems will continue to provide the core of instrumentation and seepage monitoring programs at most TMFs, including Cobre Panamá.

UAV/drone surveys score well in the ranking criteria but score low in the data category because it is not clear how effective they may be in detecting seepage. They should function well when seepage coincides with "bulging" in embankments, results in temperature changes, or when seepage visibly daylights through embankments. The downstream migration of seepage in groundwater (beyond SCFs) would not be detected. UAV surveys may be more useful in detecting seepage in embankments and in the shallow subsurface upstream of SCFs. Periodic embankment surveys are the most appropriate application of this technology.

Incorporation of selected technologies into best available practices

BAPs include management systems, operation procedures, techniques, and methodologies that have proven to reliably manage risk and achieve performance objectives (MAC, 2021). While a BAP is an operating philosophy, proper technology selection and incorporation is a cornerstone of BAP development. This section presents a brief overview of how the selected technologies (BATs) can be incorporated into operational best practices.

The technology selection process described above confirm that some our identified BATs had already been incorporated into BAPs at Cobre Panamá, including the use of a robust seepage detection and monitoring network. At the time of this study, the TMF team had already upgraded much of the

instrumentation network with telemetry and was ordering new flow meters for the SCF systems as part of the commitment to continuous improvement. Some of the recommendations reflect ongoing practice.

Enhanced downgradient monitoring network with telemetry

The current monitoring network could be improved to provide a more robust seepage detection, particularly if combined with telemetry and dashboards. Specific improvements that could be considered include:

- Develop an instrumentation plan describing location, construction, and rationale for new VWPs, piezometers, and monitoring wells to augment the existing downgradient monitoring network.
- Installation of additional downgradient monitoring points at select locations
- Continuation of routine water quality sampling and analyses at the expanded network
- Equipping most/all monitoring points with automatic measurement instrumentation and Wi-Fi or satellite-based telemetry

Data management practices and dashboards

In addition to an enhanced instrumentation and monitoring program, automated data upload and data screening using dashboards are particularly useful for rapid identification of seepage at monitoring points after water quality monitoring events. Specific improvements that could be considered include:

- Linking telemetry systems to a central database
- Enabling automatic upload of laboratory analyses into the central database
- Development of user-friendly dashboards with automatic screening of seepage indicator parameters with dashboard notices/alerts
- Integrate with Trigger Action Response Plans (TARPs) or other established alert levels and Emergency Response Plans (ERPs)

Perimeter fiber optics

Installation of perimeter fiber optic cables represents state-of-the art seepage detection technology, but at high capital cost. It can be installed around the TMF to measure temperature, strain, and acoustic measurements in real-time. Under this option, fewer additional VWPs and monitoring points would be needed, potentially offsetting some of the capital costs associated with this option.

Periodic/supplemental studies

Based on the review of available technologies, it would be difficult to detect seepage transport through embankments or the shallow subsurface upstream of SCFs using traditional techniques if the perimeter fiber optic sensors are not installed. In this case, periodic embankment-specific surveys would be useful. These

surveys may include:

- UAV/drone photography with thermal + HD cameras
- Data evaluation for embankment geometry changes and zones of temperature anomalies
- If seepage is detected downstream of embankments, and preferential seepage pathways are suspected or identified during UAV survey, applied tracer studies may assist with identification and mapping of seepage flow patterns.

Mitigation action plan

A mitigation action plan describes the steps and actions that will be taken within a defined timeframe to further evaluate and mitigate the release. Example actions that could be included in a mitigation plan:

- Confirm concentrations with repeat/duplicate sampling
- Confirm trigger level exceedances are a result of seepage impacts through more detailed geochemical assessment of water quality data (potential including EDA/ML techniques)
- Confirm seepage releases and flow pathways using supplemental studies
- Summarize results of assessments and submit a mitigation work plan within a defined timeline of seepage detection and confirmation.

As part of mitigation plan development, site should consider whether baseline studies are required. For example, if fiber optic lines are not installed, baseline geophysics or SkyTEM along key areas such as embankment toes may provide useful starting information. When a seepage release is detected downgradient, these lines can be repeated to identify preferential flow paths.

Periodic review and revision of seepage monitoring strategy

After BATs have been implemented and monitoring and mitigation plans have been updated, the overall monitoring program should undergo periodic review as part of BAPs, to make sure that it meets changing demands of the TMF.

- Conduct internal annual reviews and periodic external reviews of the seepage monitoring strategy
- As the TMF height increases, consider the suitability of the monitoring network the meet stated goals and objectives
- Evaluate new /evolving technologies where appropriate. When evaluating new technologies, they should be compared to the matrix selection criteria and weighting to see how they compare to existing options

Consideration of analytical and numerical modeling approaches

There are significant operational advantages to having a robust TMF water balance, seepage models, and

numerical groundwater flow models. The value in these approaches is influenced by the amount of available supporting data and the quality of the site conceptual hydrogeologic model. During site operations, the amount of available data is continually increasing, and sites interested in implementing BAPs should periodically update and improve the site water balances and numerical models.

A well-constructed, properly calibrated local-scale 3D numerical groundwater flow model can provide many advantages for an operational TMF, and this is one of the highest scoring technologies in the scoring matrix (Table 2), in part due to the predictive capabilities. Development of a 3D numerical groundwater flow model will not only assist with seepage detection and monitoring, but it will help to understand the potential impacts of future construction activities and expected discharge to various drainage components, and it will enable the identification of flow paths, velocities, and seepage fluxes within the foundation and beyond. Many operational TMFs maintain a robust model for this purpose.

Conclusion

This paper contains a comprehensive review of the best available technologies for seepage detection and monitoring at tailings facilities, and a proposed approach to assess them – with an example application at the Cobre Panamá TMF.

The most applicable technologies at any site will be dependent on several factors, including site conditions (geology, hydrogeology, tailings configuration, etc.), operational considerations, and the available team to implement them. When selecting and ranking BATs, selection criteria should only be established with input from the onsite operational team, who have working knowledge of day-to-day conditions and implementation constraints. It is not constructive to recommend "state-of-the-art" technologies if they are impractical to implement or if the necessary capital cannot be allocated.

Technologies that did not score well at Cobre Panamá may have greater applicability at other sites, and a low score in our assessment should not be a discouragement to considering these technologies at other sites where conditions may be different.

The current systems employed to monitor TMF seepage at Cobre Panamá are equivalent to or surpass common practices observed at many tailings facilities globally. Undertaking regular studies to update conceptual hydrogeological models, combined with the commissioning of this study – in the absence of any regulatory requirement or external motivating factor – indicates a commitment to continuous improvement. In short, BAP implementation was already well underway at the time of this assessment.

Finally, although this study focuses on BATs, we believe that BAPs are equally if not more important in establishing and maintaining robust detection, monitoring, and mitigation programs. Our discussion of BAPs is limited for the sake of brevity, and because they are even more site-specific than selection of BATs due to greater reliability on organizational factors.

Standardizing Sediment Porewater Passive Samplers to Measure Metal Availability at Mine Sites

Florent Risacher, Geosyntec Consultants International Inc., Canada
Jason Conder, Geosyntec Consultants Inc., USA

Abstract

Dialysis passive samplers, also called peepers, have been used to measure the availability of metals at contaminated sites for decades, but have remained largely underused at mine sites. Peepers are a type of passive sampler that function by allowing metals to diffuse from the sampled media, through a membrane, into laboratory-provided water. After an equilibration period, the peepers are retrieved, and the solution is analyzed for metal(oids) and reported as a concentration in water that can be easily compared to water criteria or used in fate modelling. Despite more than forty years of research, passive sampling lacks a set of standardized protocols, which has led to greatly varied methodologies, thus hindering the use of peepers for regulatory and decision-making purposes at mine sites.

To advance peeper technology, Geosyntec conducted a three-year study comprised of a review of the literature to document past successes/limitations, a series of laboratory experiments aimed at refining a set of standard methods, and a field deployment to demonstrate the developed best practices. This work culminated in the development of a guidance document that provides a comprehensive reference for industry practitioners and regulators and answers key questions for the successful application of the technology for decision making.

To facilitate the dissemination of the technology and provide additional tools for water quality and tailings management, this paper will synthesize a brief overview of the technology and the importance of measuring metal(oids) availability. Additional information about the relevance of the technology for the mining industry, such as the use of peepers to measure metal speciation and organo-metal complexes, will also be discussed. This work is conducted as part of an Environmental Security Technology Certification Program (ESTCP) project funded by the U.S. Department of Defense.

Measuring metal availability

Sub-aqueous sediments, wet tailings and various saturated media (herein referred to as sediments) containing high concentrations of inorganic constituents, primarily metals and metalloids, present significant challenges at many mine sites. Biologically available constituents in sediments can be characterized by measurements that seek to quantify the concentration of freely dissolved contaminants (Cfree) in sediments and sediment porewater (Conder et al., 2015; Cleveland et al., 2017). This approach presents an advantage over measuring the total extractable concentration of inorganics in bulk sediment (USEPA, 2005), which can overestimate the fraction of inorganics that are mobile and biologically available (Peijnenburg et al., 2014). Cfree measurements can provide a superior quantitative understanding of metals in sediment (compared to bulk analysis of metals in sediment) that is particularly useful in filling a variety of data gaps typical of environmental site investigations, such as environmental fate, availability, nature and extent, ecological risks, speciation, source control, and remedial performance.

A multitude of methods have been developed to measure the availability of metal(oids) in sediments such as mechanical extractions and acid volatile sulfide. Mechanical sediment porewater analysis usually consists of collecting bulk sediments, which are mechanically squeezed, or centrifuged, to produce a supernatant liquid (porewater) that is then filtered to extract the water for analysis (Gruzalski et al., 2016). The mechanical extraction process poses challenges due to the heterogeneity of sediments, the high reactivity of some inorganic analytes, and chemical and physical disturbances of the sediments. These factors can cause the concentration of dissolved inorganics obtained from analyzing a mechanically extracted sample to deviate from the concentration of available metals in sediment porewater (Peijnenburg et al., 2014). For example, it is recognized that sampling disturbances can affect redox conditions (Teasdale et al., 1995; Schroeder et al., 2020), thus leading to an under- or over-representation of inorganic chemical concentrations relative to the true dissolved phase concentration in the sediment porewater (Wise, 2009; Gruzalski et al., 2016).

Analysis of acid volatile sulfide and simultaneously extracted metals (AVS/SEM) in bulk sediment is often used to evaluate metal availability in sediment (USEPA, 2005). This measurement evaluates bioavailability of divalent metals (cadmium, copper, lead, nickel, and zinc) via a weak acid extraction of a bulk sediment sample (i.e., SEM measurement). Along with measuring and normalizing a chelating agent (AVS), the approach can provide a quantitative value of available divalent metals. Sample-specific AVS/SEM values can be compared to a conservative threshold that, if exceeded, may indicate the need for additional toxicity testing or evaluation due to the potential for toxicity (USEPA, 2005). This approach has the advantage of using simple procedures in the field (e.g., collecting a bulk sediment sample), relatively simple data evaluation (USEPA, 2005; DeForest et al., 2022), and a relatively high acceptance and familiarity among regulatory stakeholders. However, the AVS/SEM approach is primarily limited to

cadmium, copper, lead, nickel, and zinc, and the quantitative estimate produced by the analysis is primarily limited to evaluating the need for aquatic toxicity testing, rather than more broad data uses in nature and extent evaluation or fate and transport.

Sediment porewater dialysis passive samplers

Sediment porewater dialysis passive samplers, also known as "peepers," were developed more than 45 years ago (Hesslein, 1976) as a potential approach to circumvent challenges associated with other methods of sampling inorganic chemicals in sediment. Peepers are inert containers with a small volume of purified water ("peeper water") capped with a semipermeable membrane. Peepers usually feature a protective cap or structure that secures the membrane to the peeper chamber. Peepers are typically prepared under clean laboratory conditions and can be shipped directly to the field site. Various commercial providers exist, and some universities may also have the equipment to construct their own samplers. Deploying a peeper consists of inserting it into the sediment, where it is left for a period of a few days to a few weeks. During this time, passive sampling is achieved via the principle of diffusion, as the enclosed volume of peeper water equilibrates with the surrounding aquatic matrix via transport of inorganics through the peeper's semipermeable membrane (Figure 1; Risacher et al., 2023a). After an equilibration period, the peeper is retrieved, and the peeper water is transferred to a storage container and analyzed for inorganics in the same manner as a typical surface water sample. The results from the analysis are then reported as a concentration in water (i.e., milligram per liter of water [mg/L]).

Peepers have numerous advantages over other sampling approaches, including:

1. Minimal sediment disturbance during sampling which allows to preserve existing sediment structure.
2. Limited exposure of the sample to the atmosphere which prevents highly sensitive redox compounds to react.
3. Minimal risk of the peeper reflecting surface water overlying the sediment that can accidentally contaminates porewater during collection via suction methods.
4. Peepers can provide availability data on any metal, not just divalent metals measured in the AVS/SEM approach.
5. Data from peepers are on a mass per volume basis (i.e., mg/L or µg/L), which facilitates use of the data in fate models, and comparisons to risk-based criteria for water.
6. Peepers integrate Cfree over the deployment period, averaging any changes of the concentration.
7. Peeper chambers can be stacked in a frame to provide porewater concentrations over a vertical sediment profile at higher resolution than conventional extraction methods; and
8. Some passive samplers also contain a Performance Reference Compound, or reverse tracer, which

can help ensure equilibrium has been reached after sampling.

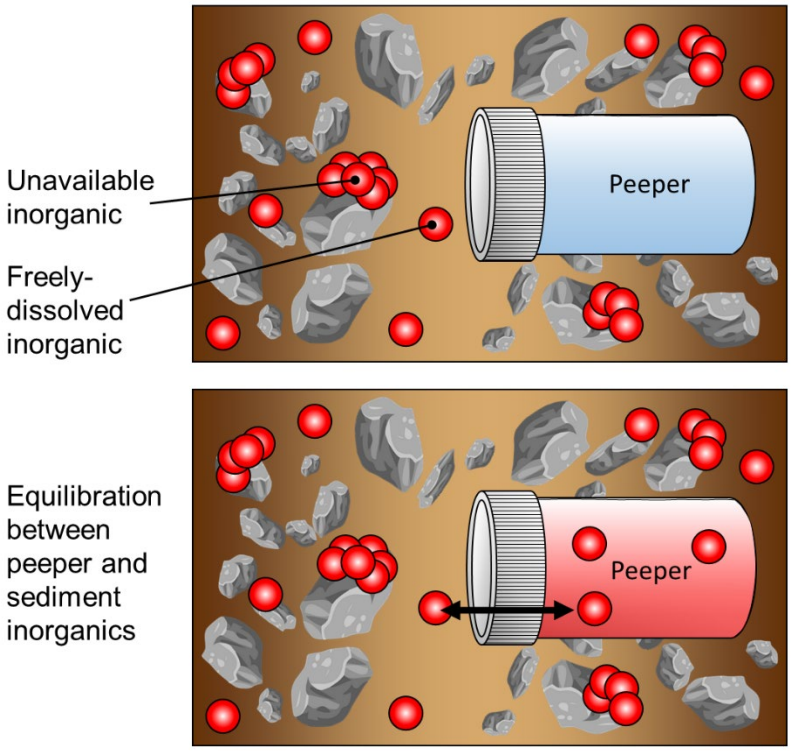

Figure 1: Conceptual illustration of peeper passive sampling in a sediment matrix, showing peeper immediately after deployment (top) and after equilibration between the porewater and peeper chamber water (bottom)

Using peeper data

Peeper data can be used to enable site-specific decision-making in a variety of ways throughout the mine life cycle. Peepers can provide information on 1) nature and extent; 2) sources and fate; 3) the potential direct toxicity to aquatic life; 4) the potential bioaccumulation of metals in aquatic life; 5) the efficacy of remediation and source control; and 6) assessing speciation.

Nature and Extent: Peepers can be helpful in characterizing the presence and availability of metals and inorganics in aqueous media at mine sites. Multiple peeper deployments in sediments can help delineate areas of increased metal availability in the same manner as traditional bulk sediment sampling. Peepers are especially helpful for sites that may not be conducive to traditional bulk sediment sampling. For example, substrates that are comprised of coarse, relatively inert materials, such as gravel or fine fluid materials that may be difficult to sample with sediment grab or coring techniques. Collecting and analyzing such material can be challenging as much of the inorganics present in the sample may be more associated with the porewater phase rather than the solid phase. Explicit measurement of Cfree in the porewater of coarse or fine fluid substrate samples can provide a more robust and precise measurement in these cases.

Additionally, at sites where hydrological disturbances (pumping, groundwater flux) may be influencing the nature and extent of inorganics, peepers have a distinct advantage to bulk sediment sampling or other point-in-time measurements, as peepers can provide an average measurement that integrates the variability in the hydrodynamic and chemical conditions over time.

Sources and Fate: A considerable advantage to using peepers is that the numerical product of a peeper measurement is Cfree, a concentration that is expressed in units of mass per volume (e.g., mg/L or µg/L). Cfree provides a common unit of measurement for evaluating the presence of inorganics across multiple aquatic media such as sediment, tailings, surface water, stormwater, and groundwater. For example, synchronous measurements of Cfree using peepers deployed in tailings and the surface water above can elucidate the potential flux of inorganics from tailings to surface water (or vice versa). Paired measurements of Cfree and bulk metals in sediment can also allow site-specific sediment-porewater partition coefficients to be calculated. These values can be useful in understanding and predicting fate, especially in situations where the potential dissolution of metals from a substrate are critical to predict, such as when sediment is dredged or when tailings are deposited sub aqueously.

Direct Toxicity to Aquatic Life: Peepers are frequently used to understand the potential direct toxicity to aquatic life, such as benthic invertebrates and fish. A Cfree measurement obtained from a passive sampler, such as a peeper deployed in sediment or surface water, can be compared to toxicological benchmarks for aquatic life to understand the potential toxicity to aquatic life and to set remediation goals (USEPA, 2017). Benchmarks are concentrations of chemicals that are associated with adverse effects (or a lack of adverse effects) to aquatic life and are usually obtained from peer-reviewed laboratory toxicity studies in which aquatic life are exposed to known concentrations in water. Formal regulatory benchmark values are available in the form of aquatic life criteria promulgated by environmental agencies such as the USEPA and various states. These benchmark or screening values can be directly used with Cfree measurements and incorporated with more sophisticated approaches, such as the Biotic Ligand Model (Santore et al., 2022) to understand the potential for toxicity and need to conduct additional toxicological testing or ecological evaluations. Cfree measurements and benchmark values can also be applied in aquatic toxicity studies performed in the laboratory with samples of sediment or water, specifically using peepers to understand links between elevated inorganic Cfree measurements and toxicity.

Bioaccumulation of Inorganics by Aquatic Life: Peepers can also be used to understand site-specific relationships between Cfree and concentrations of inorganics in aquatic life. For example, measuring Cfree in surface sediment from which organisms are obtained and analyzed can enable the estimation of a site-specific uptake factor or predictive model relationship. This Cfree-to-organism uptake factor (or model) could then be applied for a variety of uses, including predicting the concentration of inorganics in aquatic life if measurements in organisms are unavailable, or estimating a Cfree value at a

concentration in aquatic life that would be safe for consumption by fish, wildlife, or humans. Because several decades of research have found that the correlation between Cfree measurements and bioavailability is usually better than the correlation between measurements of chemicals in bulk sediment and bioavailability, Cfree-to-organism uptake factors (or models) are likely to be more accurate and precise than uptake factors based on bulk sediment (e.g., Biota Sediment Accumulation Factors).

Evaluating Remediation and Source Control Efficacy: Passive sampling has been used widely to evaluate the efficacy of remediation and source control treatments such as active amendments, thin layer placements, and capping to reduce the availability of chemicals at sediment sites. A particularly powerful data use is a simple comparison of baseline (pre-remedy) Cfree in aqueous media to Cfree in aqueous media after the remedy has been applied. Peepers can be used in this context for inorganics, allowing the remedy's success to be evaluated and monitored in laboratory benchtop remedy evaluations, pilot scale remedy evaluations, and full-scale remediation monitoring.

Assessing Speciation: Metal speciation, especially for organo-complexes, has been given more attention in the past few years due to the increased toxicity and environmental impact compared to their inorganic forms. Peepers can be used to assess the speciation of multiple metal(oids) species in aqueous media, such as arsenic, mercury and selenium, thus providing better understanding of the availability and the potential risk to aquatic organisms. Sulfur speciation can similarly be conducted which can help identify early signs of acidification of pit lakes (Whaley-Martin et al., 2023).

Conclusion and additional resources

Despite more than forty years of research, passive sampling for inorganics has had limited uses in the mining industry as a decision-making tool. This paper aimed to provide a brief overview of passive sampling for inorganics and its potential uses at mine sites, in the hope of providing industry practitioners with another tool for site assessment. Additional resources such as a guidance document, standard operating procedure, and video demonstrations can be found on the SERDP/ESTCP website.

Preliminary Assessment of the Environmental Impacts of Artisanal Gold Mining: The Case of the Kashozi Mining Site, South Kivu, DRC

Akonkwa Mudekuza Kepler, Université Officielle de Bukavu, DRC
Alex Kalonji-Kabambi, Université Officielle de Bukavu, DRC
Bwemere Ciribuka Grâce, Université Catholique de Bukavu, DRC/Université Officielle de Bukavu, DRC

Abstract

Artisanal gold mining is one of the sources of income for the population of the eastern Democratic Republic of Congo (DRC). But this activity still fails to consider tailings management and environmental protection measures for the entire life cycle of an artisanal mine.

In this study, research was carried out for the preliminary assessment of heavy metal contamination levels in the waters and sediments of the Luzinzi River, which borders the Kashozi gold mining site in Walungu, South Kivu province, DRC.

To achieve this objective, the methodology was to conduct field observations to get information about the gold mining and processing circuit at the site. Samples of water and sediment from the Luzinzi River were taken, and laboratory analyses were conducted to determine the physico-chemical parameters and chemical and geochemical composition of the samples.

The results showed that the pH of the waters studied was acidic to neutral (between 5.09 and 6.09), and that these waters were also poorly conductive (between 37.6 to 43.9 µS/cm). Analysis of heavy metals in water and sediments revealed largely elevated levels of heavy metals such as As, Cd, Cr, Cu, Fe, Mn, Ni, Pb, Se, and Zn, compared with the DRC mining regulations and the World Health Organization (WHO) standard for drinking water.

Analysis of these results led to the conclusion that surface waters and sediments in the study area were polluted with heavy metals, notably As, Cd, Cr, Cu, Fe, Mn, Ni, Pb, Se, and Zn, and that this pollution was due to gold panning activities in the area.

Finally, the last objective of this ongoing study was to formulate recommendations concerning alternatives to the use of mercury and the rehabilitation of the polluted environment.

Introduction

Artisanal mining is any small-scale operation involving the extraction and concentration of mineral substances from primary outcropping or underground and/or secondary deposits and the recovery of valuable minerals and metals using manual or traditional methods and processes (Dembele, 2021). Artisanal and small-scale mining (ASSM) involves individual miners or small enterprises with limited capital and production. It is generally a decentralized production system. ASSM is seen as an operation with a diverse range of mining activities, little mechanization, and labor-intensive (Bikubanya and Radley, 2021).

In South Kivu, as in other provinces of the DRC, artisanal mining originated to meet the survival needs of the population. It has attracted several thousand individuals, including young people, and employs a considerable number of people on a precarious basis. It is well known that there are currently more artisanal gold mining sites than industrial ones in the province of Grand Kivu. Small-scale gold mining using traditional techniques, now uses chemicals (cyanide, mercury, etc.) that pollute the environment, particularly river water, air, and soil. As a result, populations living in areas with artisanal mining operations are exposed to several forms of health risk.

Artisanal miners are responsible for extracting the ore from the mine (in the case of underground galleries), which they clean at the edge of streams (after crushing and grinding if necessary) to carry out an initial concentration (Bauma, 2017), and then mercury is mixed in. The mercury binds with the gold in the ore, creating a gold-mercury amalgam that excludes other elements. The miners then heat this amalgam over an open-air flame. The mercury then evaporates and escapes into the air, while the pure gold is isolated for sale on the market (Human Rights Watch, 2010). Gold mining is a source of considerable environmental and health impacts and challenges. These include landscape, health, ecology, and hydrogeology. The risks most often cited are the “uncontrolled release of acid mine effluents,” heavy metal discharges that are dangerous for the long term, and suspended matter discharged into watercourses and thus degrading aquatic ecosystems (Bauma, 2017).

Heavy metals are considered serious pollutants of the aquatic environment, due to their persistence and tendency to bioaccumulate in aquatic organisms. They have toxic effects when organisms are exposed to concentration levels higher than those which they normally require, causing harmful effects on fish and humans through the food chain (Oumar et al., 2014). Poor management of mine tailings is a source of pollution for the environment (surface water and groundwater) and it is essential to control what is released into the environment so as not to exceed a certain threshold, in order to ensure the protection of ecosystems and human health.

In the DRC, the mining code and regulations govern the quality of water and mining effluents to be discharged into the environment. These regulations prohibit the discharge of wastewater, mine drainage, mine tailings, waste or any other contaminant into surface waters or within one hundred meters of a source

of drinking water or food for humans or livestock. All contaminants must be stored and treated in such a way as to eliminate any risk of water pollution. No stream, lake, or river may be used for partial or total wastewater treatment purposes. Also, no dilution of wastewater is permitted (Règlement minier RDC, 2018). Unfortunately, these regulations and mining code are not always respected due to weak official enforcement structures and lack of awareness (Nkuba et al., 2019).

This paper presents a preliminary assessment of the environmental impacts of artisanal gold mining: the case of the Kashozi mining site in South Kivu province, DRC. The objective is to evaluate the level of heavy metal contamination in the waters and sediments of the Luzinzi River, which borders the Kashozi gold mining site. The following sections present the study area and the methodology, and then presents, interprets and discusses the preliminary results.

Methodology

Description of the study area, climatic, mineralization, and geological context

The Kashozi *groupement* (grouping), where the gold mining site is located, is one of the fifteen administrative groupings of the Kaziba chieftaincy in the DRC (Figure 1). It is located at 02.50'18.8" south latitude and 028°49'26.2" east longitude, approximately 60 km southeast of the town of Bukavu in South Kivu province (Rumama, 2017).

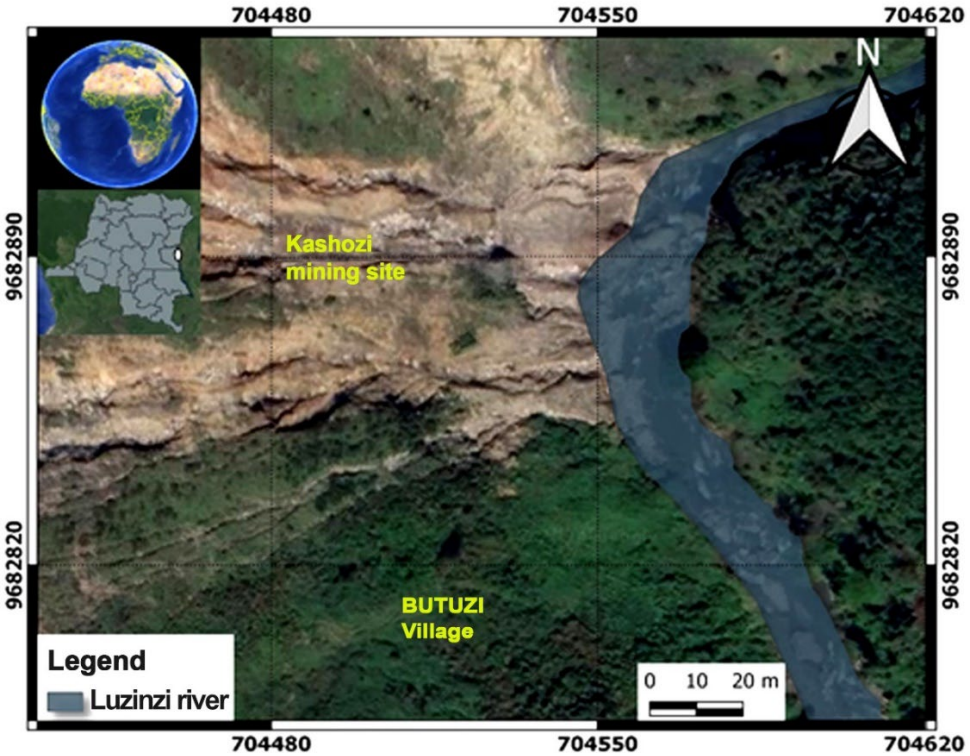

Figure 1: Location of the Kashozi mining site in South Kivu, DRC

With altitudes ranging from 1,800 to 3,200 m, the Kashozi grouping reaches to the Mubuga highlands. Its hydrography consists solely of rivers, including the Kalango, Kaderhe, Nachibundu, Muguka, Lulindja, and Luzinzi rivers. Kashozi has an equatorial climate modified by altitude (Ndeko et al., 2018).

Figure 2: Topography overview around the Kashozi mining site

Rainfall is abundant, with an average annual rainfall of 1,500 mm. Average annual temperatures range from 17 to 18°C and daily temperatures average from 12 to 22°C (Buhendwa and Bwira, 2019). There are two seasons, a long rainy season lasting 9 to 10 months, from September to June, and a short a short dry season lasting 2 to 3 months (from June to September).

In terms of local geology, Kashozi lies in the Upper Kibaran of Kivu, in the Nyangezi *"Synclinorium d'Itombwe"* sector. This sector is approximately 3,000 to 3,500 m thick and consists of conglomerates with quartzite elements at the base. This is followed by conglomerates topped by phyllades. Then a mixed formation (glacial formation of unknown origin), a schistosandstone formation and tillite with various pebbles at the top (Kalalizi, 2014).

At Kashozi, gold mineralization occurs in the form of intrusions in the rocky mass of the hillside and alluvial deposits in the Lunzizi riverbed. There is alluvial mining in the Lunzizi river and underground mining in drifts on the hillside. Artisanal miners use sluices and pan for washing and concentration. Gold miners add a little mercury to the concentrate to make the amalgam, which they then heat. In the case of primary and secondary deposits, there is no method for managing tailings, which are discharged directly into the environment (Figure 3).

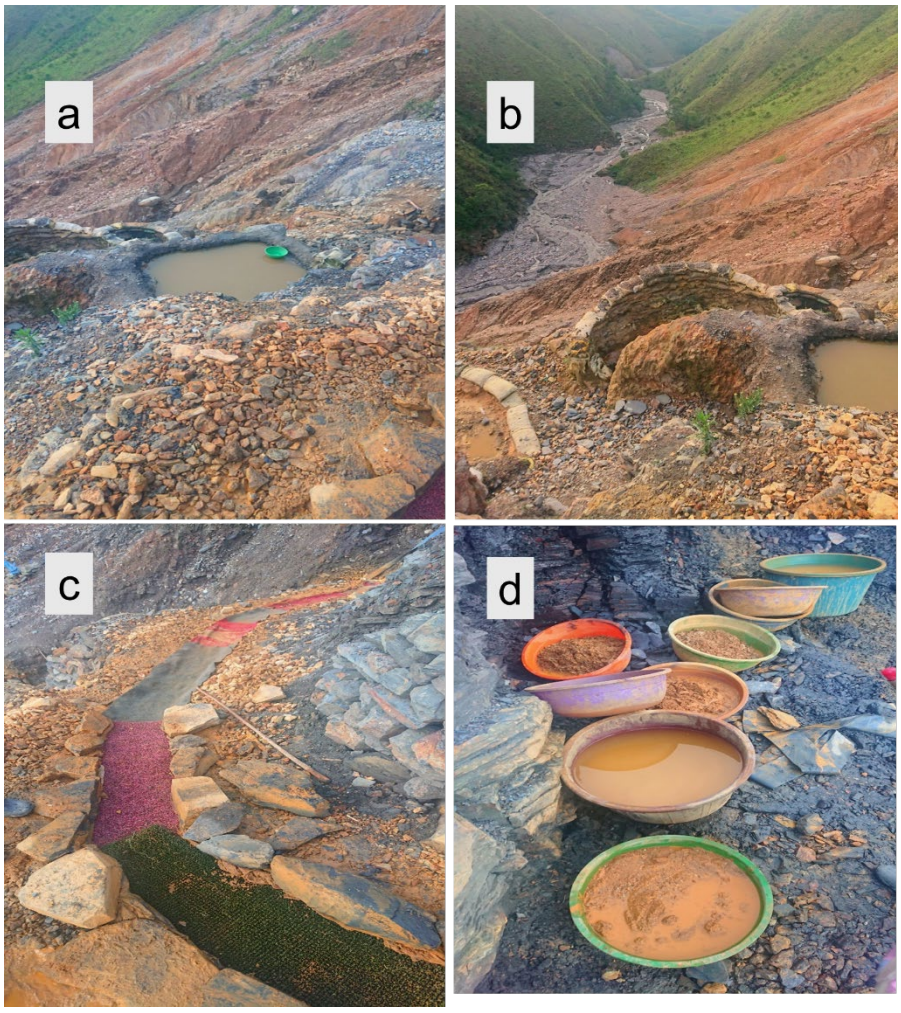

Figure 3: Artisanal mining workspaces and material at the Kashozi mining site: wash basin (a), Luzinzi River (b), slice (c) and pan (d)

Sampling and materials preparation

The following components were necessary to achieve the objectives of this study:

1. Field work, which involved field observations and studying the gold mining and processing circuit at the site, as well as taking water and sediment samples.
2. Chemical and geochemical analysis of samples at the laboratory to determine metal concentrations in surface water and sediments around the Kashozi site.
3. Discussion and interpretation of the results in relation to similar work carried out in the area or elsewhere, the directives of the DRC mining regulation, and the criteria for drinking water according to the World Health Organization (WHO) standard.

Sampling was carried out while the artisanal workers were washing the ore on the hill. After drawing up a sampling plan and getting the equipment ready, the first water sample was taken from the wash water

coming from the washing of ores on the hill. The second water sample was taken from the water upstream of the river, as it was before it encountered the water discharged from the mine. The third water sample was taken at the point where the mine and river waters meet. Seven other samples were taken downstream of the meeting point, spaced 5 m apart (the last sample was therefore taken 35 m from the meeting point of the river and mine waters). At each water sampling point, the pH was measured.

For sediment samples, the first sediment sample was taken on the hillside in the washing basin (to obtain information on the mineralogy of the materials carried to the river by runoff during rainfall or by washing water during ore processing). The second sediment sample was taken upstream in the river in an area less impacted by artisanal mining operations. The third sediment sample was taken at the point where the mine waters meet those of the river. The fourth sediment sample was taken 5 m downstream of the meeting point. Three further sediment samples were taken in areas of low influence downstream of the meeting point. In all, ten water samples and seven sediment samples were taken to enable us to assess the environmental impacts of gold mining and processing at the Kashozi mine site (Figure 4).

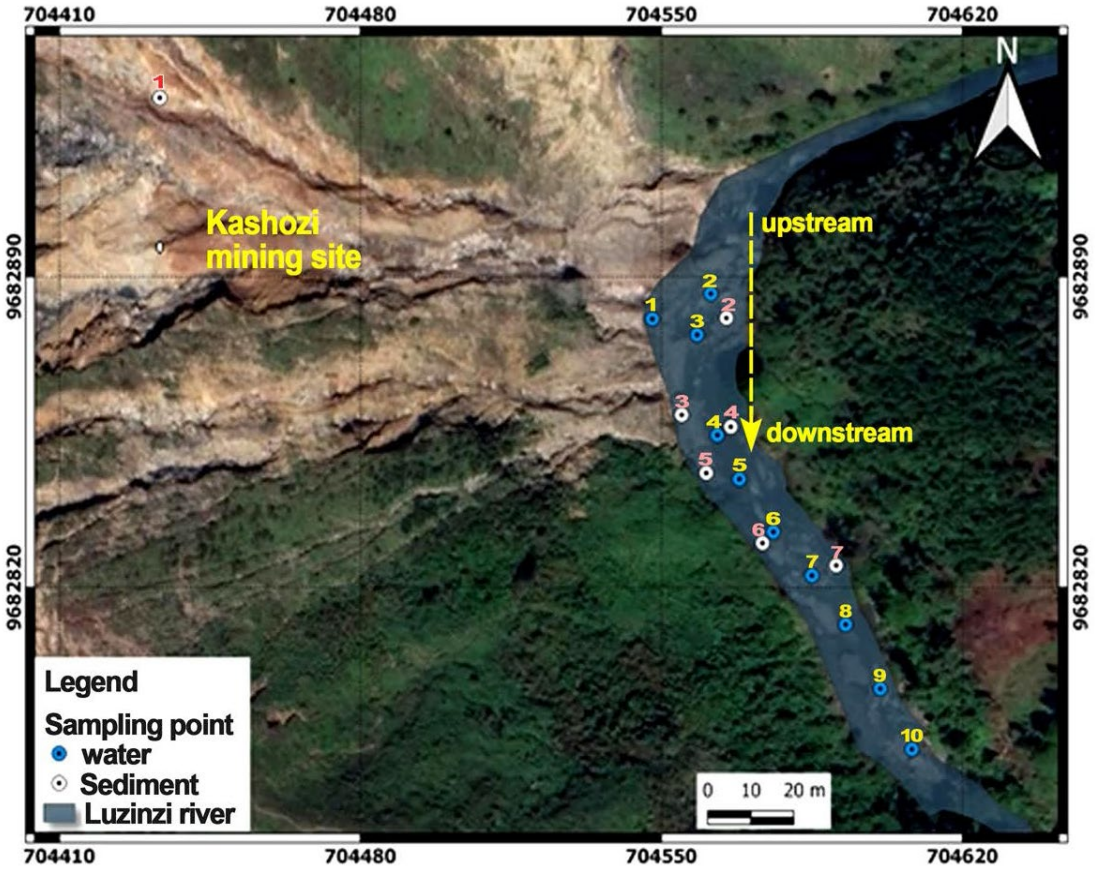

Figure 4: Sampling map of water and stream sediment at the Kashozi mining site

Liquid samples were stored in accordance with the guidelines of the Centre d'expertise en analyse environnementale du Québec (CEAEQ), which recommends 6 months' cold storage in well-closed plastic

containers (CEAEQ, 2012). To comply with this recommendation, all liquid samples were kept in a freezer (at around 0°C) until the day of laboratory analysis, which was done within less than two months.

The following equipment was used: an auger to drill into the sediment, a pH meter to measure the pH of the water at the site, 500 ml plastic bottles to collect the water samples, plastic bags to collect the sediment samples, Arc Gis and Google Earth software to map the site and locate the sampled areas, and Excel software to produce the graphs. The analyses, which were carried out at the Office Congolaise de Contrôle (OCC) laboratory over a three-day period, focused on determining the concentration levels of metals in the sediments and waters samples using two spectrometers: the Quantum RX spectrometer and the Tal instrument X spectrometer; and also on measurement of the pH and conductivity in water samples using an electric pH meter and an electronic conductivity meter, respectively (Figure 5).

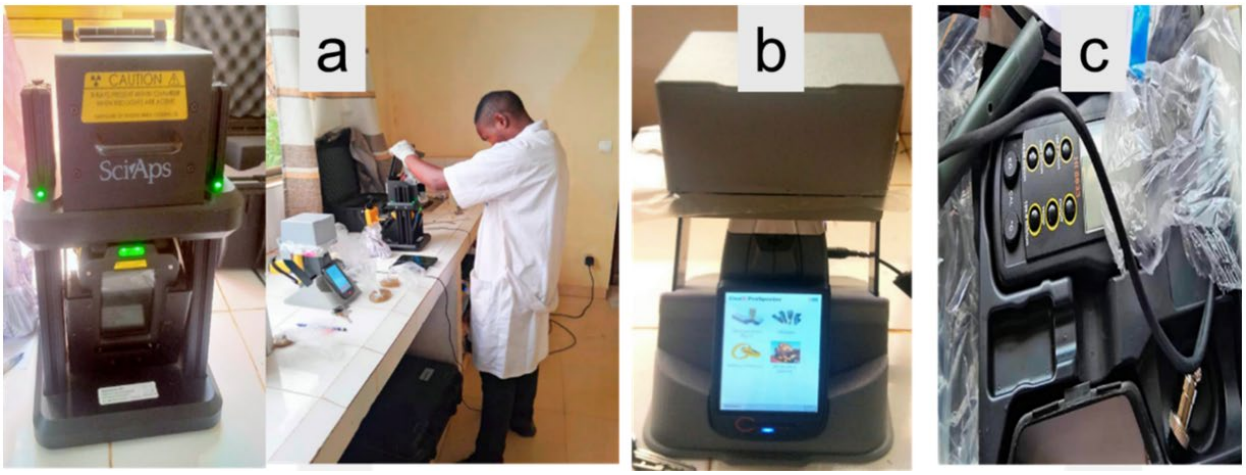

Figure 5: Laboratory analysis: Quantum RX spectrometers(a), Tal instrument (b) and conductivity meter (c)

Preliminary results

Physical characteristics of water samples

The pH values varied between 4.95 and 6.25 (site value) and between 5.09 and 6.09 (laboratory value). It should be noted that the pH varied from acidic to neutral, with mine water being more acidic than river water, and that after the confluence zone, there was regulation between mine and river water, with the pH increasing slightly further away from the confluence zone.

The pH values measured are below the WHO's optimum drinking water range (6.5 and 9.5) (OMS, 2017). This may be due to the local geological context, which is characterized by the presence of sulfide minerals, such as pyrite in association with gold. The sulfide minerals contained in the waste rock and tailings, stored in the open air, are gradually oxidized, contributing to a decrease of pH value in the environment.

In terms of conductivity, the water analyzed had values below 250 µS/cm (WHO limit). These waters are low in mineral salts and therefore poor conductors (between 37.6 and 43.9 µS/cm) (Table 1).

Table 1: Main physical characteristics of water simples

Sample number	Sample location*	pH measured on site	pH measured in laboratory	Conductivity measured in the laboratory (µS/cm)
1	Mine water before mixing with river water	4.95	5.09	42.8
2	Upstream river water before mixing with mine water	6.23	5.45	43.9
3	Meeting point of mine and river waters	5.08	5.28	37.6
4	5 m downstream of the meeting point	5.56	5.31	40.0
5	10 m downstream of the meeting point	5.6	6.09	42.2
6	15 m downstream of the meeting point	5.8	5.58	43.8
7	20 m downstream of the meeting point	6.05	5.56	43.1
8	25 m downstream of the meeting point	6.15	5.55	42.6
9	30 m downstream of the meeting point	6.25	5.62	41.0
10	35 m downstream of the meeting point	5.91	5.35	43.7

* See also Figure 4 for samples location

Chemical results of water samples

The results in Figure 6 show an increase in concentration of the majority of chemical elements in the water. As can be seen from the graph, the elements with the highest concentrations, exceeding 30,000 mg/l and reaching 100,000 mg/l for some elements, are: Aluminum (Al), Iron (Fe), Potassium (K), Silicon (Si), and Titanium (Ti).

Given the difference in concentrations, we can assert that the Luzinzi river water was polluted long before it was impacted by Kashozi mining activities. This may be due to mining at other sites upstream of the Kashozi mining site (e.g., the Mufumbé site, etc.), and also to the local geology through the processes and mechanisms of weathering, erosion, leaching, and sedimentation.

High concentrations of heavy metals such as As, Cd, Cr, Cu, Fe, Mn, Ni, Pb, Se, and Zn are noticeable in water samples, and these concentrations are well above DRC mining regulations and WHO standards.

Figure 7 shows the difference in concentration between the upstream maximum and minimum measured concentrations and the concentration requirements in the DRC mining regulations at the final effluent point and the drinking water quality proposed by the WHO.

Although it is used in the gold recovery process (by amalgamation), Hg does not appear in the water and sediments sampled and analyzed at the Kashozi site. This can be explained by the fact that the amalgam is burnt outside the mine site.

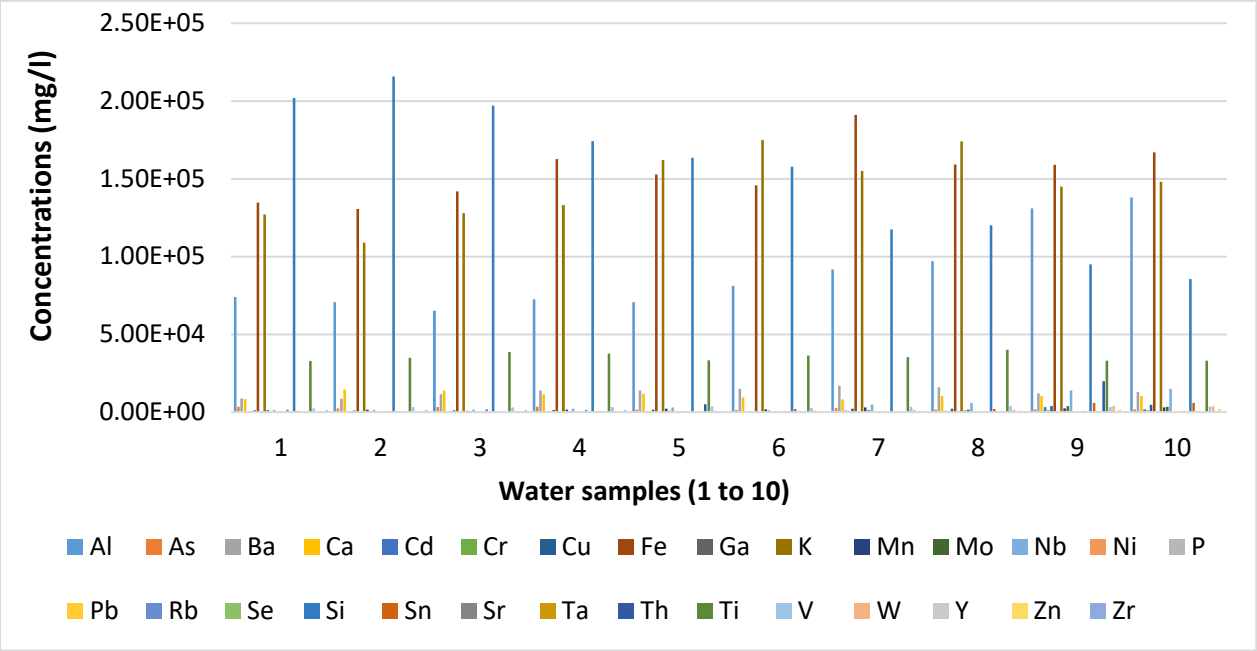

Figure 6: Chemical results of water samples
(see also Figure 4 and Table 1 for location of samples)

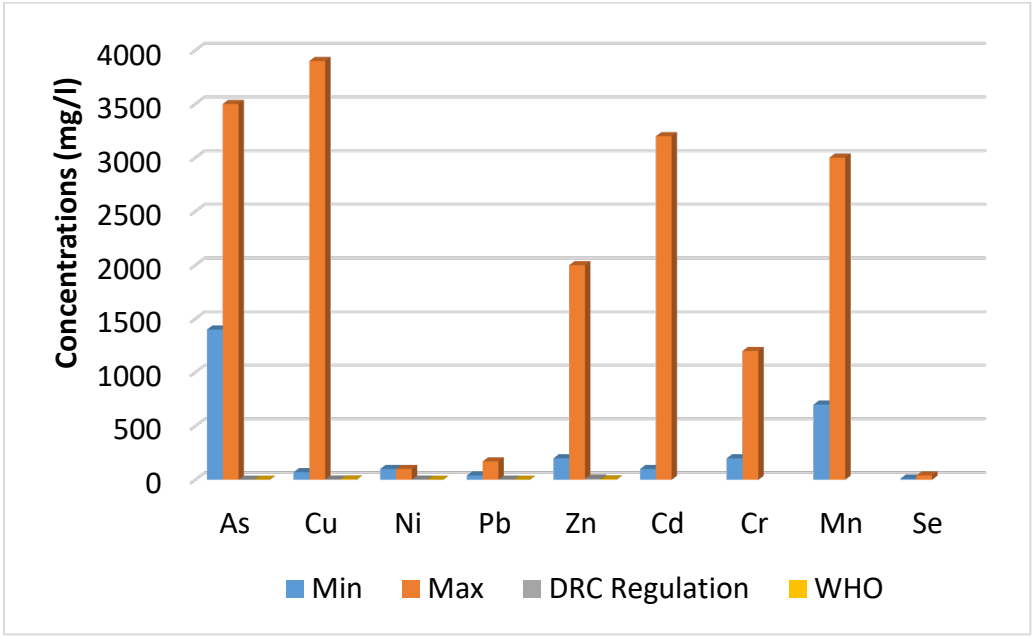

Figure 7: Upstream measured concentrations, compared to the DRC mining regulation and WHO standards

Geochemical results of river sediment samples

As with the water samples, the graph in Figure 8 shows that, the elements with the highest concentrations, exceeding 15,000 mg/l and reaching 100,000 mg/l for some elements, are: Aluminum (Al), Iron (Fe), Potassium (K) Silicon (Si), and Calcium (Ca).

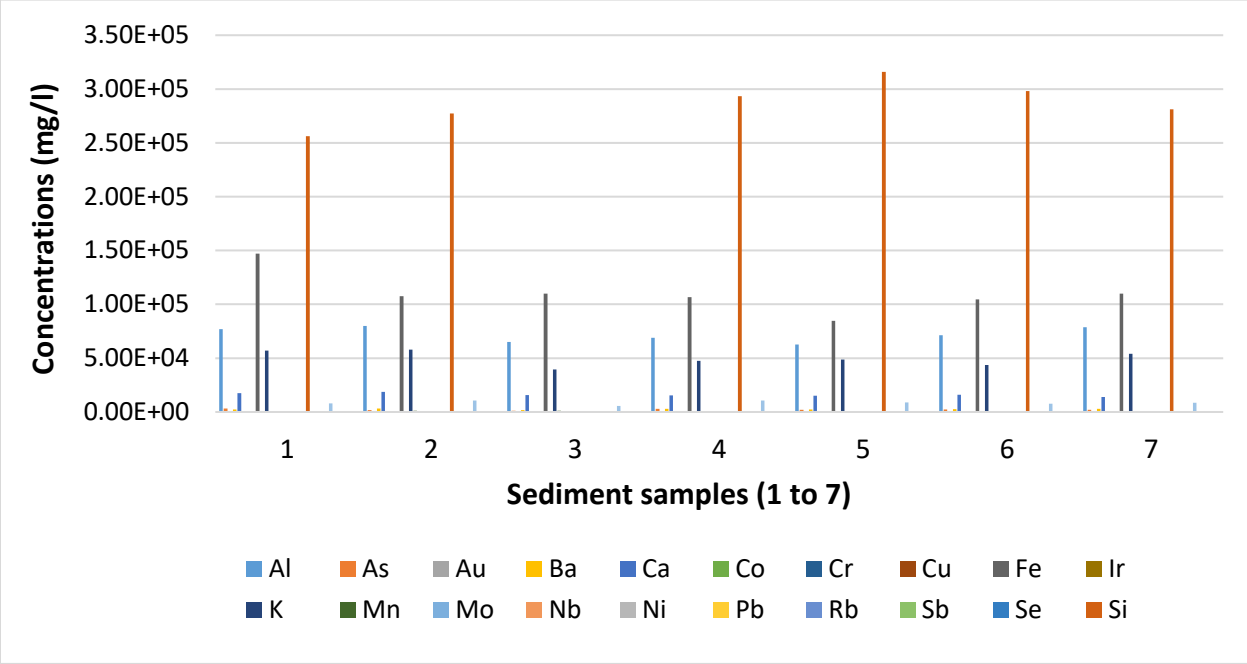

Figure 8: Geochemical results of river sediments samples

The high concentrations of silicon (> 200,000 mg/l and iron > 100,000 mg/l) may be due to the fact that silicon is more abundant in the earth's crust, and also because pyrite is among the main minerals making up the rocks at the mining site.

Chemical element concentrations in the washing basin are almost identical to sediment concentrations in the zone of low influence upstream of the river. There is a drop in concentration at the percolation zone, followed by a slight increase in concentration as the river flows downstream of the percolation zone.

Heavy metals such as arsenic (As), chromium (Cr), copper (Cu), iron (Fe), lead (Pb), and tin (Sn) are also present in high concentrations in the washing basin, while vanadium (V) and zinc (Zn) are present in high concentrations in the sediments upstream of the river (Figure 8).

Given these results we can say that the mine has little influence on the sediments of river. This can be explained by the fact that the river crosses the site in the form of a torrent with a low sedimentation rate, which means that the particles in the river from the mine or from run-off do not have time to settle.

Probable origin of high metal concentrations

The metals are of natural origin. The Nyenyezi deposit in Kaziba supplies the Kashozi processing site with ore. It is of the vein type, with schists (phyllades) and quartzophyllades as the host rocks. These rocks alternate with quartzites. Mineralization is essentially gold-bearing, with iron oxides as accompanying elements. The high concentration of iron can be explained by weathering and erosion phenomena, but even more so by the activities that lead to its exposure on the surface. From a mineralogical point of view, this could be explained by the fact that iron is found in pyrite, copper in chalcopyrite, and calcium in calcite and ankerite. These minerals constitute the mineral paragenesis of orogenic gold deposits (Nkere, 2022).

Selenium may come from suspended clay minerals. Copper could come from the alteration of quartzites but also, in accordance with the regional geology, from malachite and/or azurite (Rumama, 2017).

The results of this study show high levels of heavy metals in water samples, such as As (1,400 – 3,500), Cd (100 – 3,200 mg/l), Cr (200 – 1,200 mg/l), Cu (70 – 3,900 mg/l), Iron (13,500 – 166,900mg/l), Mn (700 – 3,000 mg/l), Ni (100 mg/l), Pb (40 – 170 mg/l), Se (10 – 40 mg/l), and Zn (200 – 2,000 mg/l). Most of these grades are higher than those found by other authors in studies carried out at other sites in the South Kivu province (e.g., Wenga, 2022; Bazikange, 2022). We can therefore confirm that the Luzinzi River is indeed polluted with heavy metals as a result of the leaching of mine tailings from the gold mining and processing circuit.

Conclusion

The aim of this study was to assess the level of heavy metal contamination in the waters and sediments of the Luzinzi River, potentially due to artisanal gold mining at the Kashozi mine site.

To achieve this, the methodology consisted of carrying out on-site observations of the treatment circuit; and taking water and sediment samples and analyzing them (in situ and in the laboratory) to determine physical parameters (water conductivity and pH) and geochemical composition of stream sediments and the chemical composition of water samples.

With regard to physical parameters, the analyses show that the pH of the waters is acidic to neutral (between 5.09 and 6.09) and therefore below WHO standards for drinking water (between 6.5 and 9.5), but these waters are also low-conducting (between 37.6 to 43.8 µS/cm) and therefore perfectly within WHO standards (EC < 250 µS/cm).

Analysis of heavy metals in water showed high levels of As (1,400 – 3,500 mg/l), Cd (100 – 3,200 mg/l), Cr (200 – 1,200 mg/l), Cu (70 – 3,900 mg/l), Iron (13,500 – 166,900 mg/l), Mn (700 – 3,000 mg/l), Ni (100 mg/l), Pb (40 – 170 mg/l), Se (10 – 40 mg/l), and Zn (200 – 2,000 mg/l), compared with mining regulations and WHO standards for drinking water.

Analysis of these results led to the preliminary conclusion that surface waters in the study area are polluted with heavy metals, in particular As, Cd, Cr, Cu, Fe, Mn, Ni, Pb, Se, and Zn. The pollution observed is largely due to mining activities in the area. The results of this study suggest that this is long-standing pollution, dating back to the start of artisanal mining activities in the sector.

In view of the partial results of this study, which confirm the pollution of the study area by heavy metals, the following recommendations can be made:

1. Implement existing legislation (deemed sufficient but generally not applied).
2. Establish an institutionalized system for monitoring pollution of the hydrographic network in active artisanal mining areas.
3. Ban the use of mercury when concentrating gold.
4. Raise awareness among populations about the potential risks involved in consuming polluted river water without prior treatment.
5. Build a lagoon purification system with hyper-accumulating species of heavy metals in order to treat mining effluents before their release into the natural environment.

Acknowledgements

The authors would like to acknowledge Mr. Ciza Murhabazi Emmanuel, candidate engineer at the Mining School of the Université Officielle de Bukavu, for his help with the fieldwork, and the staff of the Mining School and the Office Congolaise de Contrôle laboratory for their collaboration.

Implementation of Saturated and Unsaturated Seepage Analysis in a Polymetallic Tailings Storage Facility: A Case Study

Abstract

Tailings dam failures around the world have brought tailings storage facilities (TSFs) under intensive evaluation by experts in the field of engineering. Several working groups and government agencies have emphasized the importance of risk management associated with TSFs. Therefore, numerical analyses to aid in decision-making are often appropriate support tools. The implementation of numerical models can have advantages associated with the design, planning, operation, and closure of a TSF. However, to reduce the uncertainties associated with numerical analysis, these must be accompanied by the application of the observational method. Thus, this paper presents a case study in which a saturated and unsaturated flow numerical model was implemented, which has helped in decision-making to reduce the associated risks before, during, and after the operational periods of a TSF. The case study highlights the analysis methodology, which included stages of calibration, verification, and prediction of the drainage conditions of the TSF. The results show the benefits of numerical seepage modeling, which, under appropriate evaluation criteria, can be a supportive tool for decision-making in the management and control of a TSF. Finally, some experiences gained over the three years of observation of the case study are highlighted.

Introduction

Water flow analyses are a specific evaluation of the design, planning, operation, and closure stages of a tailings storage facility (TSF) (Mittal and Morgenstern, 1976). From a geotechnical perspective, these analyses focus on estimating saturation, pore pressures, and seepage that can influence the short- and long-term stability of the TSF (Finke Morrison, 2022; Beier et. al., 2023). Historically, there are records of several collapses directly or indirectly related to water flow through these structures (Alexander, 1986; Macklin et

al., 2006). Although water flow is not the sole contributing factor, it is one of the primary ones (Azam and Li, 2010; Lyu et al., 2019).

Several morphological, hydrogeological, and operational factors influence water flow behavior in a TSF (Fredlund and Dakshanamurthy, 1981). Identifying each of these factors is essential for a clear understanding of its hydraulic characteristics. Given this condition, the geotechnical engineer must actively collaborate with hydrology and hydrogeology specialists to develop the conceptual and numerical simulation of water flow within the TSF. However, the development of both elements must be conducted under the principles of saturated and unsaturated flow concepts (Lam et al., 1987; Cooley, 1983).

Based on the above, the objective of this paper is to demonstrate the methodology for implementing a saturated and unsaturated seepage numerical model for monitoring, planning, and decision-making in a tailings storage facility. The general results of the case study, collected over a three-year observation period, are highlighted. It is hoped that this publication will encourage the development of specialists with a hydro-geotechnical focus capable of conceptualizing hydraulic behavior and its implications for the stability conditions of tailings dams.

Case study

The case study is a representative cross-section of an upstream tailings dam with a height of 45 m and an average slope of 2H:1V (Figure 1). The TSF operation is based on cycles of excavation and deposition of tailings using the conventional spigots method.

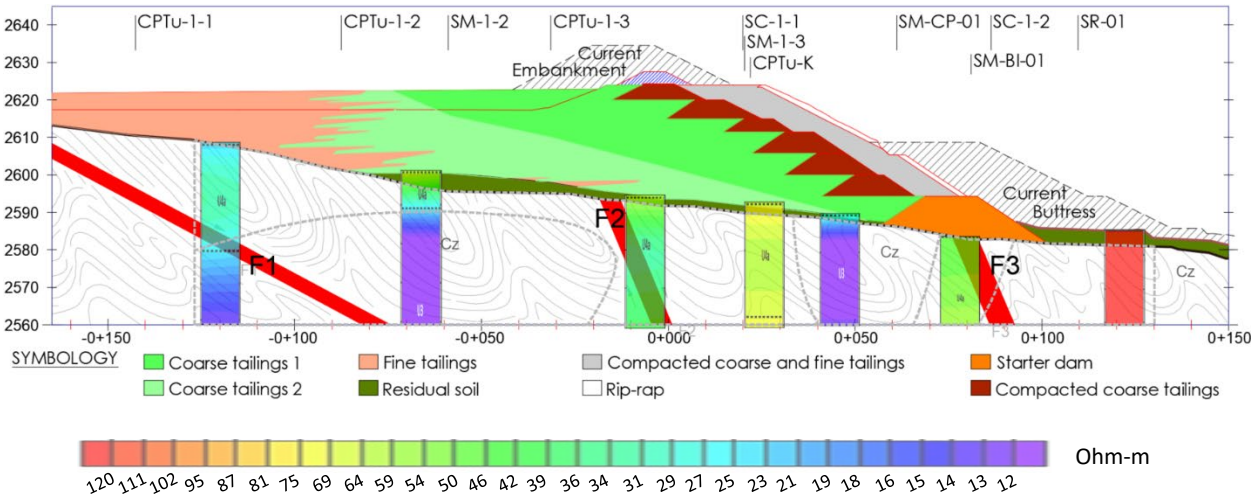

Figure 1: Cross-section view of the TSF

The material characterization of the TSF was based on geophysical, geotechnical, and geological investigations. The geological study characterized the foundation as limestone rock with shale intercalations. Three inactive and permeable geological faults, designated as F1, F2, and F3, were also

identified. Geophysics identified low resistivity zones (0-20 Ohm-m) associated with potential saturation areas related to the location of the geological faults. The interpretation of geotechnical exploration helped in the classification of tailings according to the fine content (%F) and the normalized soil behavior type index from the CPTu (Ic-SBTn): coarse tailings 1 (%Fines ≤ 25 and Ic-SBTn ≤ 2.0); coarse tailings 2 (25 < %Fines ≤ 50 and Ic-SBTn≤2.6); and fine tailings (%Fines ≥ 50 and Ic-SBTn ≥ 2.6). A cross-section of the TSF is shown in Figure 1.

Saturated and unsaturated tailings properties

The coefficient of permeability ($k_{Measured}$) was determined based on laboratory tests, in-situ tests, and empirical relationships. The analysis distinguished the hydraulic conductivities in the horizontal and vertical directions, expressed as k_x/k_y ratio (Table 1). It should be noted that the hydraulic conductivities are expressed using the geometric mean and the standard deviation as a decimal logarithm.

Table 1: Saturated hydraulic conductivity and fitting parameters for the SWCC

Material	$k_{y\ Measured}$ (m/s)			$k_{y\ Calibrated}$ (m/s)		Fredlund and Xing (1994)				
	σ_{std}	k_{mk}	k_x/k_y	k_y	k_x/k_y	$\theta_{w\ sat}$	a_f (kPa)	n_f (-)	m_f (–)	h_r (kPa)
Coarse tailings 1	0.2	2.16E-06	~2	1.55E-06	15	0.49	10.1	1.9	1.5	40.0
Coarse tailings 2	0.4	3.86E-07	~2	5.33E-07	15	0.46	11.7	2.2	1.0	55.0
Fine tailings	0.6	1.52E-08	~2	3.29E-08	15	0.40	765.1	0.9	1.7	7500
Compacted coarse tailings	0.5	4.18E-06	–	5.0e-07	1	0.30	13.0	1.0	0.7	1500
Starter dam	–	3.34E-06	–	2.39e-06	1	0.30	0.9	4.7	0.6	6.0
Residual soil	–	1.42E-06	–	1.72e-08	1	0.50	0.6	4.6	0.6	2.5
Faults	–	1.53E-04	–	2.50e-05	1	–	–	–	–	–

The unsaturated tailings property functions (Soil Water Characteristic Curve – SWCC and Hydraulic Conductivity Function – HCF) were defined through estimation procedures based on four stages: 1) Fitting the tailings grain-size distribution curves with the Fredlund et al. (2000) equation; 2) Estimating the SWCC from grain-size data using the Arya and Paris (1981) or Aubertin et al. (2003) method; 3) Fitting the estimated SWCC with the Fredlund and Xing (1994) equation; and 4) Estimating the HCF using the Fredlund et al. (1994) equation. Table 1 summarizes the fitting parameters for the SWCC and the saturated hydraulic conductivity for the HCF.

Conceptual model

The conceptual model for the case study is illustrated in Figure 2. The essential features of the conceptual model are highlighted below Figure 2.

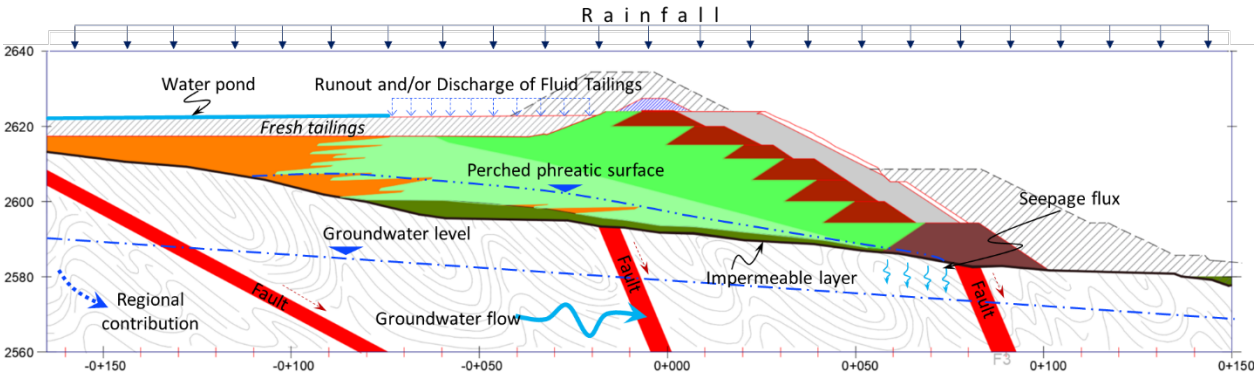

Figure 2: Conceptual model for the case study

- Regional contributions and groundwater flows are associated with runoff that infiltrates through the slopes and contributions from the upper part of the basin.
- Faults act as preferential flow paths that influence the saturation and desaturation of the foundation.
- An impermeable layer partially extends through the footprint of the TSF, limiting seepage toward the foundation and creating a perched phreatic surface. The discharge of the perched phreatic surface occurs at the base of the starter dam, where the impermeable layer was removed during its construction.
- The main seepage to the perched phreatic surface comes from the operational periods of the TSF.
- Surface infiltrations through the beach area depend on the water pond, tailings deposition, and rainfall. These input variables contribute to the saturation of the TSF.

Numerical modeling

The seepage analysis was conducted for a two-dimensional section representing the maximum cross-section of the TSF. The analysis was performed under a transient regime that involved both saturated and unsaturated flow conditions. Evaluation was performed using the commercial software Seep/W (Geoslope, 1991-2021), which solves the Richards equation (1931) with the finite element method (FEM). The mesh was adjusted based on geometric changes in the section, comprising over ~10,000 triangular elements and 5,250 nodes (Figure 3).

Boundary conditions were based on the conceptual model described in the previous section (Figure 2). Details of each boundary condition are described in the following points (see also Figure 3):

- Rainfall ($q_{Rainfall}$): represented by a function given by the average of annual daily rainfall over a 40-year period. It was verified to prevent unrealistic pressure heads on the model surface.
- Groundwater flow (HGW): idealized as constant hydraulic heads assigned at the boundaries of the numerical model, inducing gradients for the interaction of the TSF with the foundation.

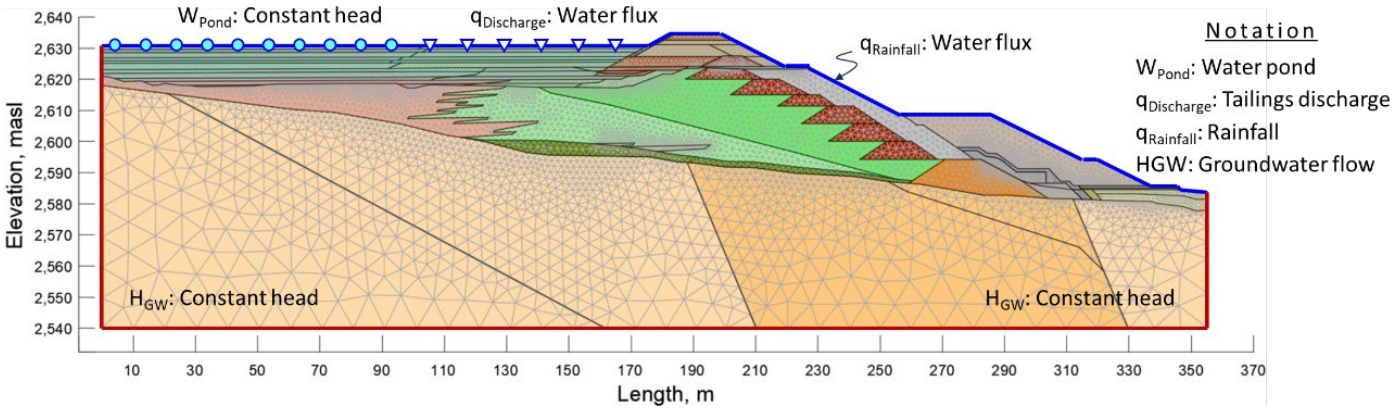

Figure 3: Numerical model and boundary conditions

- Water pond (W_{Pond}): given by a constant head associated with the water levels related to the slope of tailings deposition.
- Beach length: defined as the average monthly value of the monitoring data.
- Fluid tailings discharge ($q_{Discharge}$): incorporated as a unit flux considering the number of spigots, discharge rates, solids content in the tailings mixture, the average tailings runout from the spigots to the water pond, and a width equivalent to the separation between two adjacent spigots. The unit flux was applied as a function simulating the spigot cycle, maintaining the discharge rate for a 24-hour period at 10-day intervals, representing the 11 operational spigots. Throughout all stages of the numerical modeling, the unit flux was made dependent on the infiltration rate to prevent the development of unrealistic pressure heads on the model surface.
- Fresh tailings: associated with the storage curve of the TSF and tailings with high permeability.

The methodology and criteria adopted in the numerical modeling are summarized in Table 2.

Discussion

The calibration stage focused on simulating the water level readings in observation wells (PO) and electric piezometers (PZE) (Figure 4). The calibration period was set from July 2020 to March 2021. Since water level readings began with the tailings deposition, calibrations were updated based on field observations. The outcome of this stage was a numerical model with calibrated conductivities ($k_{Calibrated}$) (Table 1) capable of simulating the water level changes at PO and PZE. Although a temporal lag in the response of the model was identified, the absolute changes in pore pressures matched well with field records.

Table 2: Procedure and stages of analysis

No.	Stage	Description
1	CALIBRATION[1]	(Figure 4)

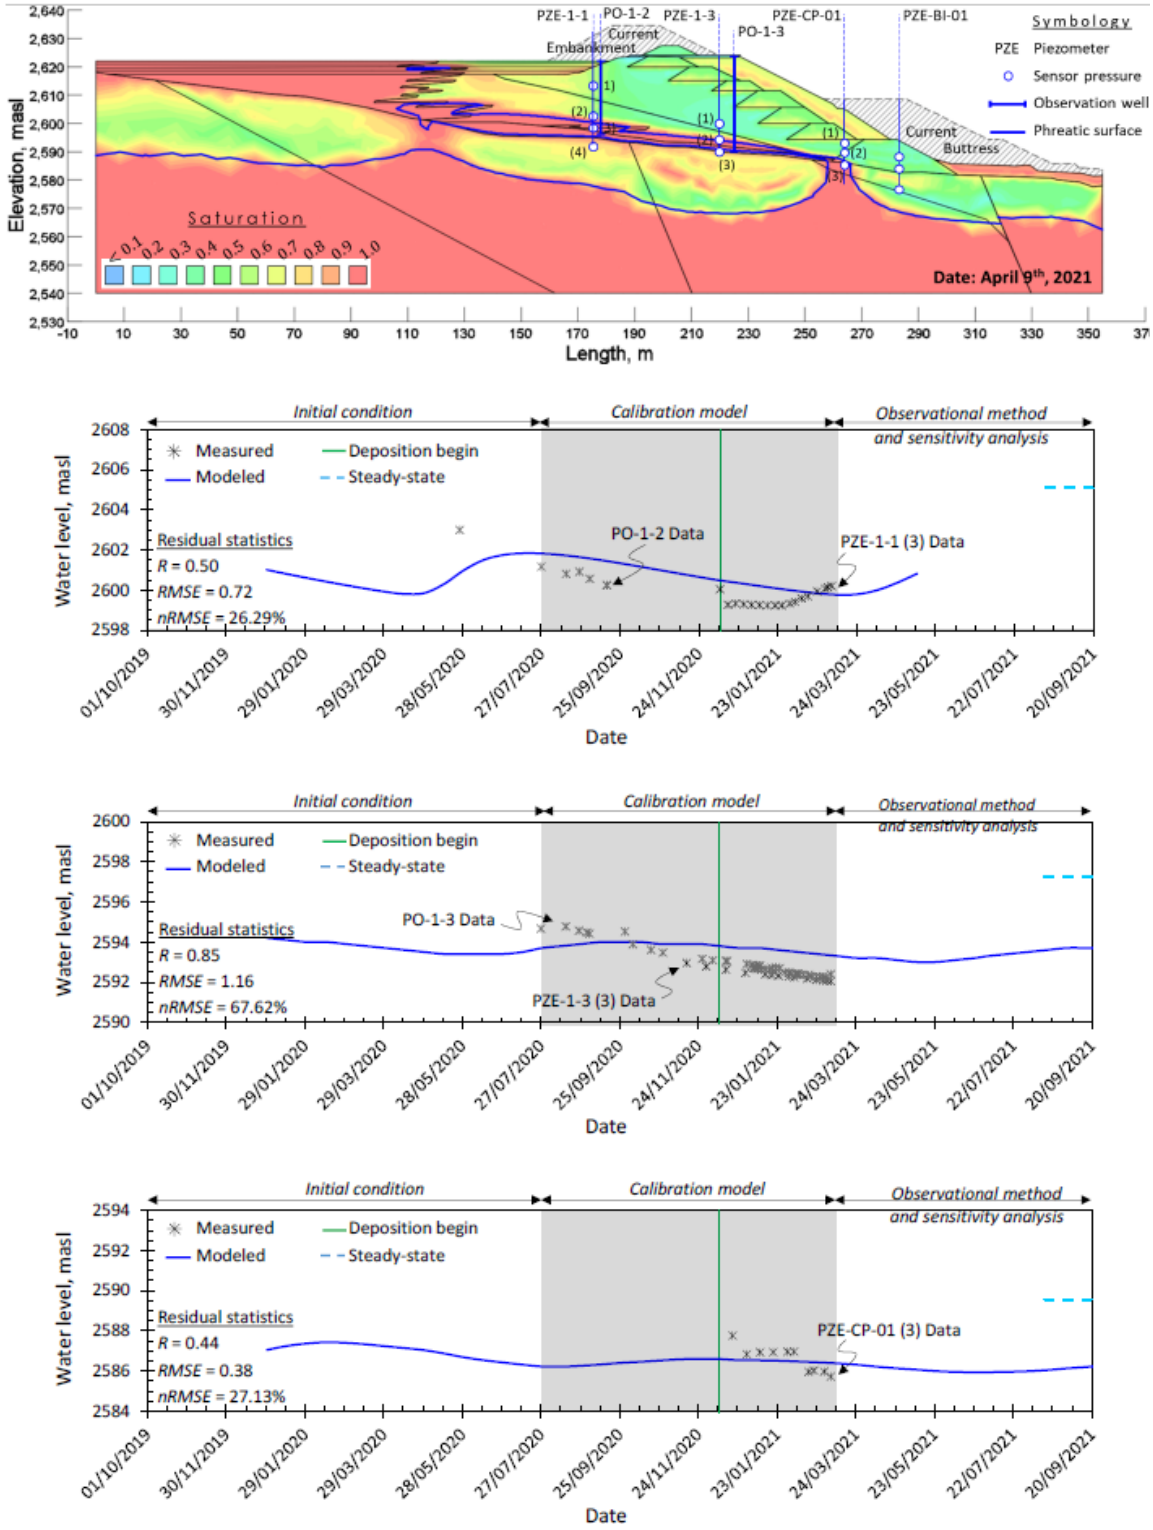
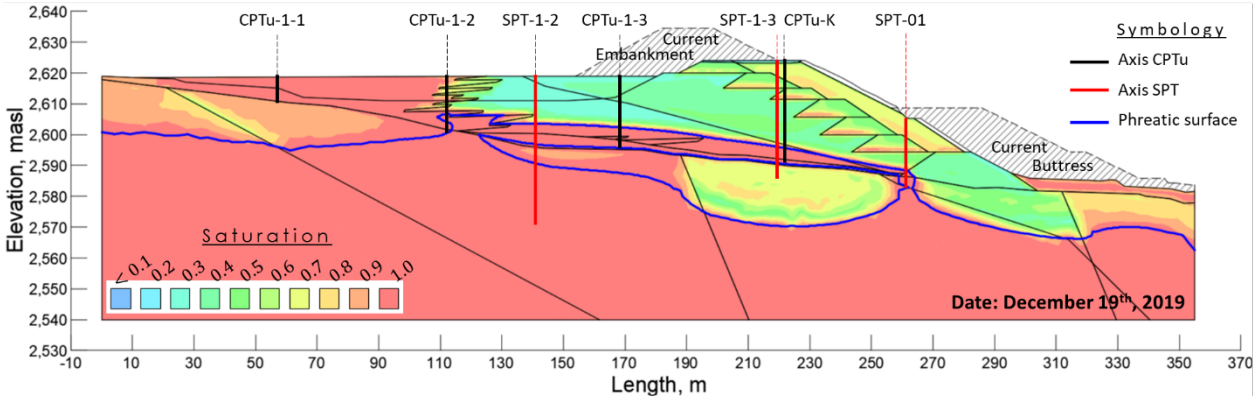
4.1	True predictive case	Evaluation of the most representative operational conditions reconciled with the TSF operator

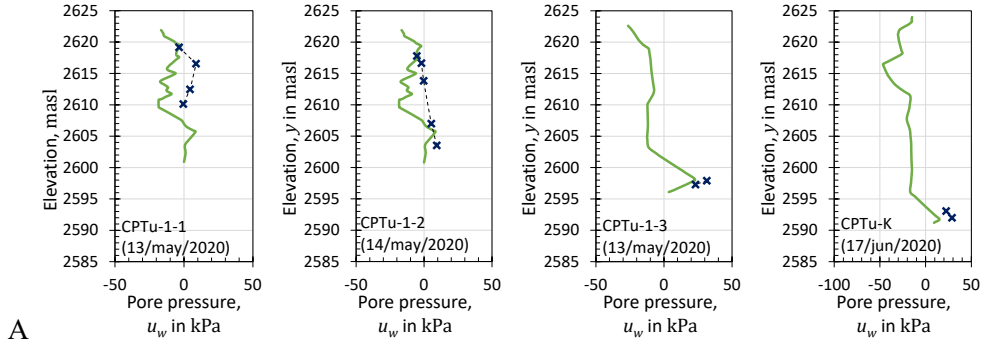
Notes:
[1] This stage includes the analysis of an "initial condition" that defines a phreatic surface linked to a specific date of the TSF. The "initial condition" precedes the operational simulation of the TSF, representing the starting condition of the numerical model.
[2] To minimize non-uniqueness issues, a single calibration parameter was adopted.
[3] Qualitative verifications.
[4] Assumes a relationship between the pore pressure (u_2) of the CPTu and tailings saturation. It is inferred that an increase in u_2 may be associated with a high water content or saturation.
[5] Assumes the estimation of saturations based on water content profiles from SPT.
[6] Due to space limitations, these are not included in this publication.

The validity of the calibration model was assessed during the verification stage. This phase relied on qualitative correlation of modeled saturation and pore pressure profiles with those obtained from geotechnical exploration campaign (CPTu and SPT) (Figure 5). Profile comparisons were made for a time equivalent to the date of each sounding. The results in Figure 5 (Row A) showed an adequate match between both pressure profiles, particularly in zones below the water table. For pore pressure (u2) and modeled saturation profiles (Figure 5, Row B), both variables exhibited a direct relationship. Each pressure increase was associated with perched saturation zones (Sw ≥ 80%). Regarding saturation profiles (Figure 5, Row

C), the match between estimated and modeled values showed a suitable correlation, with modeled trends remaining within measured limits.







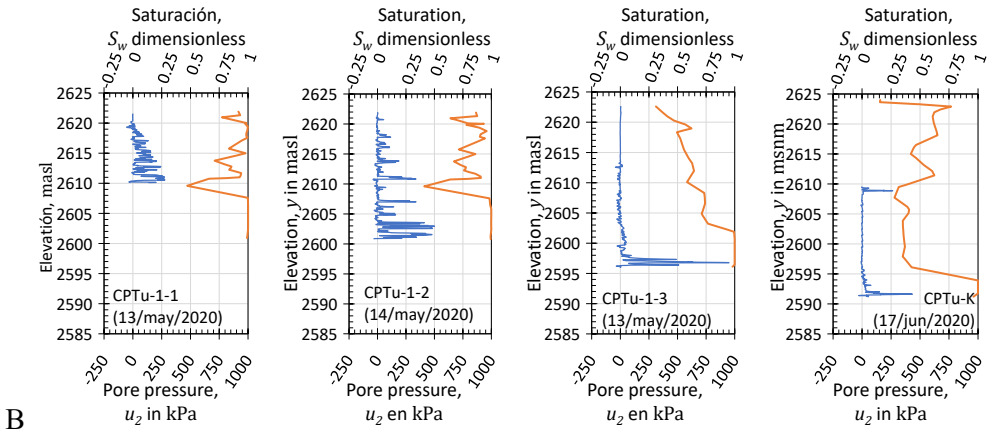


Figure 4: Calibrated model results

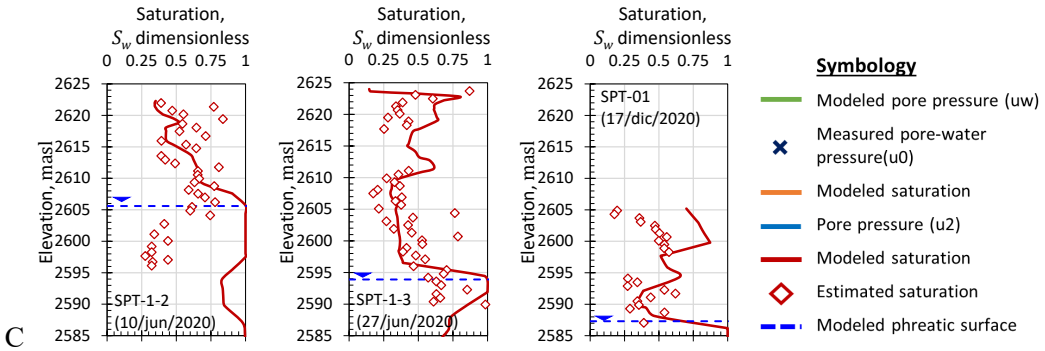

Figure 5: Verification model results

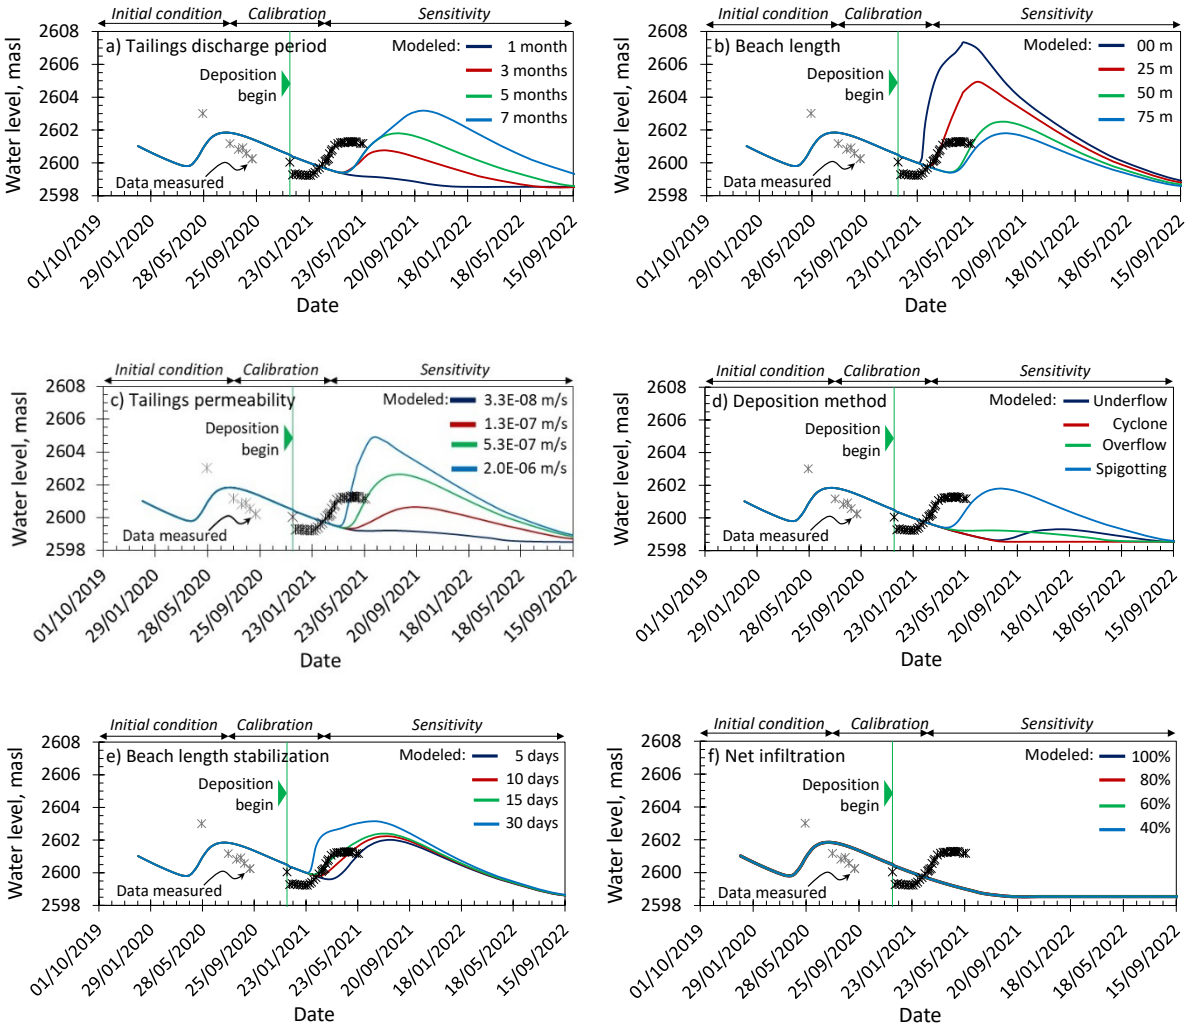

Figure 6: Sensitivity results

The outcome of the calibration and verification stages enabled the development of a sensitivity analysis to establish the operational plan, with careful consideration of potential increases in water levels and saturations that could impact the stability conditions of the TSF. The results from each scenario contributed to the establishment of operational controls and risk levels during and after the operational period of the TSF. Figure 6 illustrates some results, highlighting the variation in water levels for piezometer PZE-1-1 (3).

Each stage of the analysis has led to the implementation of a numerical model capable of capturing the hydraulic conditions of the TSF. Although the numerical model has been complemented by the observational method, it has proven to be an effective tool in the decision-making process during operational periods and extraordinary events at the TSF. Figure 7 shows the historical record of three years of observations and numerical modeling related to the case study.

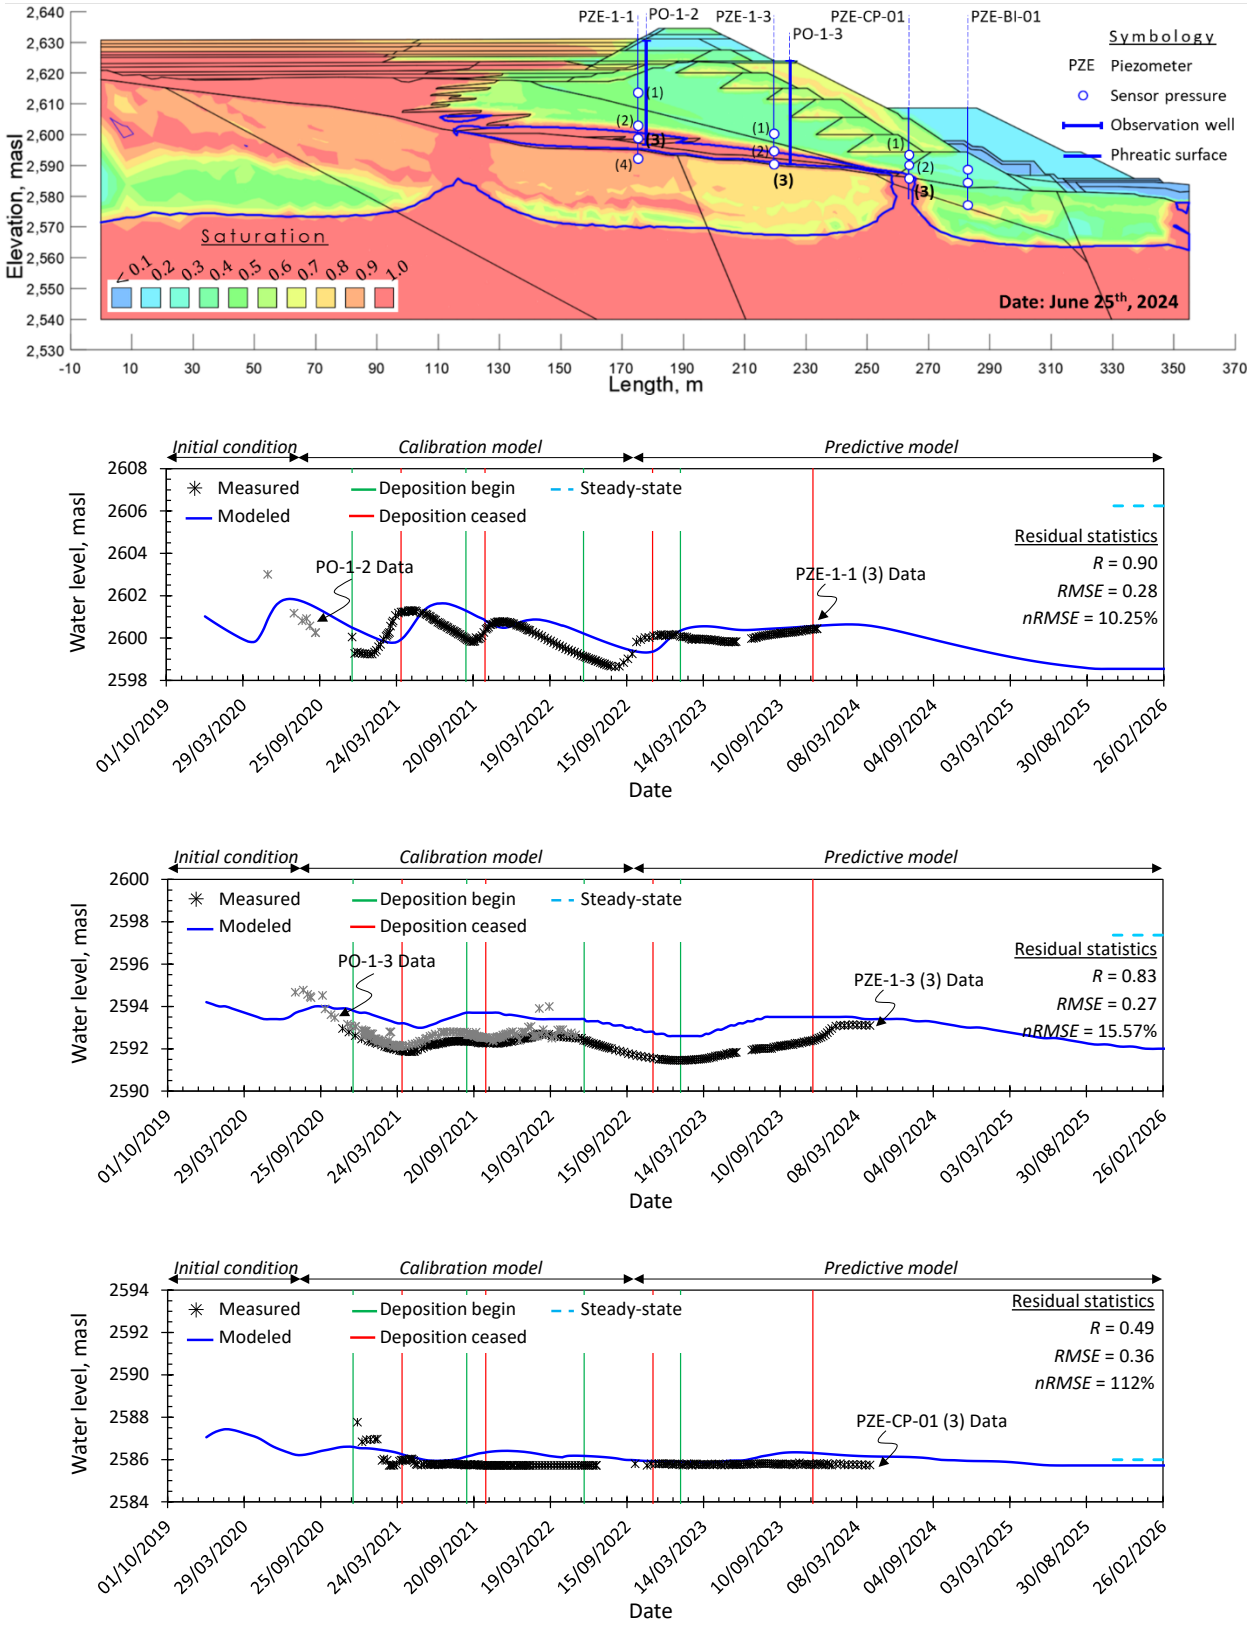

Figure 7: Predictive model and data measured

Conclusion

This article presents a case study where numerical seepage analysis is implemented as a tool for monitoring and estimating the drainage conditions in the TSF water management. The results obtained over three years of monitoring allow for the following conclusions:

- The analysis of hydraulic conductivities showed that anisotropic flow does not depend on the tailings microstructure but rather on the layering of coarse and fine tailings associated with discharge points (such as segregation, spigot location, operation method, etc.).
- Numerical modeling is a tool that should be complemented by the observational method. Deviations between measured and modeled conditions lead to the verification of either the numerical model or field conditions. In both cases, the agents that modify the expected behavior of the TSF must be identified. Collaboration between the designer and the TSF manager is essential to identify each agent.

This study presented a successful case of a two-dimensional (2D) seepage analysis. However, it is important to note that three-dimensional (3D) effects influence the water flow behavior within a TSF. While these effects can be partially simplified in the main drainage section, appropriate simplifications of the boundary conditions and a clear conceptualization of the numerical model are required.

Saturations can be a topic of discussion in geotechnical engineering, primarily due to challenges with sample recovery during the exploration campaign. Therefore, considering additional verification variables is justified as a process to enhance the certainty of the numerical model by incorporating direct field measurements that can correlate with the analysis results.

Seepage analysis should not be limited to water level estimations alone. Saturation zones or perched phreatic surface should be of interest, especially as these factors can influence the stability of the TSF.

The assessment of the type of material stored in the TSF should be conducted as a specific analysis. Coarse tailings, with higher infiltration rates, promote increased water levels and may be seen as unfavorable for the TSF. Conversely, fine tailings, with limited infiltration rates, tend to result in lower water level increases within the TSF, thereby considered a favorable condition. However, it should be noted that the low hydraulic conductivity and water retention capacity of fine tailings can lead to the development of saturations or perched phreatic surfaces, which may represent preferential failure planes affecting both local and global stability of the TSF.

Numerical modeling of saturated and unsaturated flow is a tool that can support the development of monitoring, operational, and closure plans for a TSF. However, the analyses and results should always be complemented by the observational method for effective decision-making. Regardless of the predictive capability of the numerical model, there will always be uncertainties.

The response in water levels may show a delay in relation to the start and end of TSF operations. The response time will depend on the wetting front, which can be influenced by agents such as hydraulic conductivity, water retention capacity, and the degree of saturation of the materials. Sensitivity assessments can provide key elements for decision-making, allowing for effective operational control of the TSF.

The degree of correspondence between measured and modeled data is often subject to the judgment of the modeler. Temporal or elevation lags may be evident and can impact the calculation of residual errors. However, the response of numerical model to operational periods and absolute increases in water levels can be representative of the actual condition. Therefore, the numerical model may be considered acceptable.

Abstract

The installation of mining dams is a common method to store mining tailings due to their technical and economic benefits. Nonetheless, they can pose serious socio-environmental effects in case of failures, especially in water bodies, threatening water security and drinking water supply, and undermining Sustainable Development Goals (SDGs). Thus, considering the recent mining dam collapses – especially in Minas Gerais, Brazil (Mariana, 2015; Brumadinho, 2019) – laws and regulations have been either published or amended to ensure stricter rules around the operation and safety of mining dams. In those regulations, ensuring that an Emergency Preparedness and Response Plan (EPRP) for mining dams is in place in case of an adverse event is required, including an Emergency Action Plan for Drinking Water Supply (EAP-DWS). However, there are numerous challenges in preparing an EAP-DWS, including: the difficulty of gathering reliable data; the construction of the plan in conjunction with stakeholders; the deployment of structuring actions in complex scenarios; and the constant updating of current legislation. Moreover, in order to ensure that the EAP-DWS is operational, emergency drills need to be carried out to check the efficiency of the action plans and to train and engage all the participants. The aim of this paper is to share the experiences, challenges, and lessons learned in drawing up EAP-DWSs in the context of mining dam collapses. This sharing of experiences is fundamental to increasing municipalities' water security and strengthening emergency response plans to guarantee access to drinking water in crisis scenarios.

Introduction

Mining activity has been growing globally due to various factors, among which population growth,

economic advances, and consequently the increased demand for minerals, stand out. Associated with the rise in mining activity is the increase in the production of mining waste, and thus, tailings storage facilities (TSFs).

Among the different types of technologies and methods for storing these tailings, the construction of dams is commonly applied due to its technical and economic advantages. However, in the event of a rupture, they can have deleterious social and environmental effects, especially concerning the water-environment nexus – altering the quality of water bodies and consequently making their catchment, treatment, and use impossible, at least temporarily.

In this context, historically, a number of dam rupture events have occurred, and in Brazil, the collapses of structures in Mariana (2015) and Brumadinho (2019) were significant in terms of social, environmental, and even legislative aspects (Guimarães et al., 2022). Given the risk of dam collapses, regulations have been published or amended to ensure stricter rules on the operation and safety of dams in Brazil. Among these regulations, the guarantee of an Emergency Preparedness and Response Plan (EPRP) for mining dams in case of an adverse event is a prerequisite for environmental licensing. Among the sections that make up this plan, specific actions to ensure the supply of drinking water to potentially impacted populations stand out.

Not only in Brazil, but internationally as well, changes have occurred in response to these events. In 2020, the Global Industry Standard on Tailings Management (GISTM) was published, aiming to prevent similar failures in the future and provide transparency in the management and executive oversight of TSFs. This global standard was developed by a multidisciplinary panel of experts, including the International Council on Mining and Metals (ICMM), the United Nations Environment Programme (UNEP), and the Principles for Responsible Investment (PRI). In addition, an advisory group conducted extensive public consultation with affected communities, government representatives, investors, organizations, and mining industry stakeholders, analyzing best existing practices along with experiences from previous tailings disposal structure failures (Dladla and Ramsamy, 2022).

The GISTM is organized around six thematic areas, encompasses 15 principles, and has 77 auditable requirements. However, its adoption is challenging, requiring significant changes in various aspects, including ensuring water security. Meeting specific requirements, such as Requirement 2.2, which covers water resources, demands continuous effort to map and assess water quality in potentially affected areas. Furthermore, Requirement 1.1 – ensuring human rights, for which a basic or fundamental right is access to safe drinking water – implies the need for a range of activities to guarantee access to water, ranging from developing emergency drinking water supply plans to implementing structural actions to ensure water security in potentially impacted areas.

Given these points, it is evident that the journey towards structures compliant with the GISTM standard requires persistence, integration, and a multifaceted approach to ensure safety and protection at all stages of the project. Thus, the development of emergency water supply plans is more than a legal requirement; it is also compliance with and adherence to international standards that aim to guarantee a fundamental human right.

Water supply in the scope of EPRPs for mining dams

Ensuring the availability of safe drinking water has become an increasingly significant challenge. On a global scale, water security, in terms of both quantity and quality, has been identified as one of the primary challenges in water management (ANA, 2021; MacAlister et al., 2023). The task is more complex in multi-use watersheds, with probable spatial and temporal imbalances between water supply and demand (Chen et al., 2020). This is further exacerbated by extreme and more frequent climatic changes and the limited resilience of public water supply systems (de Melo et al., 2021), as recently recorded in the state of Rio Grande do Sul, Brazil.

The issue of water security is on the agenda of various organizations, notably the United Nations and the Organization for Economic Co-operation and Development. In this context, the need to prevent crises in the drinking water supply sector is emphasized to ensure compliance with the sixth Sustainable Development Goal (SDG-6), establishing a new paradigm in water resource management (United Nations in Brazil, 2024). SDG-6 focuses on ensuring the availability and sustainable management of safe drinking water and sanitation for all by 2030, recognizing these as fundamental human rights and vital components for sustainable development. Globally, billions of people still lack access to drinking water, and inadequate sanitation poses serious health risks. Thus, SDG-6 aims to address these challenges through the promotion of water conservation, sustainable water resource management, and the development of efficient sanitation infrastructure (Ogunbode et al., 2024).

It is important to highlight that cooperation between countries, international organizations, and industrial sectors is essential to achieving the SDGs, especially SDG-6. For example, the mining sector can contribute by:

- adopting responsible practices to reduce social and environmental risks;
- investing in technologies that promote efficient water use in their operations;
- collaborating with other countries and organizations to share knowledge and experience in water and sanitation-related activities; and
- developing emergency water supply plans to ensure access to this universal right in emergency situations (Saenz, 2023).

This context includes the development of Emergency Action Plans for Drinking Water Supply (EAP-DWSs) in the event of mining dam collapses, which could potentially impact drinking water supply systems. The emergency actions proposed in such plans must consider providing a minimum per capita volume of drinking water sufficient for basic needs and maintaining the health of potentially affected populations. Relevant literature indicates a minimum per capita value ranging from 15 to 30 L/person per day, sufficient to meet basic hygiene and food needs. Considering that in emergency situations it is not possible to satisfy all water needs and demands of the affected population, the initial focus should be on survival. However, as the situation and human, logistical, operational, and other resources permit, the water supply should be increased for other uses, considering the scaling up of drinking water volumes to be supplied in the developed plans (FUNASA, 2018; WHO, 2013).

In an emergency, beyond the need to guarantee fundamental rights – aligned with the SDGs and adherence to the global standard (GISTM) – the provision of drinking water to the population poses significant challenges for the developers (mining companies) and competent authorities, even in high-income countries with high security in the water supply sector (Bross et al., 2019).

Therefore, this paper aims to present how EAP-DWSs are developed in the context of potential impacts on water supply systems resulting from mining dam collapses, as well as the challenges faced in the development of these plans.

Development of emergency action plans for drinking water supply and challenges faced

In developing EAP-DWSs, various important issues must be considered, such as the amount of water needed and available for supply, transportation logistics, available resources, and responsible parties involved. Thus, some central questions must be explored when developing the plans: (i) Who needs to be supplied? (ii) How much water is needed? (iii) From where will the water be sourced? (iv) How will the water be distributed? (v) For how long is the emergency supply planned? and (vi) Who will provide the water supply?

In this context, Figure 1 presents a summary of the main steps for developing EAP-DWSs. The first action involves the developer's (mining companies) contact with the stakeholders involved (water supply service providers, municipal emergency response agencies, and other responsible parties) to introduce the topic, discuss applicable legislation, present flood maps, and request primary data from the public water supply system. After receiving the data, as well as collecting relevant information available in public databases, the impacts concerning the flood map are consolidated and characterized. Based on the characterized impacts, solutions for emergency services to the affected population are proposed through action protocols scaled at emergency levels (defined according to the geotechnical conditions of the

structure). Once the plan is constructed, the developer forwards the document to public agencies and stakeholders responsible for acknowledgment and validation. Finally, the plans are filed with the competent authorities, made available to stakeholders, and, if possible, published digitally.

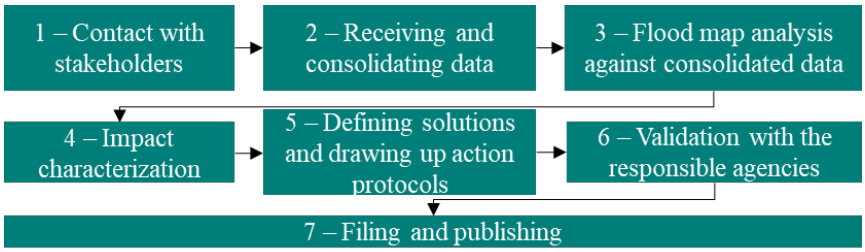

Figure 1: Summary of the steps for developing EAP-DWSs

Conducting these stages, and consequently consolidating an operational and effective emergency action plan for drinking water supply, encounters various specific challenges, which will be addressed below in this paper.

Data collection from the drinking water supply system

For the development of the plan, it is essential to have detailed knowledge of the municipal water supply systems to accurately characterize the potential impacts and to propose assertive solutions. One way to achieve this characterization is through secondary data, which are publicly available information sources. Although this is an easily accessible option, it has several challenges and weaknesses, such as: (i) the data may be outdated and may not reflect the current conditions of the municipality; (ii) there may be multiple sources for the same information, often conflicting, making it difficult to identify the correct data; (iii) some data may be erroneous, possibly due to typographical errors; and (iv) data is generally only available for water catchment and water treatment plants (WTPs), making it impossible to assess impacts on other system components (water mains, reservoirs, pumping stations).

Therefore, the ideal is to obtain primary information directly from the drinking water supply system, provided by the municipality or the service provider. However, this approach also presents obstacles, such as: (i) smaller municipalities may not have this information and may need to conduct surveys, requiring specialized labor that is often unavailable in these areas; and (ii) there may be a lack of engagement from service providers, leading to delayed, incomplete, or even no responses.

Thus, obtaining both primary and secondary information on the municipal water supply system faces adversities and impasses. While primary data are generally more accurate, the aforementioned difficulties – such as the lack of information in smaller municipalities and low engagement from service providers – make the use of secondary data an alternative for developing the EAP-DWSs. If the EAP-DWSs are developed with secondary data, it is necessary for the developer, together with public agencies, to strive to

obtain the primary data and incorporate them in a subsequent plan revision. Moreover, even when the document includes primary data, updates, at appropriate times – or when the legislation requires (each 3 years for the current legislation) – are essential to incorporate changes in city infrastructure and their water supply systems.

Stakeholder engagement

Engaging stakeholders in the plan development process is crucial and challenging. As such, it is essential that the agency responsible for regulating the development of these plans clearly defines the roles and responsibilities of those involved. Generally, the main parties involved are the developer, the water supply service provider, and the municipal emergency response agency.

Developer, water supply service provider, and municipal emergency response agency

It is crucial that these parties maintain efficient communication, based on the responsibilities established by legislation. Otherwise, engagement may be hindered from the start due to the lack of a solid legal basis. Additionally, it is recommended that the timeframe for plan development involves not only the developer but also the other stakeholders involved, according to their responsibilities. A current challenge in Brazil, especially in Minas Gerais, is that the developer has defined deadlines for plan development, while the service provider and the municipal emergency response agency, although part of the process, do not. This can result in a lack of collaboration or in timelines incompatible with legal requirements. Therefore, it is crucial that the regulatory agency clearly establishes roles, responsibilities, and deadlines in the process for all stakeholders.

Beyond these issues, some challenges for good stakeholder engagement can be observed. When it comes to water supply service providers, their involvement is crucial since they possess detailed knowledge of the municipal water supply systems they serve, allowing for a more accurate characterization of potential impacts. Additionally, these providers have the expertise to define solutions that could be implemented in emergencies. However, in some cases, providers refuse to participate in this process, especially in joint plan development and data provision, arguing that this data is sensitive and cannot be disclosed. In other situations, the water supply service provider has such a small team and simple infrastructure that it struggles to share these demands with developers in addition to their daily responsibilities.

Mutual aid plan – synergy between developers

In addition to engagement between the developer, the water supply service provider, and the municipal emergency response agency, a relevant challenge is fostering synergy between developers (other mining companies) in the development of plans and, if possible, in creating Mutual Aid Plans. These plans promote collaboration between companies, public agencies, and the community. But why is this exchange of

experiences, resources, and cooperation between companies important during the creation of EAP-DWSs?

The answer becomes clear when identifying the main problem that arises without this cooperation: many developers share similar flood areas that may result in the same impacts on the water supply systems of specific municipalities. If each developer works alone, there will be distinct solutions, resources, and plans for the same problems. The municipality, in turn, will have to deal with multiple solutions for a single problem, creating redundancies and unnecessary complications. Furthermore, the plans, once finalized, need to be simulated to ensure their applicability and correct potential errors. Imagine a municipality simulating five different plans for the same impact on its water supply system? This overburdens municipal resources and generates inefficiencies. In the long term, this lack of synergy can significantly slow down the process. Therefore, collaboration between developers (other mining companies) not only optimizes resources but also accelerates the implementation of effective and cohesive solutions.

On the other hand, the time for conducting dam break studies and the deadlines for submitting them to the agencies vary for each developer, making plan compatibility challenging. If it is not possible to provide this synergy from the beginning of the studies due to individual deadlines, it is recommended to adopt approaches that allow continuous adjustments as the process matures. Technical working groups among developers can be formed with frequent agendas to discuss the topic and join efforts in plan development. Another point to consider is that if developers have already developed different plans for the same impacts, municipalities could indicate the most suitable plan, adopting a single option for the municipality.

Addressing complex scenarios

In assessing potential impacts on the drinking water supply system, it is essential to consider complex scenarios where the consequences extend beyond the scope of emergency response, sometimes requiring prior structural actions and more robust solutions to ensure a minimum drinking water volume required by legislation during the emergency and return to the normal public water supply. These scenarios are characterized by several factors that amplify challenges and require more detailed technical and strategic approaches, as discussed below for three scenarios dealing with high flow impacts, isolated areas and low water availability. Furthermore, these cases highlight the necessity of mutual collaboration between the parties (drinking water service provider and the municipal emergency response agency).

High flow impacts

In situations where the number of affected people in a municipality exceeds 100,000 inhabitants – usually scenarios impacting high flows in the supply system (i.e., > 300 L/s) – proposing an efficient emergency response is challenging. This is because the calculated resource quantities in the plan can be so high that some points of attention arise: (i) If water trucks or other vehicles are adopted, do the roads support this

high quantity? (ii) Has the developer mapped suppliers capable of meeting this high demand? (iii) Does the developer have the capacity to allocate many support teams for these situations?

In some cases, operationalizing these plans requires prior planning and execution of structural actions. This can include reinforcing water treatment plant (WTP), physically protecting water catchments and WTPs, opening access routes, installing reservoirs, implementing alternative water mains, drilling wells, among other measures.

It is recommended that these actions be linked to the dam's emergency levels (based upon the TSF geotechnical conditions), allowing them to be executed in a scaled, programmed manner, prior to a rupture event. With the implementation of these measures, the impacts on the water supply system resulting from a potential rupture are minimized, making an efficient emergency response feasible or, in some cases, eliminating the need for emergency intervention.

Isolated areas

Another complex scenario occurs when the impact is associated with road obstruction by the flood map, creating isolated areas. This blockage hinders water distribution logistics and delays repairs to potentially affected supply structures. In these cases, if possible, alternative land access routes must be planned. If this is not feasible, the use of aircrafts should be evaluated as a last resort. This resource is not relatively easy to obtain in large quantities during an emergency and requires complex logistics.

A recent example of using aircrafts in emergency water supply response occurred due to the floods in Rio Grande do Sul, Brazil, starting in April 2024. This was one of Brazil's largest climate tragedies, affecting approximately 900,000 people across 400 municipalities, with an estimated mobilization of 2500 vehicles and 42 aircraft for emergency response in various isolated access areas (Agência GOV, 2024). In this context, Brazilian Air Force (FAB) helicopters played a significant role in emergency drinking water supply. In addition to distributing bottled water to the isolated population, the aircraft were responsible for transporting a power generator to a water treatment plant, restoring the water supply to some neighborhoods that had been without water for three days, and transporting a nearly 2.5-ton water pump capable of pumping 500 L/s (EB, 2024; FAB, 2024).

Therefore, in plans identifying multiple isolated areas, it is advisable to include structural actions related to the dam's emergency levels. Relevant measures for this scenario include opening alternative accesses and implementing water catchment and reservoir systems for emergency situations.

Low water availability

Impacts in regions with low water availability represent an additional challenge, as the response capacity is limited by local water resource scarcity. In such areas, any interruption in the supply system can have severe consequences due to the difficulty in finding alternative water sources.

In these circumstances, it is also recommended to conduct studies and implement structural measures prior to a potential collapse, associated with the dam's emergency levels. Developing integrated water resource management strategies and promoting technological alternatives for water treatment are imperative. This includes evaluating the feasibility of implementing rainwater catchment and treatment systems. Additionally, the construction of infrastructure to supply water from neighboring regions, adopting rotational supply systems, and creating emergency reservoirs can be viable solutions to ensure supply resilience in crisis situations.

In conclusion, addressing complex impacts on the drinking water supply system requires a combination of detailed planning, infrastructure investments, adopting integrated management, and scheduling studies and structural actions linked to the dam's emergency levels. This ensures the system's resilience in the face of different crisis scenarios, securing continuous and safe water supply for the population.

Serving buildings of public interest

Buildings of public interest refer to those that provide essential services to society, such as daycare centers and public educational institutions, hospitals and units for public health care, and collective housing facilities. Ensuring an emergency drinking water supply to these locations is a complex challenge that requires careful planning and coordination.

Data availability

To ensure effective emergency water supply, it is essential that data on these establishments is available and up to date. However, as previously mentioned concerning the acquisition of municipal water supply system data, the same issues apply to data on buildings of public interest. In many cases, municipalities do not have a centralized or updated registry of this information. Therefore, one of the primary challenges is creating a centralized system for collecting and updating information on such buildings and essential services, involving collaboration among different levels of government, institutions, and service providers.

Prioritizing emergency response

The water supply of buildings of public interest must be treated with the utmost priority both in planning and in emergency response. During emergencies, it is crucial to allocate larger volumes of water to these buildings to ensure that essential services are not interrupted. Additionally, the logistics of distributing water to buildings of public interest can be complex and must be considered separately from the rest of the population. Factors such as distance, accessibility, storage capacity, and demand must be carefully evaluated. In densely populated urban areas, effective coordination among different agencies and service providers is essential for an effective plan.

In summary, prioritizing the emergency response to these buildings requires a specific approach, considering their particularities and the collaboration of all involved. The community's resilience depends on the continuous functioning of these essential services.

Adherence to constantly changing legislation

The constant changes in legislation regulating the topic of water supply within EPRPs represent a significant challenge for the development and implementation of these plans. Although these regulations are published with the aim of improving the subject, each new legislative change requires revisions of the already prepared documents, directly impacting the maturity of the process.

The continuous need for review also demands efficient communication among stakeholders. Each legislative change must be promptly communicated and understood by all involved, including municipalities, service providers, and regulatory agencies, to ensure that all parties are aligned and can adequately contribute to the necessary revisions.

For example, in Minas Gerais, Brazil, in the past five years, approximately eight standards, including resolutions, decrees, terms of reference, and technical instructions, have been published regarding EPRPs for Mining Dams with an interface in water supply (Minas Gerais, 2019, 2020, 2021a, 2021b, 2022, 2024a, 2024b; Brazil, 2022, 2024). These publications required the re-evaluation of the prepared documents or introduced new guidelines to the process.

It is crucial that the regulatory bodies improve the legislation, but at a frequency that is consistent with the process and with due care to ensure that different agencies do not issue conflicting standards or guidelines on the same subject.

Implementation of plans

The implementation of EAP-DWSs aims to ensure that the affected population has access to drinking water in emergency situations. To ensure that these plans are effective in such situations, the implementation can be divided into three main phases: (i) engagement of all agents involved in the emergency; (ii) assessment of the necessary resources; and (iii) simulation of the plans.

Engagement of those involved in the emergency

The engagement of agents involved in the emergency refers to the active participation of all sectors or individuals with actions and responsibilities described in the plans, which is fundamental to ensuring the success of their implementation. Examples of agents or sectors with responsibilities in the plans, based on the Incident Command System (ICS) – a US methodology for Command and Control of emergencies – include: the EPRP coordinator; the logistics section, responsible for all services (e.g., supply of people,

equipment, transportation, supplies) and logistical support needs within the plan; the planning section, which manages information and encompasses the environment and resource management units.

Engaging people in the implementation of these plans can be challenging for various reasons, particularly those related to communication; understanding of responsibilities, i.e., making them feel part of and responsible for the plan; and monitoring their responsibilities and actions throughout the plan's effective term.

Therefore, overcoming these challenges requires a strategic approach that includes effective communication among all involved, assignment of specific and objective roles, accountability for processes and results, and training of those involved through courses and drills. The need for engagement extends not only to the internal teams of the developer but also to the water service provider and emergency response agencies. These agencies are essential to ensure public safety while emergency drinking water is supplied.

Resource assessment

The assessment of resources for the implementation of plans involves the stages of identification, analysis, and management of these assets to ensure effectiveness in actual emergencies. These resources can include human resources, which consider the labor, skills, and knowledge required; and logistical resources, which consider the use of materials and equipment, such as water transport vehicles, bottled water, mobile treatment stations, aircrafts, among others.

The challenges related to these resources in implementation are mainly due to the difficulty of allocating the necessary quantity in an efficient manner. Therefore, thorough advanced planning is of the utmost importance, including verification of the availability of internal resources and the establishment of umbrella contracts with suppliers to prevent the unavailability of these items from becoming a limitation in emergency response.

Given the above, it is concluded that for the implementation of EAP-DWSs, it is necessary to have properly sized and trained teams, ensuring that the agents involved in the plans are aware of their actions and responsibilities. It is also crucial to have access to qualified internal specialists and external service providers, as well as appropriate logistical resources and equipment.

Plan simulation

Simulations play an important role in evaluating and exploring impact scenarios arising from dam failures, as they are a way to predict the behavior and outcomes of a plan before activation. These drills not only help identify improvements in the plans but also promote greater engagement of the agents involved and keep resources and teams prepared to face an emergency. However, challenges are encountered in this area, especially when it comes to complex scenarios.

The challenges related to simulations in general, and particularly in more complex scenarios, as discussed earlier, arise due to the logistical effort needed to obtain resources, as these plans may encompass many water transport vehicles, various supply routes, the need for mobile treatment stations, among other resources that increase the cost and time required to execute these drills. In addition to the resource aspect, one of the main challenges is performing maneuvers in the supply systems in plans that foresee rotational supply to the community. Finally, there are also the challenges of information management and ensuring the engagement of all the players involved.

Overcoming these challenges requires a planned approach and a commitment to continuous improvement. Regarding EAP-DWSs, an approach found to face these challenges is the scalability of simulations. The scalability of these drills helps reinforce theoretical knowledge about the plans, promote the engagement of all agents involved, allocate resources efficiently, and ultimately simplify the simulation stages. This scalability involves creating a program of exercises, training, and drills: (i) Exercises aim to provide a theoretical and comprehensive understanding of what the plan is and the fundamental points of knowledge. (ii) Training aims to guide the activation flow and the actions of each responsible person in the emergency, in addition to addressing any questions. (iii) Drills aim to test participants in the practical execution of their roles and responsibilities in an emergency, while in a controlled and risk-free environment. Finally, it is important to find a balance between reality and simulation, especially in complex scenarios. Excessive simplification may neglect important aspects, while a simulation too close to reality can become impractical. Therefore, it is crucial to identify the critical points of the plan that need to be trained and kept true to reality, while others can be simplified.

Conclusion

The experience presented in the development of emergency action plans for drinking water supply in the context of impacts on supply due to mining dam failures can be a valuable source of information for developing guidelines for emergency drinking water supplies. Such guidelines need to be uniform, detailed, and transnational, aiming to meet the targets of the SDGs as well as the GISTM standards, in line with sustainable development. However, given the various challenges presented, when developing such plans, local specificities must be taken into account, considering demographic, territorial, socioeconomic, and cultural aspects, as well as the different phases of emergencies and the players involved, aiming for the effective implementation of the plan at the time of an emergency.

Geotechnical Issues

TAILINGS AND
MINE WASTE 2024

Exploration of Passive Desaturation of In-place Tailings Using Wicking Geosynthetics

Kendall Monley, WSP, USA
Joseph Scalia IV, Colorado State University, USA

Abstract

As global demand for metals and critical minerals increases, so too does the production of tailings and tailings storage facilities (TSF). A common assumption is that the water initially contained in a TSF will drain down to an unsaturated condition after deposition of new tailings ceases. However, a review of literature on geotechnical and hydrotechnical conditions of legacy TSFs (TSFs that have stopped receiving tailings) in arid environments illustrates that achievement of unsaturated conditions in internal fine-grained layers may not always occur. As the tailings are deposited, layers of finer and coarser particles are interbedded causing the formation of capillary barriers. This may ultimately result in finer-grained layers held at near saturation after draining down. The fine-grained layers are more susceptible to liquefaction concerns and can necessitate costly remedial actions to ensure geotechnical stability. In this study, I explore in-situ dewatering via use of capillary (wicking) geotextiles, and the effectiveness of the wicking geotextiles. The employed wicking geotextiles have been used successfully in roadway applications to prevent migration of water into the subgrade, but implementation for tailings dewatering is novel. Column experiments were created to emulate stratigraphy seen in legacy TSFs. Column testing reveals the wicking geotextiles accelerated saturated and unsaturated dewatering by 2.8 times the rate of natural drying processes. This promising approach to passively dewatering tailings warranted additional study.

Introduction

There are more than 17,000 tailings storage facilities (TSFs) globally, with ~40% (~6,800 TSFs) active or currently operational (Spencer et al., 2022). The remaining 60% exist in some form of inactive (mining paused), closure, or post-closure status, deemed legacy TSFs. Due to a lack of available site data, the geotechnical conditions of legacy sites are often generalized. One frequent assumption is that relatively uniform tailings deposits have undergone, or are in the process of undergoing, drain down of stored water under gravity and are now unsaturated. However, based on reports from legacy tailings facilities in arid (Hardy et al., 2003; Casey et al., 2022) and non-arid environments (Godley and Quaglia, 2023) this

assumption may not be reflective of the state of many legacy TSFs.

Figure 1 is a schematic of the development of saturated fine-grained layers from initial deposition to the final configuration of the TSF. Continuous heterogenous tailings deposition results in segregation of particle sizes. Deposition of newly segregated tailings above previously deposited material results in interbedded layers of fine and coarse tailings. Over time, the tailings will drain excess pore water under gravity; however, as the tailings transition to an unsaturated state, drain down of the confined fine grain layers will be impeded, thus producing permanent interbedded near-saturated fine grain layers with liquefaction potential.

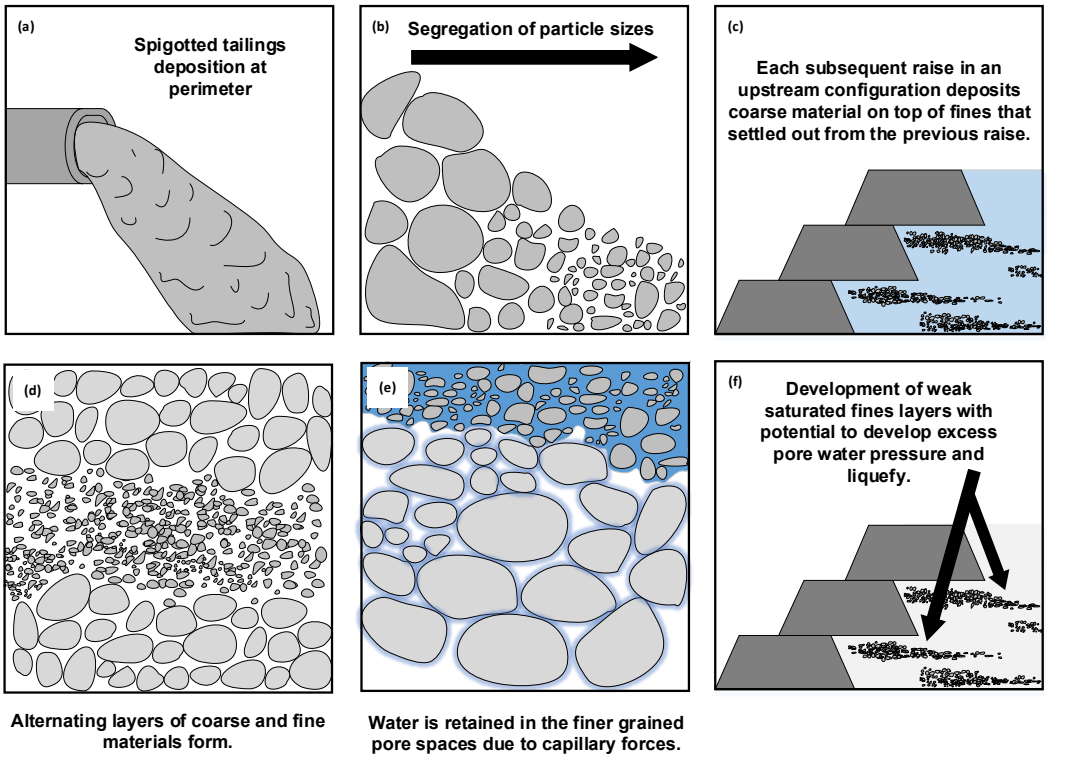

Figure 1: Schematic progression of TSF construction, drain down, and retention of saturations

The soil water characteristic curve (SWCC) and the hydraulic conductivity function (HCF) are illustrated in Figure 2 (Fredlund et al., 2012) and provide insight into the development of these permanent near-saturated layers. The upper bound of hydraulic conductivity (Figure 2b) represents the saturated condition. Initial gravity drain down occurs due to saturation throughout the tailings. As both layers begin to desaturate, the suction at the two-media interface is effectively equal. The coarser tailings pores drain more rapidly than the finer tailings pores, and as a result the coarse tailings hydraulic conductivity drops lower than that of the finer tailings. The point at which the coarser soil will stop admitting water can be

approximated as the height of capillary rise (H_c) within the soil. H_c can be translated onto the SWCC (Figure 2a), and the associated suction is denoted Ψ_H. Hydraulic conductivity decreases rapidly after reaching the inflection point value as suction increases due to increased tortuosity and reduced area for flow.

Capillary barriers form at the interface of the two homogenous soils of contrasting pore size (i.e., coarse- and fine-grained tailings) and limit the movement of water through the system under unsaturated conditions (Stormont and Anderson, 1999). The result is interspersed near permanently saturated fine-grain layers confined by coarse layers with extremely low hydraulic conductivities.

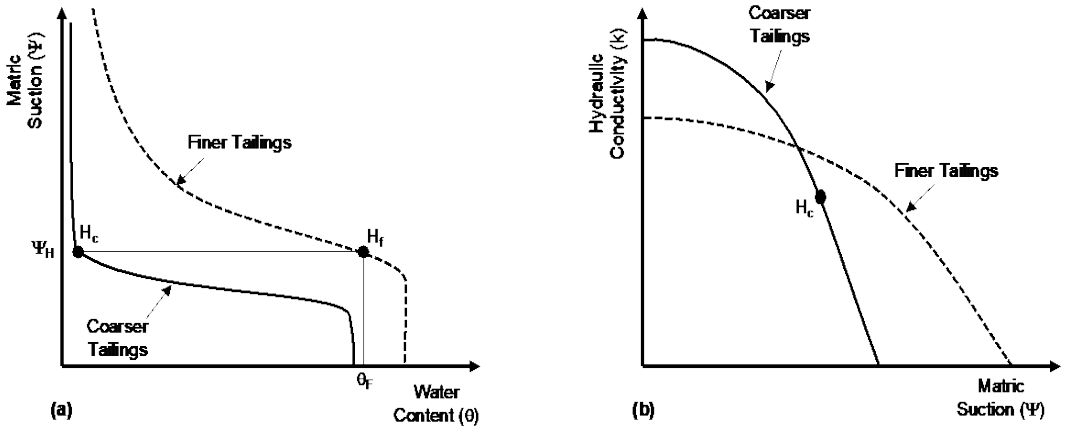

Figure 2: (a) Soil water characteristic curve (SWCC) and (b) hydraulic conductivity function (HCF) for finer- and coarser-grained tailings (derived from Khire et al., 1999)

Retention of saturated, or near-saturated, conditions often elevate geotechnical stability concerns for TSFs, particularly seismic stability and susceptibility to flow liquification. Long-term retention of near-saturated conditions yields conservative assumptions of full saturation and may drive financially costly and environmentally disruptive mitigation efforts. Common industry practice is to assume that tailings are fully saturated until a value of less than 60% saturation is reached.

Global initiatives to enhance water stewardship in mining are a significant driver for tailings dewatering. However, this option makes material handling (i.e., transport and placement) more difficult and expensive in comparison to pumping slurry tailings (Carneiro et al., 2018). Additionally, dewatering practices that occur prior to deposition are not a solution for existing (active and legacy) TSFs, without significant capital investments or implementation of remining practices. Dewatering existing tailings in-situ (i.e., after tailings have been deposited) offers numerous benefits, the most significant being the ability to densify the deposit, thereby reducing the likelihood of generating positive pore water pressures during seismic or similar events.

There are two main categories into which in-situ dewatering methods are divided: active and passive. Active dewatering requires continuous energy or reagent inputs. While passive dewatering operates using

low intensity or minimal energy inputs beyond initial installation, such as prefabricated vertical wick drains (Adams et al., 2017). Both methods are primarily designed around the removal of pore water that is under positive pressures or draining permeable strata. Thus, additional tools are needed for the removal of water retained in fine strata by capillary barriers in TSFs.

Wicking geotextiles

Wicking geotextiles are a recent advancement designed to remove moisture from roadway embankments or subbases (Lin and Zhang, 2018). The cross-section of the fiber is shown in Figure 3. This geotextile, created from weaving high-tenacity polypropylene filaments and deep-grooved nylon-wicking fibers, produces a coherent drain by effectively wicking water from soil pores. The diameters of the wicking fibers range from 30 to 50 μm and the width of each groove is between 5 and 12 μm (Zhang and Connor, 2015).

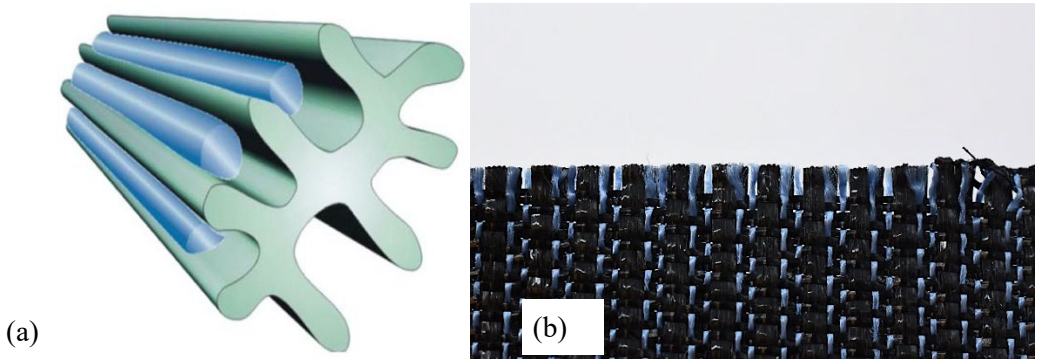

Figure 3: (a) Wicking fiber cross-section (Lin and Zhang, 2018) and (b) close-up of wicking (blue) fibers

There are several unique properties of the wicking geotextile. The wicking fibers have hydrophilic and hygroscopic properties that provide enhanced lateral drainage along the plane of the geosynthetic, meaning that the nylon will pull water from the surrounding soil pores and then provide a conduit for the water to the surface along the inner channels (TenCate, 2022). In addition, wicking geotextiles have greater air-entry values, compared to non-wicking geotextiles, allowing for the development of capillary force or suction to remove moisture from soils in unsaturated conditions (Lin et al., 2016).

The geotechnical advantages of wicking geotextiles have been proven in transportation and roadway studies. Guo et al. (2019) summarized the available studies and projects that demonstrated the effectiveness of the wicking geotextile as a drainage material. Zhang et al. (2014) and Lin and Zhang (2018) estimated that due to the suction difference induced by the relative humidity between the unsaturated soil, geotextile, and air, a large hydraulic gradient is formed; thus, the geotextile can absorb water from the surrounding soil and transport to the exposed/atmospheric end. Zornberg et al. (2017) reported field studies in which the daily water content reduction was evaluated in the soil column from a nearly saturated condition. This study

determined that the wicking geotextile was more effective in reducing the water content than the non-wicking geotextile under the same conditions. Additionally, the drainage function of the wicking geotextile continued at a lower water content than the non-wicking geotextile.

The success observed by the geotextile in the field of transportation indicates a promising ability that may be transferable to other engineering applications such as tailings dewatering. Assessing the capability to dewater tailings fines is a novel application explored in this research.

Methodology

Column experiments, in which tailings were confined between layers of fine and coarse sand, were constructed and conducted to assess the in-situ capillary water dewatering capabilities of the wicking geotextiles. Filtered tailings from a confidential precious metal mine, herein referred to as Mine P, as well as a fine and a coarse sand, were used for testing. Filtered tailings were dewatered at the mine during pilot-scale tests before shipment to Colorado State University.

Two capillary geosynthetics were used in this study. Wicking geotextile 1 is a prototype material and wicking geotextile 2 is sold commercially under the name H2Ri by TenCate Geosynthetics. The characteristics of wicking geotextiles 1 and 2 are the same and summarized in Table 1.

Table 1: Mechanical properties of wicking geotextile 1 and 2

Mechanical Properties	Test Method	Unit	Minimum Average Value
Wide Width Tensile Modulus (CD)	ASTM D4595	kN/m	77.0
Tensile Modulus @ 2% Strain (CD)		kN/m	15.8
Permittivity	ASTM D4491	s^{-1}	0.4
Flow Rate		L/min/m2	0.1222
Pore Size (050)	ASTM D6767	µm	85
Pore Size (095)		µm	195
			Maximum Opening Size
Apparent Opening Size	ASTM D4751	U.S. Sieve (mm)	40 (0.425)

Column construction

Column experiments were created to emulate the previously described stratigraphy observed in legacy TSFs. The final set-ups are shown in Figure 4. The tailings used in the column experiments were created at 50% solids contents. The columns were created by depositing layers of varying granular sizes into clear PVC columns to force the development of capillary barriers. One end of the column was plastic welded to a square base plate and the column was sealed with silicone caulk to prevent water loss through the bottom

of the system. Columns were weighed at regular intervals to observe water mass loss and to determine the change in solids contents corresponding to the new total masses.

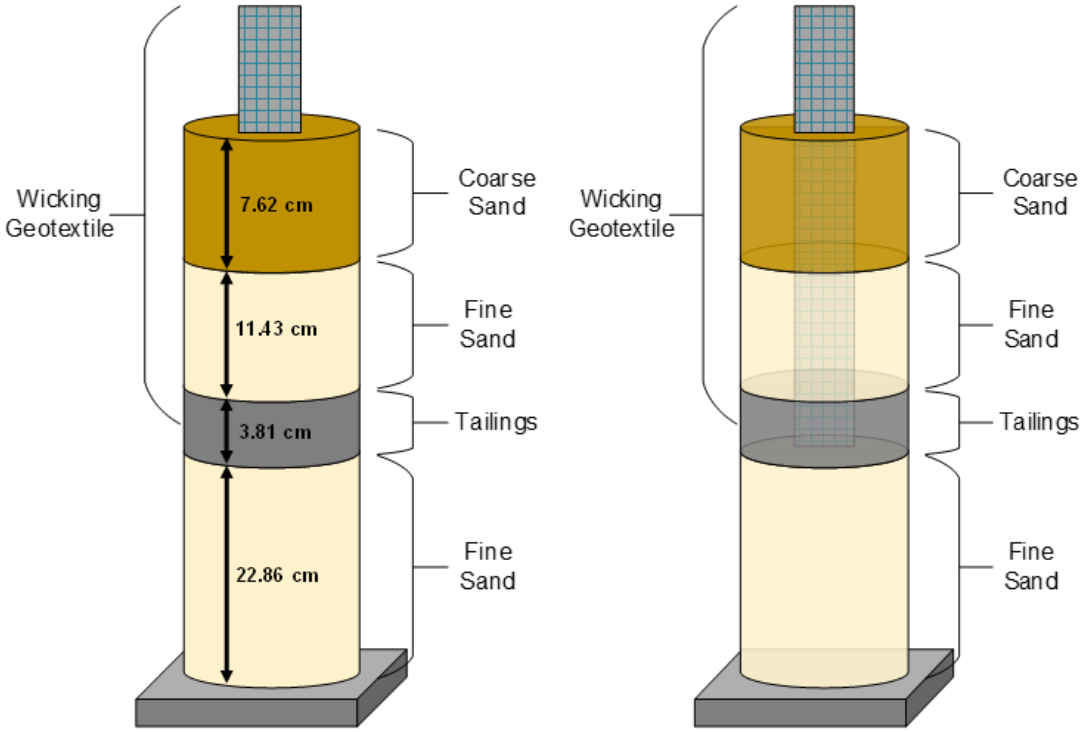

Figure 4: Tailings columns created at 50% solids contents: digital renderings

Results

The van Genuchten (1980) equation was used to calculate the volumetric water contents of the fine sand and tailings:

$$\theta = \theta_r + (\theta_s - \theta_r)\left[\frac{1}{1+(\alpha\psi)^n}\right]^m \quad \text{(Equation 1)}$$

where θ_r is the residual volumetric water content, θ_s is the saturated volumetric water content, α is inversely related to the air entry value, n controls the slope of the SWCC, $m = 1 - n^{-1}$. The van Genuchten (1980) equation was used to calculate the unsaturated hydraulic conductivities of the fine sand and tailings:

$$K_r = \left(\frac{\theta-\theta_r}{\theta_s-\theta_r}\right)^P \left[1 - \left(1 - \left(\frac{\theta-\theta_r}{\theta_s-\theta_r}\right)^{\frac{1}{m}}\right)^m\right]^2, \; P = -2 \quad \text{(Equation 2)}$$

where K_r is the relative hydraulic conductivity, and P is a fitting parameter, usually considered -2 for fine soils. Fitting parameters to Equations 2 and 3 are provided in Table 2.

Table 2: SWCC parameters for the tailings and fine sand (tailings parameters provided by Aghazamani, 2022)

Parameter	Value	
	Fine Sand	Tailings at 95% $\gamma_{d,\,max}$
θ_r	0.01	0.004
θ_s	0.206	0.339
α (kPa^{-1})	0.833	0.013
n	3.449	1.421
m	0.710	0.296
k_{sat} (m/s)	1.2x10^{-3}	2.3x10^{-9}

The SWCCs and HCFs of the wicking geotextile 2, provided by Lin et al. (2016), the tailings, and fine sand are displayed in Figure 5.

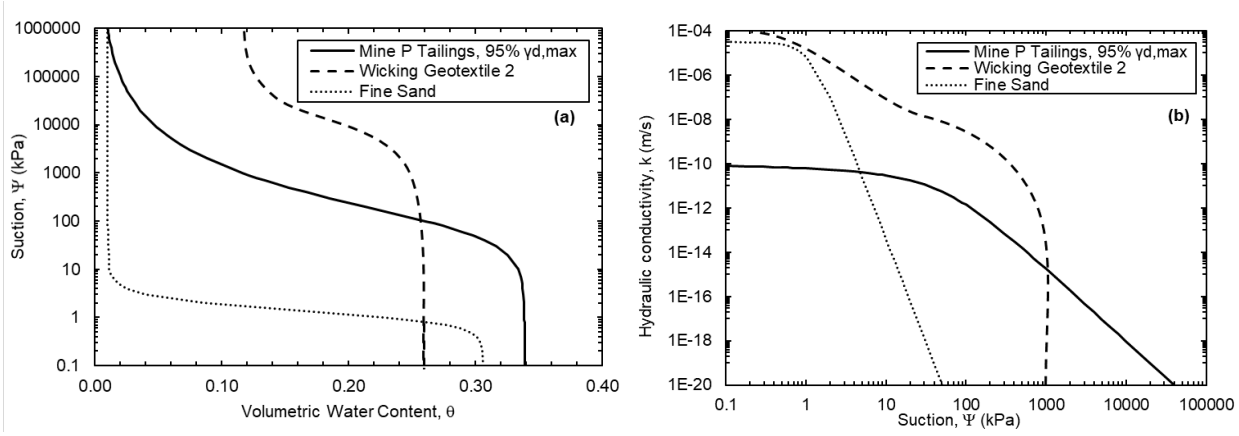

Figure 5: (a) Drying SWCC and (b) HCF curves for the fine sand, tailings, and wicking geotextile 2

The suction potential of the geotextile can be viewed in two parts: the geotextile surface, and the inter-yarn drainage path (the deep grooves that have an average spacing of 5 microns to 12 microns). Air and soil particles cannot easily infiltrate the drainage path due to the small openings. When the suction is less than 200 kPa, water movement from the surrounding soil into the geotextile multichannel is assumed due to greater unsaturated hydraulic conductivity of the geotextile. The transmissivity of the geotextile surface decreases significantly within the suction range of 45 kPa to 200 kPa, but the deep grooves remain saturated and continuously wick water into the atmosphere due to the gradient pressure difference (Lin et al., 2016). As the tailings dewater the unsaturated hydraulic conductivity of the wicking geotextile 2 is greater than that of the tailings up to a suction of around 1,000 kPa.

Beyond this point, the hydraulic conductivity of the wicking geotextile drops off significantly, and the drainage efficiency is dramatically reduced. The suction potential of the wicking geotextiles was not reassessed in this study, but based on previous findings, the estimated working range of the geotextile is up to 1,000 kPa of suction. For Mine P tailings, a suction of 1,000 kPa translates to a saturation of 28%. This is a saturation reduction of 70% beyond the capillary barrier effect of the fine sand, which resulted in retention of a saturation of 98% within the tailings layer.

Magnitude of drying and dewatering

The percent total water mass removed of the total initial water mass for each column at experiment deconstruction are presented in Figure 6a. The wicking geotextiles removed water from the tailings layer to a greater extent by test conclusion (80 days) than natural evaporation or gravity processes as shown by the control column. At the conclusion and deconstruction of the columns, the wicking geotextile 2 had removed 48% of the column water, while the control column had only lost 19% water. To support the water loss values calculated throughout the testing period, water content samples were taken from the columns at the end of testing. The final water contents observed in Figure 6b were collected from the midpoint of the tailings layer and averaged across three points at the same depth.

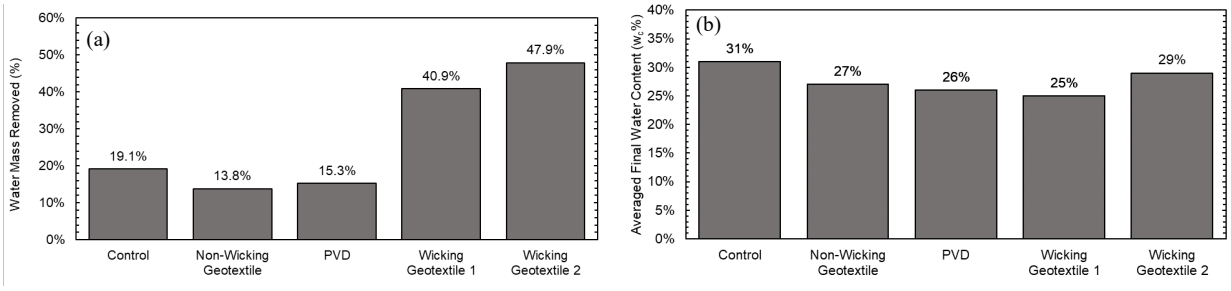

Figure 6: (a) Percent water mass removed in column tests and (b) water content samples taken from the midpoint of the columns' tailings layers

While the final water contents for each mid layer were similar, the wicking geotextile columns were observed losing more mass than the other columns during testing. Therefore, additional water content samples were taken in the layers above and below the tailings. Figure 7 presents a graphical representation of the water contents seen throughout the layering of the columns. Gravimetric water content samples taken from the lower fine sand layer in the wicking geotextiles column contained 0% moisture. While in the control and non-wicking columns water contents varied between 5% - 9%. Minimal movement of moisture into the fine sand layer above the tailings can be observed in all the columns, but further movement was impeded by the coarser grained sand. Beyond dewatering the tailings, the wicking geotextiles are effectively creating a vacuum that pulls up the water that previously drained into the lower fine sand layer during column construction (as supported by the w_c% samples = 0%).

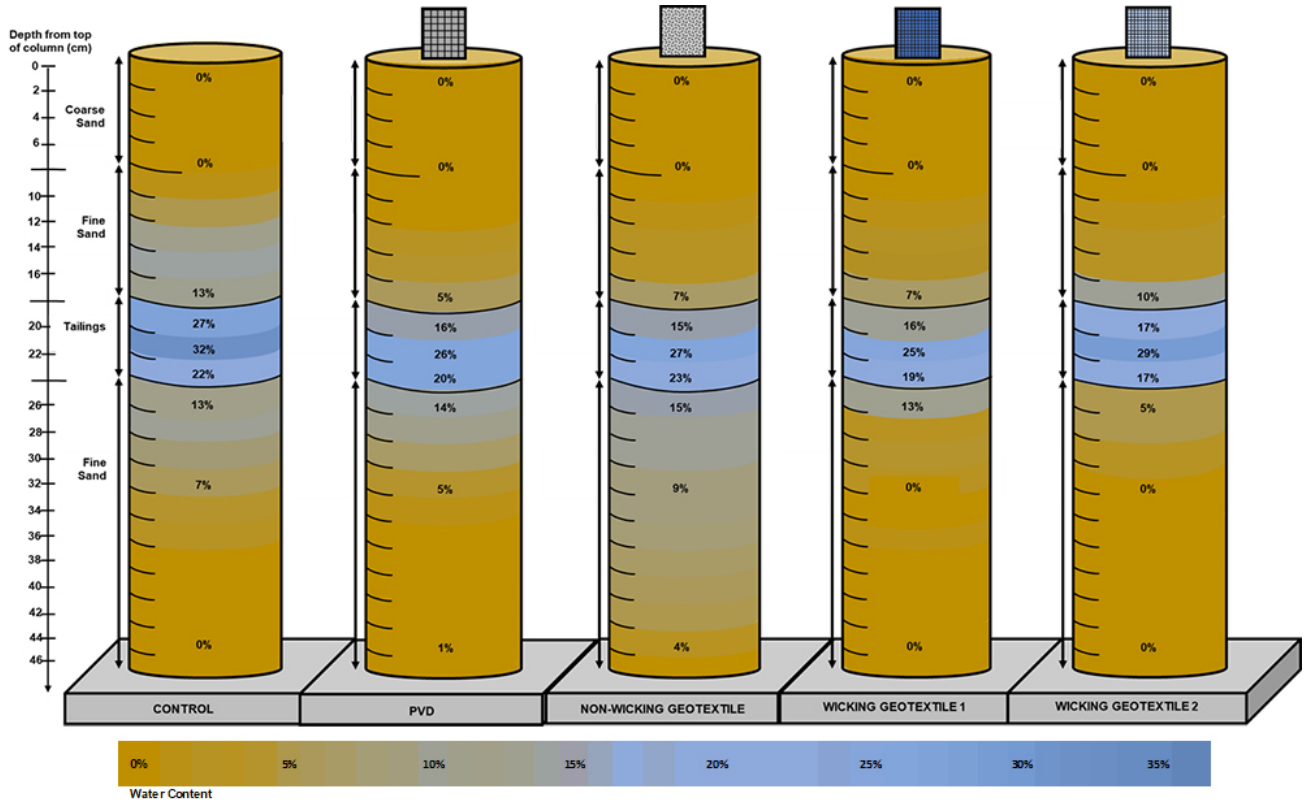

Figure 7: Column experiments schematics representing water content samples versus depth

Rate of drying and dewatering

After 80 days of allowing the columns to rest under the fume hood and weighing at regular intervals, the average rate of water removal per day for each of the columns was assessed, these values are illustrated in Figure 8. The water mass removed in grams per day of the wicking geotextile 2 was 2.1 g/day, while the control was 0.8 g/day, less than half of the rate of the wicking geotextile.

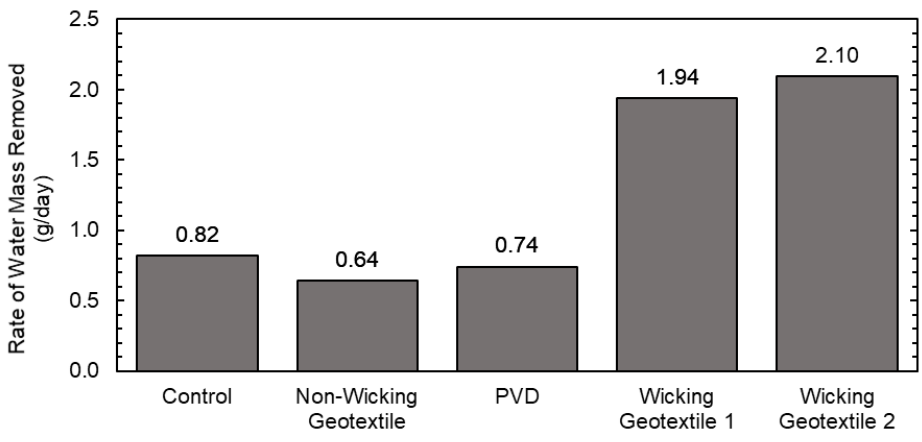

Figure 8: Rate of water mass removed from the tailings columns per day

The change in solids contents of the columns were calculated at regular intervals and these values are plotted in Figure 9. Although some water was initially observed percolating into the lowest fine sand layer upon initial construction, the amount of water was not determined. The change in solids content of the columns was therefore made with the assumption that water loss was occurring directly in the tailings beginning with an initial solids content of 50%. At the conclusion of testing, the wicking geotextiles had removed more than twice as much water than the control columns. The wicking geotextile 1 reached a solids content of 61.4% and the wicking geotextile 2 reached a solids content of 68.5%. This indicates that the wicking geotextile 2 tailings had transitioned to the paste form of the dewatering continuum. The control columns reached a solids content of 55.4%; extrapolated data predict an additional 120 days of drying would be required to reach the lower end of the paste boundary, due to the < 1 g of water mass loss per day.

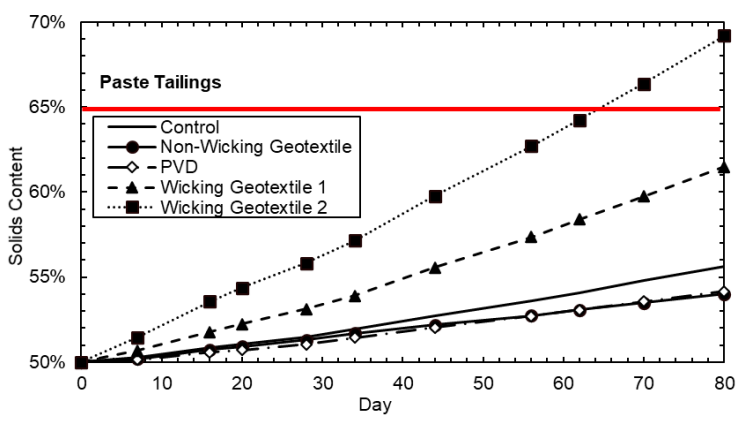

Figure 9: Dewatered paste boundary surpassed by wicking geotextile 2

Discussion

Magnitude of drying and dewatering

Dewatering beyond the 60% conservative threshold, practiced by industry, would indicate achievement of transitioning the tailings from an undrained to drained state. In the case of the column experiments, by day 80, between 41 – 48% of the initial water mass had been removed by the wicking geotextiles. The removal of this magnitude of water and the achievement of a solids content above 80% has moved the tailings into a filtered tailings dewatering state. These interim results were contradictory to the actual magnitude of dewatering of which the wicking geotextiles were capable. Due to the rapid dewatering occurring in the wicking geotextile columns, the assumption was that the tailings were at lower water contents than the tailings in the other columns. However, final water content samples presented relative uniformity for all the columns.

Rate of drying and dewatering

The ability of the wicking geotextile to accelerate dewatering and therefore reduce the consolidation period was assessed. Envisioned implementation of wicking geotextiles in a TSF were hypothesized. The two hypothetical scenarios included: a) dewatering occurring while the mine is operational and therefore both surface and pore water dewatering will be accelerated by the wicking geotextiles; and b) dewatering in a legacy TSF in which the geotextiles would need to be installed following TSF closure. In both scenarios, the wicking geotextiles theoretically aided in unsaturated dewatering and increased the consolidation rate of the tailings deposit. Accelerated drying during placement emulates filtered tailings deposition and densifies the freshly deposited tailings. Accelerated drying in-situ implies the ability to overcome capillary barriers. The column experimental results support envisioned implementations and the conclusion that increased tailings consolidation rates are expediated by the introduction of wicking geotextiles.

Overcoming capillary barriers

The wicking geotextile creates a capillary continuum from the fine-grained tailings layer to the atmosphere. Figure 7 displayed the wicking geotextiles removing water directly from the tailings layer and transferring the water to the atmosphere, overriding the capillary barriers formed by the fine grain and coarse grain sand. However, since this series of columns was deconstructed prior to an asymptote being reached, a definitive statement on the capillary dewatering success of the wicking geotextile cannot be made. Additional long-duration testing has been started concurrent to the finalization of this document. The ability of wicking geotextiles to remove both excess and non-excess pore water out of tailings is a novel characteristic. Dewatering excess pore water pressure would decrease the pressure existing within the system; then transitioning to non-excess, or hydrostatic, dewatering may aid in desaturating to a degree where overly conservative estimates of strength are not needed. At the time of writing this, no known passive methods of dewatering are available to remove capillary non-excess pore water beyond gravity drainage. This renders the capabilities of existing passive methods, such as PVDs, relatively futile for legacy TSFs in which water is already retained by capillary barriers.

Conclusion

As a potential solution to dewatering beyond excess porewater pressure, use of a wicking geotextile is proposed. Throughout the testing period, the wicking geotextiles were observed dewatering at a rate 1.5 – 2 times faster than the control. At the end of the 80-day testing period, the columns were deconstructed, and gravimetric water content samples were collected. The water content samples taken from the midpoint of the tailings layer ranged between 25 to 31% for all columns, with the control having the highest moisture content and the wicking geotextile 1 having the lowest moisture content. The following conclusions are

extracted from this study:

- Reviewed legacy TSF characterization data show that interbedded layers of near saturated fines exist within the tailings. These fine layers desaturate on the magnitude of hundreds to thousands of years, and therefore as they currently exist may pose liquefaction concerns.
- Wicking geotextiles can accelerate water removal from the tailings up to 2.8 times the rate of natural dewatering processes as illustrated by the column tests. These results highlight that incorporation of capillary geosynthetics is a potential method to enhance the rate of evaporative drying of exposed tailings.
- The wicking geotextiles have potential to overcoming in-situ capillary barriers via the inner-yarn drainage path of the wicking geotextile.

Abstract

Selbaie is a closed mine site in the Joutel-Matagami region near James Bay and the town of Rouyn-Noranda, both located in the Province of Quebec, Canada. WSP performed a geotechnical investigation at the Tailings Storage Facilities (TSF) which included seismic cone penetration tests (SCPTs) and field vane tests (FVTs), as well as advanced laboratory testing including direct simple shear (DSS) tests, among others. These tests were completed to characterize hard rock mine tailings as well as foundation soils.

Contrary to clays and sands, transient materials such as tailings can undergo partially drained conditions during in-situ SCPTs performed at the standard penetration rate of 2 cm/s. For this reason, at one location in the Selbaie mine TSF, duplicate (A/B) SCPTs were performed within a 3-meter distance of each other at different penetration rates to evaluate its effects on the in-situ state and shear strength parameters of tailings, and drainage conditions. The first SCPT (A) was performed at a standard penetration rate of 2 cm/s while the second one (B) was advanced at a penetration rate of 10 cm/s.

The shearing rate is also known to influence FVT results. Therefore, FVTs were performed using an electronic vane at several locations in parallel with SCPTs. To assess rate effects on the inferred shear strength and drainage conditions, at one location, FVTs in tailings were performed at different rotation speeds including the standard rate (0.1°/s) as well as two higher vane rotation rates ranging between 0.8°/s and, 10°/s.

This paper provides results of the in-situ SCPTs and FVTs in tailings. SCPT and FVT results were analyzed using existing frameworks from the literature, including Chandler (1988), Blight (1962), and Dejong et al. (2013). It appears that higher rotation rates of FVTs could lead to undrained shearing response

according to Chandler (1988) and Blight (1962) criteria, but do not systematically lead to lower peak shear strength. As for SCPTs, the standard advancement rate was not high enough to guarantee undrained response during piezocone penetration. However, higher penetration rates led to higher sleeve friction measurements, and higher liquefied strength ratios estimated using screening-level methods.

Review of the in-situ testing program

A geotechnical investigation, including in-situ seismic cone penetrations (SCPTs) and electronic shear field vane tests (FVTs), was carried out by WSP in 2021 at the Selbaie mine site Tailings Storage Facility (TSF) located in the Province of Quebec, Canada. The TSF investigation program included 9 geotechnical boreholes, 11 SCPTs, and 9 FVT profiles. In situ soundings were accompanied by index and advanced laboratory tests for tailings characterization.

Electronic shear vane testing in tailings was carried out in boreholes within 5 m of selected SCPTs to assess the in-situ peak, post-peak, and remolded undrained shear strength. Testing was performed in accordance with ASTM D2573 (2018b). All FVTs utilized 50 × 100 mm blades to eliminate blade size effects.

Peak and post-peak undrained shear strengths were measured by rotating the vane until failure and by further rotating the vane up to 360°. The remolded strength was obtained by repeating the test after 20 turns of the vane rods. Peak and post-peak strength testing was generally performed at intervals of 0.5 m or 1.0 m, depending on the thickness of tailings. Remolded shear strength testing was generally conducted once every two (peak and/or post-peak) tests conducted.

A standard electronic vane apparatus with the standard shearing rate of 0.1°/s was used at all testing locations to align with ASTM requirements (2018b). This rate usually leads to undrained shearing in clayey materials, thus providing undrained shear strength estimates. However, in intermediate soils such as tailings, silt, and low-plasticity clay, partially drained or drained conditions usually prevail, leading to overestimated undrained shear strength measurements (Reid, 2016). This was notably observed in previous investigations at the Selbaie mine site.

To attempt to measure the undrained shear strength in tailings and evaluate shearing rate effects, a series of tests at varying shearing rates of 0.1 °/s, 0.8 °/s, and 7.5 to 10 °/s were performed with a standard and fast vane apparatus in FVT-21-02A and FVT-21-02B. These two tests, along with SCPT-21-02A/B, were performed in close proximity. Drainage conditions during FVTs were determined using a method developed by Blight (1962) and updated in Chandler (1988).

Eleven SCPTs were also carried out and deployed using a 20-tonne ramset drilling sonic rig. Testing was conducted in general accordance with ASTM D5778 (2020a). In addition to the cone tip resistance, sleeve friction and dynamic porewater pressure readings, three to five porewater pressure dissipation (PPD)

tests were performed per SCPT. These tests were used to define the equilibrium pore water pressure profile of each SCPT, which served to estimate the groundwater table level, effective stress profile, and vertical hydraulic gradients. Testing results were also used to estimate the horizontal coefficient of consolidation and hydraulic conductivity of the unit tested.

Similarly to FVTs, an analysis should be conducted to determine what drainage conditions (undrained, partially drained, or drained) prevail during SCPTs performed in intermediate soils such as tailings, silt, and low-plasticity clay. If partial drainage prevails, estimation of shear parameters should account for partial drainage effects to avoid shear strength overestimation. Partial drainage in SCPTs is inferred from parameters such as the pore pressure ratio (B_q), and the time rate of decay during pore pressure dissipation tests (time to reach 50% dissipation, t_{50}) using an approach proposed by Dejong et al. (2013).

The standard SCPT advancement rate of 2 cm/s was used at all locations in the TSF. Given that the penetration is expected to be partially drained when the standard rate is used in intermediate soils such as tailings, a duplicate test (SCPT-21-02B) was performed at a higher penetration rate of 100 mm/s next to SCPT-21-02A. SCPT-21-02B sought to assess penetration rate effects on the inferred in-situ state and tailings undrained shear strength parameters, and on drainage conditions.

Tailings characteristics based on laboratory testing

Basic tailings characteristics

Table 1 presents the results of a water content test, specific gravity measurement, and particle size distribution analyses conducted on a specimen to which tailings encountered in SCPT-21-02A/B and FVT-21-02A/B are correlated. The water content measurement was used to estimate the in-situ void ratio and saturated unit weight. The sample was classified as a silt (ML) with trace sand.

Table 1: Tailings management area tailings index test results in the vicinity of the SCPTs and FVTs in situ tests

Material Type	Sample Average Depth (m)	Water Content (%)	Fines Content (%)	Sand and Gravel Content (%)	Specific Gravity	Inferred Void Ratio[a]	Inferred Unit Weight[a] (kN/m³)
Tailings	22.10	34.8	98.5	S: 1.5 G: 0.0	2.82	0.98	18.8

(a) The void ratio and unit weight of the tailings specimen were inferred from the water content and specific gravity measurements under the assumption that the sample was fully saturated and that no disturbance occurred.

kN/m³ = kilonewtons per cubic meter; S = sand; G = gravel.

In-situ state parameter and shearing response

The characteristic in-situ state parameters (ψ_k) of the TSF tailings estimated from the Been and

Jefferies (1992) and the Plewes et al. (1992) methods are shown in Figure 1. The 80th percentile of estimated state parameters is considered for tailings. Tailings display contractive behavior as the 80th percentile of ψ_k ranged from 0.06 to 0.13 in SCPT-21-02A and SCPT-21-02B.

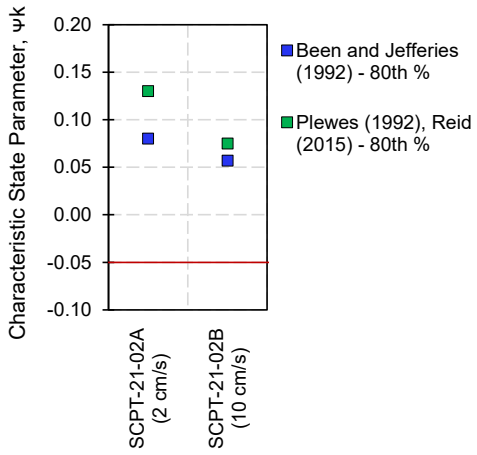

Figure 1: Characteristic state parameter using Been and Jefferies (1992) and Plewes et al. (1992) methods

In-situ testing results and interpretations

Effect of partial drainage on field vane tests

When performing FVTs at the standard rotation rate (0.1 °/s) in intermediate soils such as tailings, partial drainage may occur which can then lead to overestimating the undrained shear strength. This was observed in FVTs performed in Selbaie TSF tailings in 2018 and 2019. To assess drainage conditions of the 2021 FVTs, the dimensionless time factor, T, serving as an indication of the degree of drainage (Reid, 2016; Reid et al., 2023) was calculated for each test using an equation presented in Blight (1962) and updated in Chandler (1988). As outlined in the studies, undrained conditions would occur when the time factor is smaller than 0.05.

Figure 2 presents peak undrained shear strength ratios plotted against the estimated time factor. The data suggests that for a single rotation rate, lower shear strength ratios generally correspond to lower time factors.

In addition to the FVTs with the standard rotation rate (0.1 °/s) in FVT-21-02A, a series of tests with varying rotation rates was carried out in FVT-21-02B, located near FVT-21-02A. The shearing rates in FVT-21-02B varied between higher rates of 0.8 °/s and 7.5 to 10 °/s. Figure 2 shows that 1 out of 32 tests performed at the standard rate exhibited undrained conditions, compared to 5 out of 15 valid intermediate tests with a 0.8 °/s rotation rate and 12 out of 15 tests with the highest rates ranging from 7.5 to 10 °/s.

However, undrained shearing conditions did not necessarily result in lower strength measurements, as evidenced by the shear strength profiles presented in Figure 3. In most cases, lower measurements were obtained with the standard rotation rate, which would suggest that other phenomena such as viscous effects may affect shear strength measurement at higher shearing rates. Peak strength ratios in FVT-21-02A performed at the standard rate averaged at 0.61 and were similar in FVT-21-02B, averaging at 0.77 irrespective of the rate. It appears that due to the TSF tailings rheology, none of the rotation rates utilized could have resulted in lower shear strength values and undrained shearing conditions. Additional factors such as the principal stresses orientation and/or the shear band size and shape developing around vanes may have played a role in the interpreted results (Gylland, 2013).

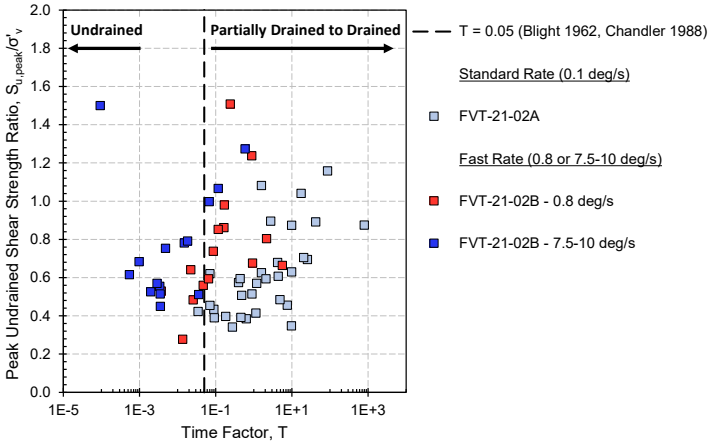

Figure 2: Peak undrained shear strength ratios measured in tailings management area tailings versus time factor

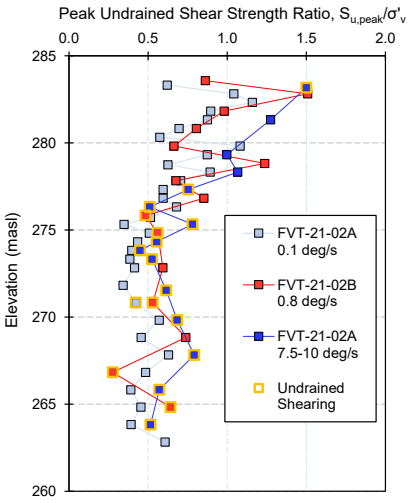

Figure 3: Peak undrained shear strength ratio profiles obtained in tailings management area tailings in FVT-21-02A/B at rotation rates of 0.1, 0.8, and 7.5 to 10 °/s

Effects of partial drainage on cone penetration tests

Results of PPD tests are presented in Table 2. Equilibrium porewater pressures inferred from the PPD tests results generally indicate hydrostatic or near hydrostatic conditions in tailings, and a downward hydraulic gradient in the underlying native soils. The following discusses results of the PPD tests conducted in tailings (Table 2):

The average time required to reach 50% dissipation of penetration-induced porewater pressures (t_{50}) was always smaller than 100 s, suggesting partially drained cone penetration according to DeJong et al. (2013).

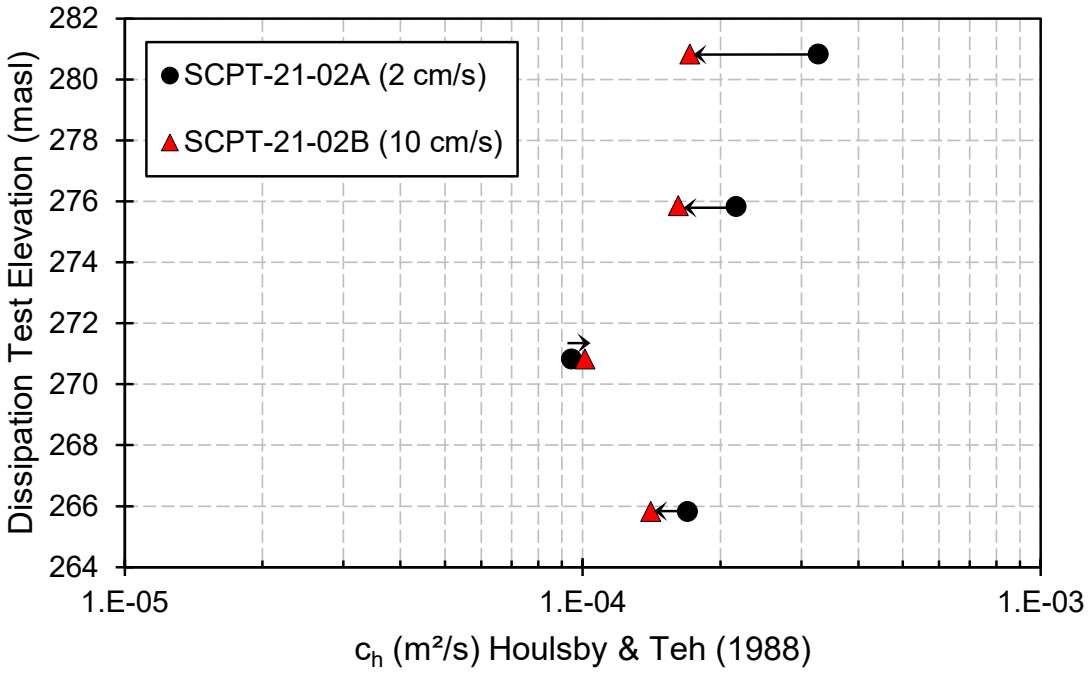
The normalized velocity was calculated from SCPT data to assess drainage conditions during cone penetration using a method developed by Dejong et al. (2013). Table 2 shows that partially drained conditions generally prevailed whereas undrained penetration only occurred in SCPT-21-02B. The latter was performed at a higher advancement rate of 10 cm/s to assess advancement rate effects on drainage conditions and SCPT parameters. Despite the higher penetration rate used in SCPT-21-02B, it was not possible to achieve fully undrained penetration at this sounding through the entire tailings deposit. However, these findings cannot be broadly applied to the entire site since this faster rate sounding was only performed in one location and other SCPTs carried out in the TSF tailings revealed spatial variability in SCPT response.

Partially drained penetration leads to underestimation of t_{50} values, which in turn results in overestimated horizontal coefficients of consolidation and hydraulic conductivity. This is apparent upon examination of Figure 4, which compares coefficients of consolidation obtained in SCPT-21-02A and SCPT-21-02B at equivalent test depths. SCPT-21-02B yielded higher normalized velocity values, suggesting less partial drainage, which resulted in lower coefficients of consolidation. Partial drainage during SCPT implies that empirical equations could potentially underestimate shear strength (Ayala et al., 2024; Boschi et al., 2023). Therefore, attention must be paid to this aspect when results of this campaign are used to assess the stability of TSF dams.

Table 2: Summary of porewater pressure dissipation test results in tailings

Material Type	Number of Tests	Time to Reach 50% Dissipation, t_{50} (s) Min-Max-Mean	Drainage Conditions During SCPT Penetration[a] (Dejong et al., 2013) at Dissipation Test Depths Fully Drained-Partially Drained-Undrained
SCPT-21-02A (2 cm/s)	4	8-20-13	0-4-0
SCPT-21-02B (10 cm/s)	4	13-19-16	0-2-2

(a) Drainage conditions can be evaluated as fully drained, partially drained or undrained using dissipation test results according to the Dejong et al. (2013) method. Analysis of SCPT-21-02A and SCPT-21-02B dissipation tests indicated that either partially drained or undrained conditions prevailed (full conditions never achieved).



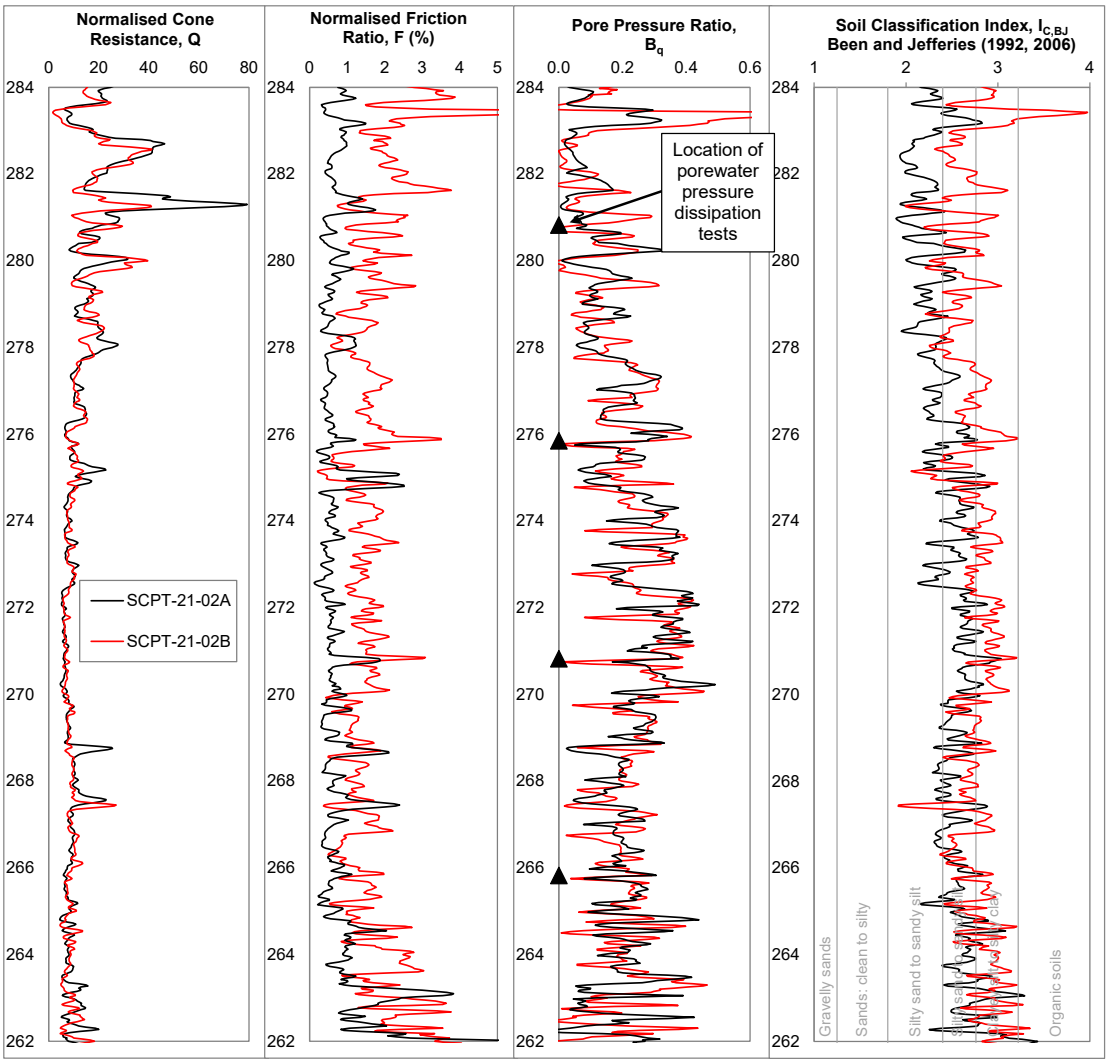


Figure 4: Comparison of tailings horizontal coefficients of consolidation estimated from SCPT- 21-02A (2 cm/s) and SCPT-21-02B (10 cm/s) porewater pressure dissipation tests data

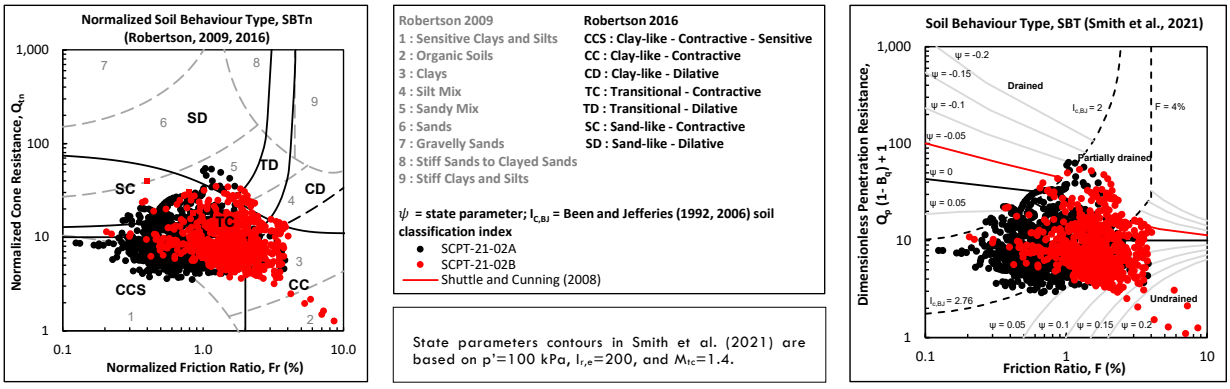

Penetration rate effects

The standard SCPT advancement rate of 2 cm/s was used at all locations except for SCPT-21-02B where a 10 cm/s penetration rate was used to assess advancement rate effects on strength parameters and drainage conditions. Figure 5 (a) presents the normalized SCPT parameters measured in SCPT-21-02A and SCPT-21-02B, performed in close proximity. It also shows the soil classification index ($I_{c,BJ}$) calculated from the Been and Jefferies methods (Been and Jefferies, 1992; Jefferies and Been, 2006). Results are also compared using Robertson (2016) and Smith et al. (2021) screening charts in Figure 5 (b) and (c), respectively. Only the friction sleeve response seemed to be affected by the higher advancement rate, with SCPT-21-02B showing distinctly higher sleeve friction measurements.

Observing changes only in the measured sleeve friction due to a higher penetration rate was reported by Smith et al. (2021) and could be attributed to SCPT sleeve measurements being potentially unreliable, particularly in intermediate loose soils such as tailings (Torres-Cruz 2021). The higher sleeve friction led to slightly higher values of $I_{c,BJ}$. For the SCPTs with an adjacent borehole, the $I_{c,BJ}$ values determined using the standard rate showed a good match with the adjacent borehole description.

a)

b) c)

Figure 5: Comparison of (a) normalized CPT parameters and soil behavior type in tailings in SCPT-21-02A (2 cm/s) and SCPT-21-02B (10 cm/s), and data plotted on the (b) Robertson (2009, 2016) and Smith et al. (2021) screening charts

When comparing SCPT-21-02A carried out at the standard advancement rate of 2 cm/s to SCPT-21-02B advanced at 10 cm/s, SCPT-21-02B consistently resulted in higher liquefied ratios irrespective of the assessment method used: Sadrekarimi (2014), Robertson (2010, 2022), and Jefferies and Been (2016) using the ψ_k estimated with the Been and Jefferies (1992) method and the Plewes et al. (1992) method (Figure 6). This would be largely attributed to the higher friction sleeve measurements in SCPT-21-02B resulting in a slightly higher behavior type index (Figure 5), higher compressibility, lower ψ_k, and higher liquefied strength. The difference observed in Robertson (2022) could be attributed to the employed correction factor parameter (K_c) that is derived from the soil behavior type index which relies on friction sleeve measurements.

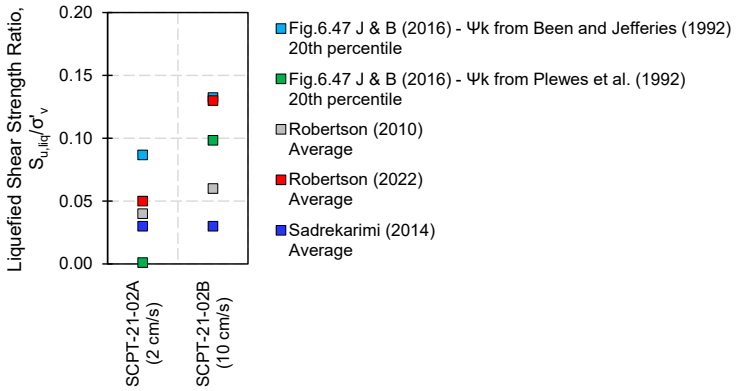

Figure 6: Liquified shear strength ratio using different methods (Jefferies and Been, 2016; Plewes et al., 1992; Robertson, 2010; Robertson, 2022, Sadrekarimi, 2014)

Summary and conclusion

A geotechnical investigation was carried out at the Selbaie TSF and included 9 geotechnical boreholes, 11 SCPTs, 9 FVT profiles, as well as index and advanced laboratory tests to obtain a better comprehension of tailings deposits characteristics.

To attempt measuring the undrained shear strength in tailings and evaluate shearing rate effects, a series of tests at varying shearing rates of 0.1 °/s, 0.8 °/s, and 7.5 °/s to 10 °/s were performed with a standard and fast vane apparatus in FVT-21-02A and FVT-21-02B. These two tests, along with SCPT- 21-02A/B, were performed in close proximity. It was observed that higher rotation rates of FVTs could satisfy undrained shearing criteria, but did not systematically lead to lower peak shear strength.

To evaluate penetration rate effects in SCPTs, SCPT-21-02A was pushed at the standard penetration rate of 2 cm/s next to a duplicate test (SCPT-21-02B) advanced at a higher penetration rate of 10 cm/s. These SCPTs sought to assess penetration rate effects on the inferred in-situ state and undrained shear strength parameters of tailings, and drainage conditions. It was observed that the rate of shearing was not

high enough to guarantee undrained shearing. However, higher penetration rates led to measurement of higher sleeve friction, and higher liquefied strength ratio estimated using screening-level methods.

In conclusion, it is recommended that penetration and/or rotation rate effects on drainage conditions, peak and post-peak shear resistance of tailings be evaluated in site investigations. These effects should be considered when selecting engineering parameters for design and/or stability analyses.

Geotechnical Challenges of Tailings Storage Facilities in Cold Regions

Morteza Esfehani, WSP, Canada

Abstract

Cold regions experience significant fluctuations in temperature, leading to freezing and thawing cycles of exposed soils. This can cause the tailings to expand and contract, leading to structural instability and potential failure of containment structures. The repeated freezing and thawing can also disrupt the integrity of the containment systems designed to hold the tailings, increasing the risk of leaks or spills. Trapped frozen tailings can have significant effects on stability as well. When tailings are deposited in an area where freezing occurs, the water within the tailings can freeze, leading to the formation of ice lenses and ice-rich layers. These frozen components can alter the physical and mechanical properties of the tailings, impacting stability in several ways. The presence of trapped frozen tailings can have long-term implications for stability. Frozen ground tends to reduce the permeability and affect the groundwater flow patterns, which can influence the stability of earthworks structures. Frozen zones can act as barriers to groundwater movement, leading to localized saturation and increased pore pressures. Preventing the formation of trapped frozen tailings in storage facilities in cold regions requires careful planning, design, and implementation of engineering measures. If deep frozen zones are detected in a tailing facility, a thorough assessment is required to determine the extent and characteristics of the affected zones. The potential risks should be identified in order to develop and implement engineering mitigative solutions. Then, comprehensive monitoring and management plans are required to track the effectiveness of mitigation measures and respond to changing conditions. Proper characterization and management of tailings are essential to prevent or mitigate potential stability risks and ensure the long-term integrity of tailings storage facilities in cold regions. The paper addresses some of these challenges, for which tailored engineering design and management strategies are necessary.

Introduction

Managing hydraulic tailing deposition in cold weather requires a comprehensive approach that integrates design, operational practices, monitoring, environmental protection, and safety considerations. Trapped frozen tailings can significantly affect stability by altering the mechanical, thermal, and hydraulic properties

of the surrounding ground. The formation of embedded layers of frozen tailings should be avoided, especially close to tailing dams, to prevent impermeable barriers, which may cause an increase in pore water pressure during thaw, and to reduce effective stress.

By implementing site-specific strategies, mining operations can effectively manage tailings in cold regions, ensuring the stability of containment structures and minimizing environmental impact. If trapped frozen tailings happens, zones are identified in a storage facility, and proper characterization and management of frozen tailings are essential to mitigate potential stability risks. This may include implementing specialized engineering designs, monitoring systems, and maintenance protocols.

Tailings depositional rate and arrangement and water management are activities that must be handled with concern in cold weather conditions. If a facility is managed poorly in sub-zero temperatures, it may degrade tailing mechanical properties and drainage efficiency by creating embedded frozen tailings layers.

The volume increase of the soil due to freezing generally results in uplift or frost heave, and the excess of pore water developing during thaw results in a loss of strength and substantial deformations. Therefore, these soils are classified as frost susceptible and thaw weakening (Arenson et al., 2007). The classification methods developed for natural soils are often valid for evaluation of the frost susceptibility of tailings. However, the influence of added reagents should be considered (Tuomela et al., 2021).

Shear strength of frozen soils

Understanding the shear strength characteristics of frozen soils helps engineers develop more accurate models and design safer and more reliable structures. Arenson and Springman (2005) have conducted extensive research on the shear strength of frozen soils. Their work also contributes to the comprehensive understanding of seasonal freeze-thaw cycles and their impact on soil stability and infrastructure performance. Here is a summary of key findings from their research.

It was shown that frozen soil resistance is temperature-dependent since the shear strength of frozen soil increases as the temperature decreases. This is due to the strengthening of ice bonds within the soil matrix at lower temperatures.

Ice content, related to the initial water content, influences the shear strength as well. Higher ice content generally increases the shear strength of frozen soils. Ice acts as a cementing agent, binding soil particles together and enhancing overall strength. However, very high ice content can lead to a brittle failure mode, where the material may crack and fail suddenly under stress.

The shear strength of frozen soils is also influenced by the rate of loading or strain rate. Higher strain rates typically result in higher measured shear strength due to the rate-dependent behavior of the ice.

Arenson and Springman (2005) conducted triaxial compression tests on frozen soil samples to determine their shear strength under various confining pressures and temperatures. The results showed a

clear increase in shear strength with decreasing temperature and increasing confining pressure. They also performed direct shear tests to measure the shear strength along predefined planes. These tests confirmed the temperature dependence and highlighted the role of ice content and strain rate in influencing shear strength. Based on their experimental data, Arenson and Springman (2005) developed empirical correlations to predict the shear strength of frozen soils. Figure 1 shows the correlations as a function of temperature, ice content, and strain rate. It was concluded that, at low ice content, the shear resistance is developed by solid grains within a frozen matrix mobilizing frictional resistance. In other words, the shear strength depends more on normal stress as more interlocking is mobilized within the low ice content frozen soil. Cohesion is present in a granular soil only if there is sufficient ice in the voids between the particles to hold them together. Because the ice matrix is responsible for this cohesion, all factors that control the strength of pure ice, such as temperature or strain rate, influence the cohesive term for the strength of frozen soils.

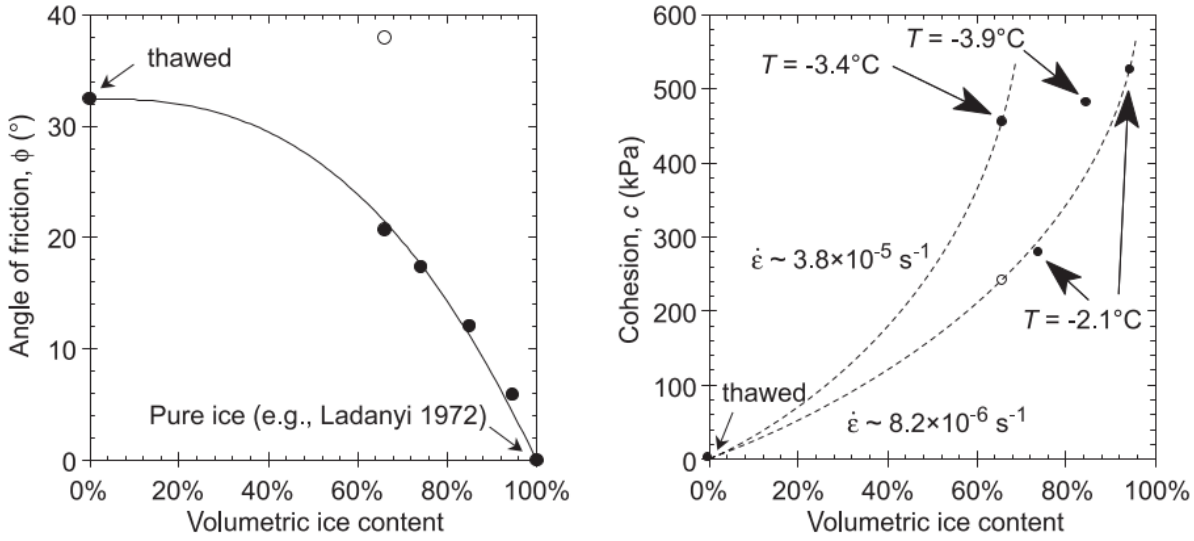

Figure 1: Shear strength parameters of frozen soils as a function of volumetric ice content and temperature (from Arenson and Springman, 2005)

Effect of freeze-thaw cycles on shear strength of tailings

Freeze–thaw cycles have a strong influence on the mechanical properties of tailings. Several researchers have investigated this subject through experimental and theoretical studies. The effects of freeze–thaw cycles on the mechanical properties and pore structure of granular tailings were investigated by Li et al. (2022). The results showed that the shear strength of the tailings decreases after freeze–thaw cycles, as shown in Figure 2. Considerable pore deformation between particles of tailings was observed after 40 freeze-thaw cycles through photointerpretation of samples.

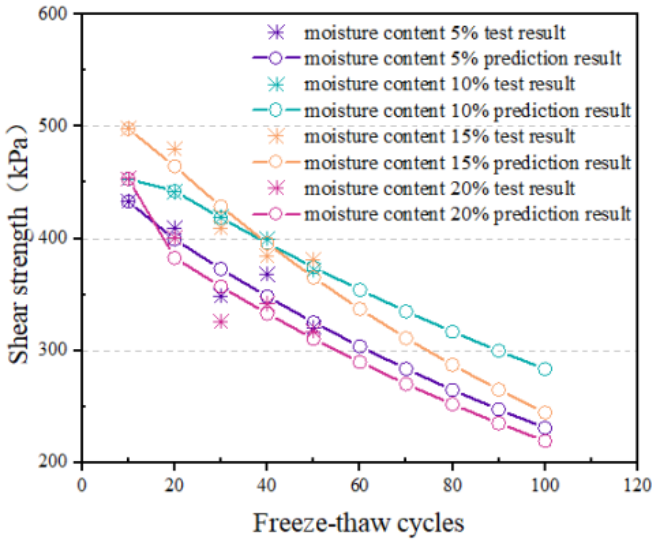

Figure 2: Peak shear strength as a function of freeze-thaw cycles (from Li et al., 2022)

Fu et al. (2021) carried out experiments to examine the role of thawing on the mechanical properties of melting glacial tills. Direct shear tests were performed on till specimens with three different dry densities and three different initial water contents after each cycle of thaw for 18 freeze-thaw cycles. Tests were carried out in undrained condition at a shear rate of about 2.4 mm/min. Figure 3 shows some of the test results. It was concluded that the cemented ice can improve the cohesive component of the shear strength of frozen soils. However, shear strength decreases considerably after the initial thawing time. The decrease is greater in soils with higher initial water content. Moreover, the shear softening decreases with increasing thawing time.

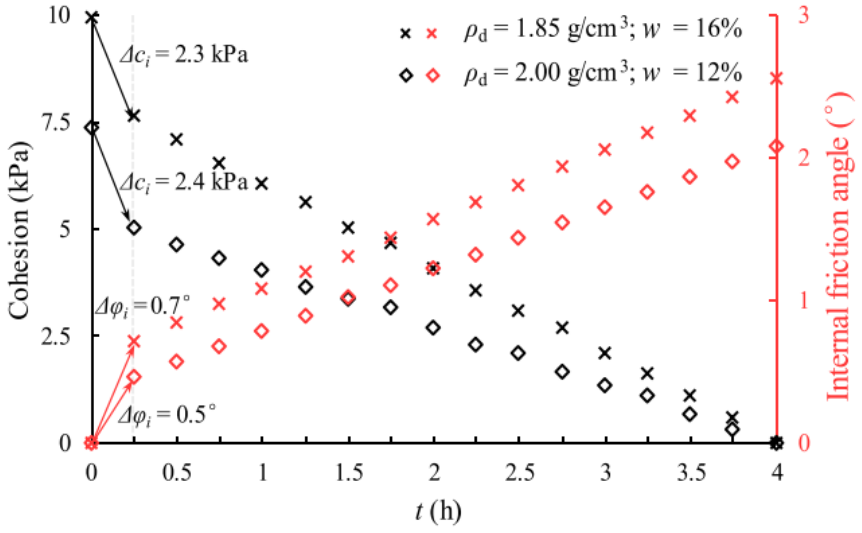

Figure 3: Test results for cohesion and internal friction angle as a function of thawing time in undrained condition (from Fu et al., 2021)

Geothermal simulation of tailing deposition rate (case study from literature)

Knutsson (2018) developed a one-dimensional geothermal model using the finite difference method. The model simulates the temperature profile in tailings where the surface elevation is increased due to deposition. The results showed that the deposition rate is the most influential factor in the generation of frozen zones. The temperature of new tailings deposited on the surface has a very small influence on the results. The type of simulations shown in Figure 4 can help to set up deposition schedules to prevent trapped frozen layers. For the case with tailings deposition, embedded layers of frozen tailings were generated with about 1.0 m of thickness. These layers remain frozen in the following seasons and are therefore regarded as permafrost. For the case with no tailing deposition (not shown here), all frozen tailings were thawed during the summer.

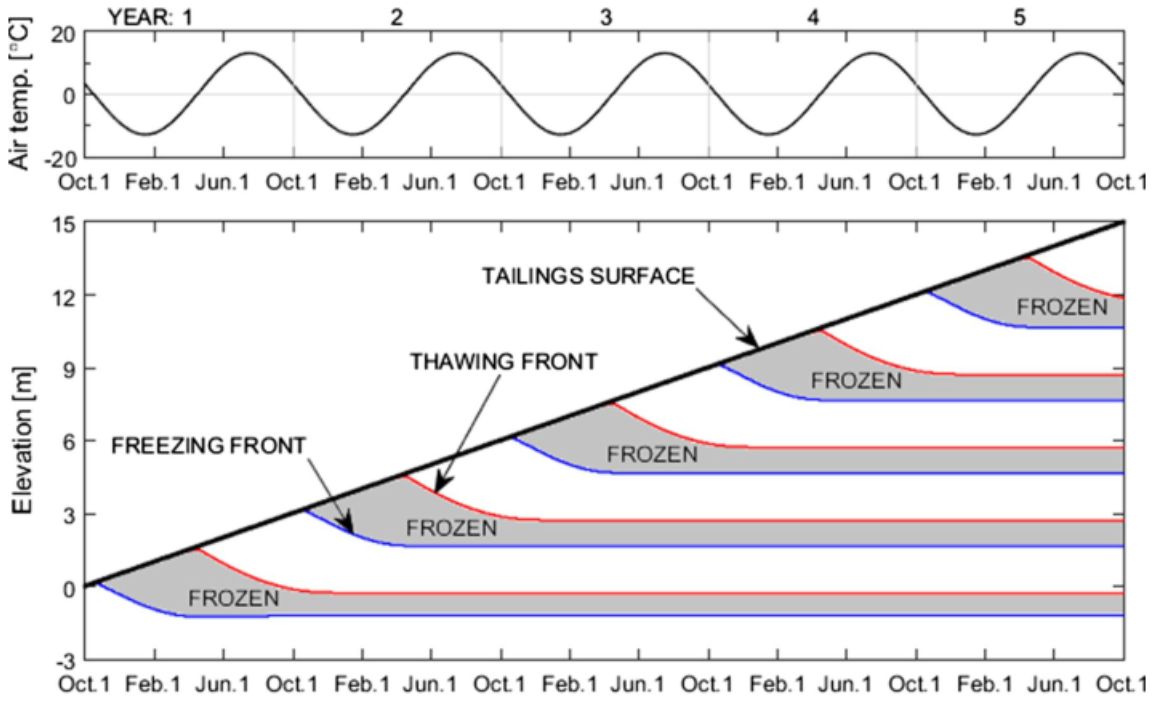

Figure 4: Freezing and thawing fronts with tailings deposition of 3 m/year (from Knutsson, 2018)

Creep deformation of frozen tailings (case-study from literature)

Limoges et al. (2022) investigated an upstream raised tailings storage facility (TSF) that showed lateral displacements indicative of a potential shearing plane. The differential lateral displacement was located at the interface with the frozen layer as shown in figure 5c. The paper discussed the design and implementation of mitigation measures, such as stability berms, to reduce the rate of lateral movement. The study identified two potential mechanisms that could impact the stability of the tailing storage facility: thaw-consolidation

and on-going creep deformation of the frozen layer. An initial strain rate of about 2% per month was recorded prior to any mitigation measures. The recorded strain rate became around 0.2% per month one year after the construction of a stability berm.

Figure 5b shows the profile of thermistor data as a function of elevation, confirming the presence of a frozen layer at a TSF. Figure 5a shows the water content profile at the same location. Interestingly, the identified frozen layer exhibits the highest water content. Figure 5c shows the recorded lateral displacement from inclinometers installed in the same sector. The highest lateral displacements were recorded at the interface of the identified frozen layer, where the highest water contents and lowest temperatures were registered.

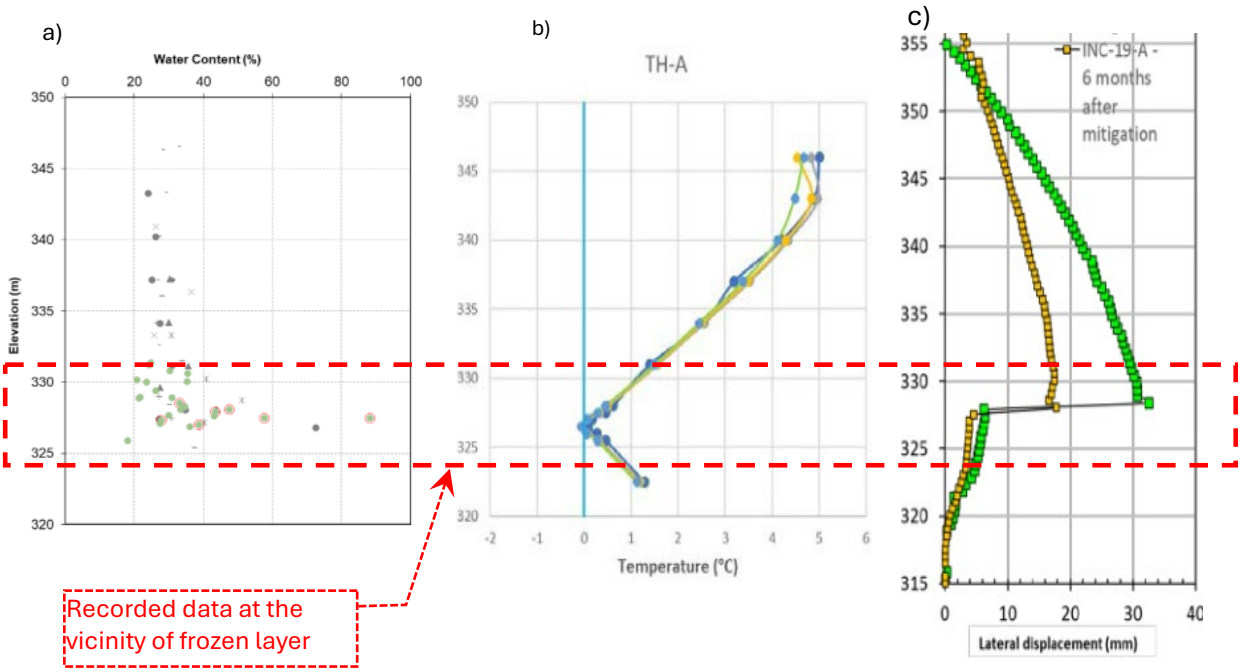

Figure 5: Recorded data in the vicinity of a frozen layer: a) water content; b) temperature profile; c) inclinometer data profile (from Limoges et al., 2022)

Prevention of trapped frozen tailings in the storage facility

Preventing the formation of trapped frozen tailings in storage facilities in cold regions requires careful planning, design, and implementation of engineering measures. Test results from Knutsson (2018) showed that the thickness of permafrost layers increases with an increased deposition rate and with increased water content. It was also shown that wet tailings must be deposited in short periods during summer to avoid permafrost generation. These precautions can help mining operations to set up deposition schedules. Thermodynamic models can identify periods of the year when tailings can be deposited in critical areas of

a deposit in order to avoid permafrost formation. They can also identify the required quantity of tailings deposition to achieve this aim.

Early site investigations, including geological and hydrological assessments, should be carried out to identify areas with a lower risk of freezing. Insulation layers beneath and around the storage facility can minimize heat transfer between the tailings and the underlying ground. Effective drainage systems within the storage facility are required to control groundwater flow and prevent water accumulation. Proper drainage helps minimize the presence of free water, which can contribute to freezing. Comprehensive monitoring programs are required to assess the effectiveness of preventive measures and detect potential issues early. Parameters such as temperature, moisture content, groundwater levels, and ground settlement should be monitored to identify signs of freezing and inform adaptive management strategies.

Mitigative actions when deep frozen zones are detected

If deep frozen zones are detected in a tailing facility, it is crucial to take prompt and effective action to mitigate potential risks and ensure the long-term integrity of the facility. Here are steps to consider:

- Assessment and monitoring: conduct a thorough assessment to determine the extent and characteristics of the frozen zones. This may involve geophysical surveys and thermal monitoring.
- Risk analysis: evaluate the potential risks associated with the presence of frozen zones, including impacts on stability, hydraulic conductivity, and environmental performance.
- Engineering solutions: develop and implement engineering solutions to mitigate the risks posed by deep frozen zones. Depending on the specific circumstances, potential solutions may include:
    - Active heating: implement heat tracing systems or other active heating methods to thaw frozen zones and prevent the formation of further ice lenses and ice-rich layers.
    - Drainage improvements: enhance drainage systems within the facility to control groundwater flow and reduce the accumulation of free water, which can contribute to further ice build.
    - Structural reinforcement: strengthen containment structures, such as dams and embankments, to withstand the additional loads and stresses imposed by frozen ground conditions.
- Adaptive management: develop a comprehensive monitoring and management plan to track the effectiveness of mitigation measures and respond to changing conditions. Implement regular monitoring of temperature profiles, moisture content, ground settlement, and other relevant parameters to detect signs of freezing and evaluate the performance of remedial actions.

- Stakeholder engagement: engage with relevant stakeholders to communicate transparently about the presence of frozen zones and the planned remediation efforts.
- Emergency Response Plan: develop an emergency response plan outlining procedures and protocols for responding to unforeseen events or emergencies related to frozen zone issues. Identify key personnel, resources, and communication channels needed to coordinate emergency response efforts to minimize potential impacts on human health, safety, and the environment.

Management of tailings hydraulic deposition in cold weather

Managing hydraulic tailing deposition in cold weather requires special considerations to ensure operational efficiency, environmental protection, and structural stability. Knutsson (2018) carried out extensive research work on the current practice in tailings management in cold regions. The following paragraphs provide some strategies and practices to effectively manage hydraulic tailing deposition in such conditions.

Risk assessment

The freezing risk can be quantified by using probabilistic methods at the design stage. The failure likelihood consequences as well as potential preventive and mitigative measures should be evaluated. To inform the design process, historical climate data should be collected for the project site, including temperature variations, freeze-thaw cycles, and seasonal trends. Hydrogeological analyses are required to evaluate groundwater flow patterns and potential seepage paths. The freezing risk increases when water infiltrates tailings and subsequently freezes.

Design considerations

At the design stage, the tailing facility should be placed in a site with minimal exposure to severe cold. Strategies should be adopted to control the ground heat loss by insulation to prevent freeze-thaw cycles. Geotechnical properties of the tailing facility components should be investigated. The physical and mechanical properties of tailings, including their thermal conductivity, moisture content, and grain size distribution govern freezing behavior. The containment structures should be designed to withstand freezing and thawing cycles, incorporating materials that retain structural integrity. Numerical models are recommended to simulate heat transfer within the tailings. These models allow for the estimation of the effect of factors like insulation, cover materials, and heat loss. Effective drainage systems should be implemented to manage water flow and prevent the accumulation of water prone to surface ice build.

Operational practices

Tailings deposition management plans should include the control of the deposition rate and layering of tailings to prevent the formation of ice lenses and frozen zones. The use of thickened tailings deposition is

recommended in the construction of containment structures to reduce water content, minimizing the risk of freezing. Active heating systems, such as heat tracing cables or thermal blankets, may be considered to maintain temperatures above freezing in critical areas. Thermal insulation to cover containment structures is another method of thermal control. The water management plan should include efficient protection of supernatant water from freezing by using heating systems or by removing it promptly.

Monitoring and maintenance

Temperature sensors should be installed throughout the tailings facility to monitor and manage thermal conditions. Remote sensing technology for real-time data collection and monitoring is recommended. Regular inspections should be conducted to identify and address any signs of freezing, thawing, or structural instability. A maintenance schedule should be implemented to ensure the functionality of drainage systems, heating systems, and other infrastructure. Strategies should be developed to properly manage any potential ice formation by mechanical removal or controlled melting. The ice removal operation should not cause any damage to containment structures or disrupt the integrity of the tailings.

Adaptation of best practices

Continuously adapt and improve practices based on the latest research and technological advancements in cold region engineering. Study successful case studies of tailings management in similar climatic conditions to apply proven strategies.

Case of paste or filtered tailing deposition

As mentioned by Neuffer (2015), filtered tailings can offer specific opportunities for cold regions tailings management relative to other approaches, including increased tolerance for differential thaw settlement associated with a degrading permafrost foundation, increased physical and chemical stability from permafrost within the stack, and reduced difficulties with water management in the winter. If exposed to sub-zero conditions, filtered tailings can freeze before being compacted. If frozen, tailings may not reach the target compaction despite the compaction effort. Filtered tailings should be kept from freezing during stockpiling and transit, and must be dumped and spread within minutes to hours. Once the lift is compacted to specification, the design may allow it to freeze (McKenna, 2023).

Beneficial case of frozen tailing barriers

The preservation of frozen tailing layers is important if oxidation of acid-generating tailings is to be minimized. As in the case study by Steffens et al. (1995), the ice and frozen tailing layers are a hydraulic barrier that controls the groundwater seepage and tends to minimize the oxidation of pyritic tailings.

Favorable perma-frost conditions were maintained to control conductive and convective heat flux. The frozen layer was preserved to ensure cold penetration during wintertime, and insulation during summer.

Conclusion

Implementing preventive measures and adopting a proactive approach to tailings management minimize the formation of trapped frozen tailings in storage facilities in cold regions. Trapped frozen tailings can have significant effects on stability. When tailings are deposited in an area with permafrost or where freezing occurs, the water within the tailings can freeze, leading to the formation of ice lenses and ice-rich layers. It can alter the physical properties of the tailings and the surrounding ground, impacting stability in several ways. Frozen ground tends to be stiffer and less permeable than unfrozen ground, which can affect the distribution of stresses and groundwater flow patterns. This can influence the stability of slopes, embankments, and other earthworks structures.

Trapped frozen tailings can disrupt the natural thermal regime of the ground, making it prone to thawing and subsidence issues. The presence of frozen tailings can also insulate the underlying permafrost, preventing it from thawing during warmer periods, which can result in differential thaw settlement.

The formation of ice lenses and ice-rich layers can act as barriers to groundwater movement, leading to localized saturation and increased pore pressures. This can weaken the stability of slopes and embankments and increase the risk of slope failure.

By taking a proactive approach to addressing deep frozen zones in tailings facilities, it is possible to mitigate risks and ensure responsible and sustainable tailings management practices. Regular reviews and updates to practices based on new research and technological advancements will enhance the management of tailing facilities in challenging cold weather conditions.

Assessment of Flow Liquefaction Susceptibility of a Tailings Dry Stack Pile Using the State Parameter and Yield Stress Ratio Approach

Marcus Vinícius Lima Dias, Vale S.A., Brazil
Dieggo Santos, Vale S.A., Brazil
Mariela Silva, Vale S.A., Brazil
Gustavo Marçal de Sousa, Vale S.A., Brazil
Marília Freire, Vale S.A., Brazil

Abstract

Flow liquefaction is a behavior observed in saturated or nearly saturated geomaterials that show a strain softening response during undrained shear, mostly observed in very loose sands and silts as well as very sensitive clays. The Cone Penetration Test with pore-pressure measurements (CPTu) has been gaining in popularity among the geotechnical community to evaluate the state of a soil profile, due to its good repeatability, detailed information of the soil stratigraphy, and extensive detailed scientific studies to guide the application of the test results. Susceptibility to flow liquefaction is typically evaluated by estimating the in-situ state parameter (ψ), since it directly correlates to the soil behaviour at large strain, as shown by Jefferies and Been (2016). Mayne and Sharp (2019) suggested the use of the yield-stress-ratio (YSR = σp'/σv0') to estimate the soil state using a threshold of YSR ≈ 3.

This paper presents an evaluation of the susceptibility to flow liquefaction of a tailings dry stack pile using the following recently published approaches: i) Mayne and Sharp (2019), using the yield stress ratio (YSR) approach; ii) Smith et al. (2021), using a generalized CPTu state parameter inversion method based on the NorSand Widget; and iii) Robertson (2021), with the updated Kc. The results obtained from the evaluation of the susceptibility to flow liquefaction indicated a good convergence between the three methodologies in the region from filtered tailings and divergence in the region from excavated tailings from a reservoir of a TSF, using the Mayne and Sharp methodology.

Introduction

Recent tailings dam failures in Brazil, such as B-I Dam (2019) and Fundão Dam (2015), highlighted the importance of evaluating susceptibility to flow liquefaction, especially for structures constructed with sand-

like materials. Many field and laboratory procedures can be used to evaluate flow liquefaction susceptibility, such as: i) grain-size distribution curves; ii) Atterberg Limits; iii) CPTu tests; iv) the Vane Shear Test; and v) the Triaxial Compression Test. Due to its good repeatability and the detailed information it yields about the soil stratigraphy, the objective of this paper is to use the Seismic Cone Penetration (SCPTu) test to assess the susceptibility to flow liquefaction of a stacking of filtered iron ore tailings. Additionally, this paper aims to show the characterization of the two types of tailings deposited in the pile.

In the mining industry there are many studies to assess flow liquefaction using methodologies proposed by Plewes et al. (1992), Olson (2001), Shuttle and Cunning (2008), and Robertson (2016). In this context, this paper presents an evaluation of the susceptibility of a stacking dry tailings to flow liquefaction using the following recently published approaches: i) Mayne and Sharp (2019), using the yield stress ratio (YSR) approach; ii) Smith et al. (2021), using a generalized CPTu state parameter inversion method based on the NorSand Widget; and iii) Robertson (2021), with the updated Kc to evaluate the in-situ state parameter. It is noteworthy that these methodologies are initial screening tools to evaluate the phenomenon, and they alone are not enough to determine whether the tailings present strain-softening and brittle behavior in undrained shear.

Methodologies – susceptibility to flow liquefaction

State parameter definition

A possible reference to be used to define the state of sandy materials is the distance between the current void ratio of the material (*e)* and the critical state void ratio (Been and Jefferies, 1985). Therefore, this distance, or state path, indicates a direct representation of the tendency for volumetric variation of the soil under shear, which defines the state parameter (ψ), according to Equation 1.

$$\psi = e - e_c \qquad \text{(Equation 1)}$$

Been and Jefferies (1985) stated that the use of the state parameter to evaluate the material behavior is fundamental, since the evaluation of the expected behavior based on parameters such as void ratio and relative density does not provide the necessary rigor. Jefferies and Been (2016) showed that samples at the same relative density showed widely different stress paths because of changed stress levels. In contrast, samples at the same ψ but different densities and stress levels showed similar behaviour. Experimental studies performed by Jefferies and Been (2016) suggested that materials with $\psi > -0.05$ indicate contractive behavior (state looser than the critical state), whereas $\psi < -0.05$ indicate ductile behavior (state denser than the critical state).

Mayne and Sharp (2019)

Mayne et al. (2023) show that the preconsolidation stress can be presented in dimensionless terms using a normalized form called the overconsolidation ratio (OCR), or equivalent yield stress ratio (YSR), which is defined by Equation 2. According to the authors, the term YSR is becoming more prevalent because the traditional OCR is associated with mechanical unloading effects, while other geologic and environmental changes can also cause an apparent preconsolidation (i.e., desiccation, compaction, cyclic loading, repeated wetting-drying and other effects).

$$OCR = \frac{\sigma'_p}{\sigma'_{v0}} = YSR \quad \text{(Equation 2)}$$

In this context, Mayne at al. (2009) propose that the yield stress (σ'_p) of soils can be evaluated from cone net resistance (q_{net}), whereas Mayne (2017) indicates that the exponent m' is a function of CPT material index (I_c), according to Equation 3 and Equation 4, respectively.

$$\sigma'_p = 0.33(q_{net})^{m'}\left(\frac{\sigma_{atm}}{100}\right)^{1-m'} \quad \text{(Equation 3)}$$

$$m' = 1 - \frac{0.28}{1+\left(\frac{I_c}{2.65}\right)^{25}} \quad \text{(Equation 4)}$$

Where σ_{atm} is the atmospheric pressure ($\sigma_{atm} = 100\ kPa$).

As the threshold defined by the state parameter (ψ = -0.05) delimits the contractive-dilative behaviour (Jefferies and Been, 2016), alternatively, a critical threshold is defined in terms of yield stress ratio. Mayne (2017) explains that the YSR_{CSL} becomes the boundary separating contractive and dilative soil behavior, according to Equation 5 and Equation 6.

$$YSR_{CSL} = \left(\frac{2}{\cos\phi'}\right)^{\frac{1}{\Lambda}} \quad \text{(Equation 5)}$$

$$\Lambda = 1 - \frac{k}{\lambda} = 1 - \frac{C_s}{C_c} \quad \text{(Equation 6)}$$

Where ϕ' is the critical friction angle, k is the slope of the recompression/expansion line, and λ is the slope of CSL on $e - p'$ plane. Given the absence of oedometer tests for the present paper, λ_{10} was defined according to Plewes et al. (1992) and the condition $\lambda = \frac{\lambda_{10}}{2.303}$ was used. Additionally, the correlation $k = 0.1\lambda$ was assumed.

Considering the purposes of calculating the yield stress ratio at the critical state, Equation 7 and Equation 8 can be recommended for the effective friction angle (Mayne, 2007).

When $I_c < 2.6$:

$$\phi' = 17.6° + 11.0°\log(Q_{tn}) \quad \text{(Equation 7)}$$

When $I_c > 2.6$:

$$\phi' = 29.5°B_q{}^{0.121}\left[0.256 + 0.336B_q + \log(Q_{tn})\right] \quad \text{(Equation 8)}$$

Where Q_{tn} is the normalized tip resistance.

Mayne and Sharp (2019) indicated that considering a range of friction angles of sands between $30° \leq \phi' \leq 45°$ and a representative value $\Lambda = 0.8$, the corresponding range of YSR_{CSL} is $2 < YSR_{CSL} < 4$, with a typical value of $YSR_{CSL} \approx 3$.

Smith et al. (2021)

Smith et al. (2021) presented a generalized method to estimate ψ from either drained or undrained CPTu tests, based upon CPTu calibrations modeled using the Widget for a wide range of NorSand calibrated soils presented in the literature.

Using Critical State Soil Mechanics (CSSM) as a theoretical foundation, the NorSand model was developed during the 1980s and 1990s, based on experience with the construction of structures on loose sands. The analysis of the occurrence of static liquefaction during the construction of these structures contributed to the development of the model, initially proposed by Jefferies (1993) and later by Jefferies and Been (2016).

Therefore, as the names suggest, the intent of the model is to describe the behavior of loose and dense sands, in both drained and undrained conditions. The NorSand model was the first model to consider the state parameter based on the CCSM approach.

Considering the NorSand model and the cavity expansion modeling, Smith et al. (2021) proposed the correction of the k' and m' values proposed by Plewes et al. (1992).

Adopting the CPTu inversion parameter framework, Smith et al. (2021) indicated that some screening level methods suffer from stress level bias, which can result in overestimation of ψ with increasing depth. According to the authors, such bias can be removed through normalization by the elastic soil rigidity index $I_{r,e}$, as well as the use of drainage condition-specific functions, as indicated by Equation 9 to Equation 16.

Drained penetration:

$$\frac{k'}{M_{tc}} = a + b\ ln(\frac{1}{\lambda_{10}}) \quad \text{(Equation 9)}$$

$$a = 13.58 - 0.52\ln(I_{r,e}) \quad \text{(Equation 10)}$$

$$b = 0.87\ln(I_{r,e}) - 0.19 \quad \text{(Equation 11)}$$

$$m' = 3.83(\lambda_{10})^{-0.31} \quad \text{(Equation 12)}$$

Undrained penetration:

$$\frac{k'}{M_{tc}} = c + \frac{d}{\lambda_{10}} \quad \text{(Equation 13)}$$

$$c = 7.36 - 4.61G_0 \quad \text{(Equation 14)}$$

$$d = 0.06 + 0.02G_0 \quad \text{(Equation 15)}$$

$$m' = \frac{\ln(10)}{\lambda_{10}} \quad \text{(Equation 16)}$$

Where for the present paper M_{tc} was assumed as the mean value of 1.45 as indicated by Jefferies and Been (2016), given the absence of tests to define the CSL.

It is noteworthy that the proposed method does not provide inversion equations for partially drained CPTu. Based on this, Smith et al. (2021) suggest the use of drained inversion equations if $|B_q| < 0.02$ and $|\Delta u| < 20$ kPa. For the undrained inversion equations, it is important to consider the dissipation test $t_{50} >$ 60 s; otherwise, the use of an alternative screening level method (e.g. Plewes et al., 1992) is indicated. Additionally, the method is not applicable to soils with atypical soil fabric or bonding.

In terms of recorded CPTu data, the proposed method relies upon the accuracy of the $F_r - \lambda$ correlation proposed by Plewes et al. (1992), and therefore also relies upon accurate measurement of f_s. McConnell and Wassenaar (2022) indicate that the F_r values can be affected by the precision of the CPTu to measure the sleeve friction in very soft geomaterials, which require special attention of data obtained from hydraulically disposed tailings.

Robertson (2021)

To estimate ψ from CPTu tests, different methods are available. In sand-like soils, with $I_c < 2.6$, Robertson (2010) suggested that the normalized cone resistance (Q_{tn}) can be associated with the state parameter using a clean sand equivalent normalized cone resistance ($Q_{tn,cs}$), according to Equation 17.

$$Q_{tn,cs} = Q_{tn}K_c \quad \text{(Equation 17)}$$

Where K_c is a correction factor to account for changing behavior with increasing fines content. In this context, Roberston (2010) suggested a link between $Q_{tn,cs}$ and ψ for sand-like soils, as indicated by Equation 18.

$$\psi = 0.56 - 0.133\, log\,(Q_{tn,cs}) \quad \text{(Equation 18)}$$

To account for partial drainage, Robertson (2021) indicated an update in the equation to calculate K_c suggested by Robertson and Wride (1998), as shown in a simplified version by Equation 19 for $I_c \leq 3.0$.

$$K_c \approx 15 - \frac{14}{1+\left(\frac{I_c}{2.95}\right)^{11}} \quad \text{(Equation 19)}$$

Finally, Robertson (2021) indicates that the modified K_c relationship should not be extended beyond $I_c = 3.0$, where undrained penetration occurs.

Tailings characterization

Geotechnical characterization

The geotechnical characterization of the iron ore tailings was conducted by examining: i) the grain size distribution curve, ii) the water content, iii) the specific gravity of soils solids (G_s), iv) the liquid limit (LL), and v) the plastic limit (PL). The location of the samples collected to perform the tests and the SCPTu analyzed are indicated in Figure 1.

Figure 1: Location of the SCPTU and samples collected in the tailings dry stack pile

Considering the disposal methods and the origin of the stacking, it can be concluded that there are two types of tailings: i) filtered tailings between the depths of 0.00 m to 8.00 m; and ii) excavated tailings from a reservoir of a TSF and air-dried between the depths of 8.00 m to 25.25 m. Two samples (AM-201 and AM-105) were collected in each of the tailing's disposed in the pile.

The grain size distribution curves (ASTM D422-63) obtained from disturbed samples collected near the SCPTu are summarized in Table 1.

Table 1: Grain size distribution curves from disturbed samples

Filtered Tailings (0.00 – 8.00 m)	Excavation Tailings from TSF (8.00 – 25.25 m)
Clay: 0%	Clay: 15%
Silt: 61%	Silt: 75%
Sand: 39%	Sand: 10%
Classification ASTM D422: Sandy Silt	Classification ASTM D422: Clayey Silt

The Atterberg Limits were also evaluated, according to ABNT NBR 6459 and ABNT NBR 7180. Both samples collected in the two types of tailings were non-plastic.

According to ABNT NBR 6457, the filtered tailings has a natural moisture content of 12.3%, while the excavated tailings from a TSF natural moisture content of 13,5%. Additionally, the average of the specific gravity of soil solids (G_s) is 3.2. Using the grain size distribution curves and the Atterberg Limits the samples were classified according to the Unified Soil Classification System (USCS – ASTM D2487). The sample of filtered tailings was classified as silt with sand (Group Symbol ML) and the sample of excavated tailings was classified as silt (Group Symbol ML).

ICOLD Bulletin 181 (ICOLD, 2021) presents a system for classifying tailings into five broad categories based on grain size distribution curve and the Atterberg Limits. Using this system, the samples of filtered tailings were classified as Hard Rock Tailings (HRT), and the samples of excavated tailings were classified as Altered Rock Tailings (ART).

Evaluation of sCPTu test

An SCPTu was performed in the iron ore tailings with a total depth of 25.25 m. Figure 2 shows the normalized parameters. Based on this, it was possible to define two regions in depth in the filtered tailings (0.00 m – 4.00 m) and (4.00 m – 8.00 m), with clear patterns of Q_t and F_r variation. It was possible to note a uniform behavior of the normalized parameters from excavated tailings. In relationship to B_q, the result showed that the material does not generate considerable porewater pressure excess. A predominant drained behavior during cone penetration was observed, since the values did not reach the interval of 0.30 to 0.50 as suggested by Schnaid (2009) for undrained behavior.

Based on the soil behavior type indexes used and on the grain size distribution of the tailings, two different regions were identified (Figure 3). Region I (0.0 – 8.0 m) is composed predominantly of sand-like tailings, with IB > 32 and Ic(R&W) < 2.60; in this region the filtered tailings were deposited. Region II (8.0 – 25.25 m) was composed predominantly of transitional behavior, with 22< IB <32 and 2.05< Ic(R&W) <

2.60, with the presence of layers of Ic(R&W) > 2.60, in this region the tailings excavated from a reservoir of a TSF were deposited.

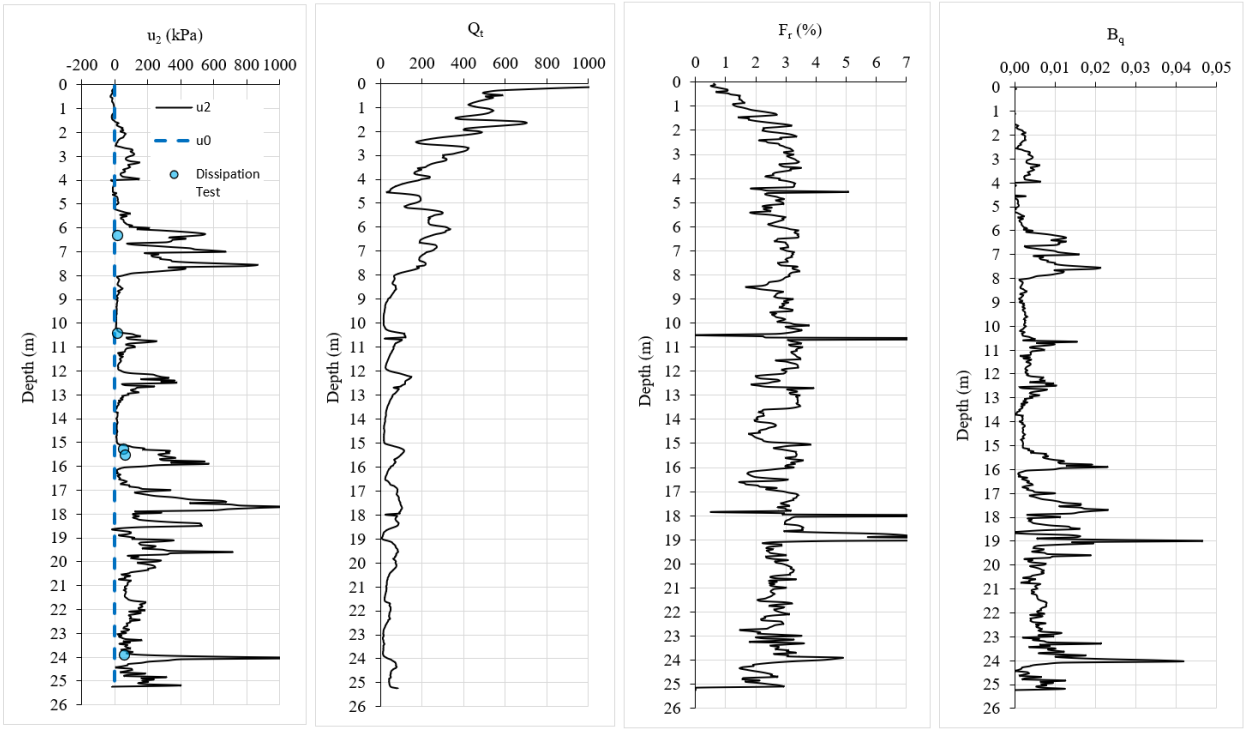

Figure 2: Results of normalized SCPTu parameters

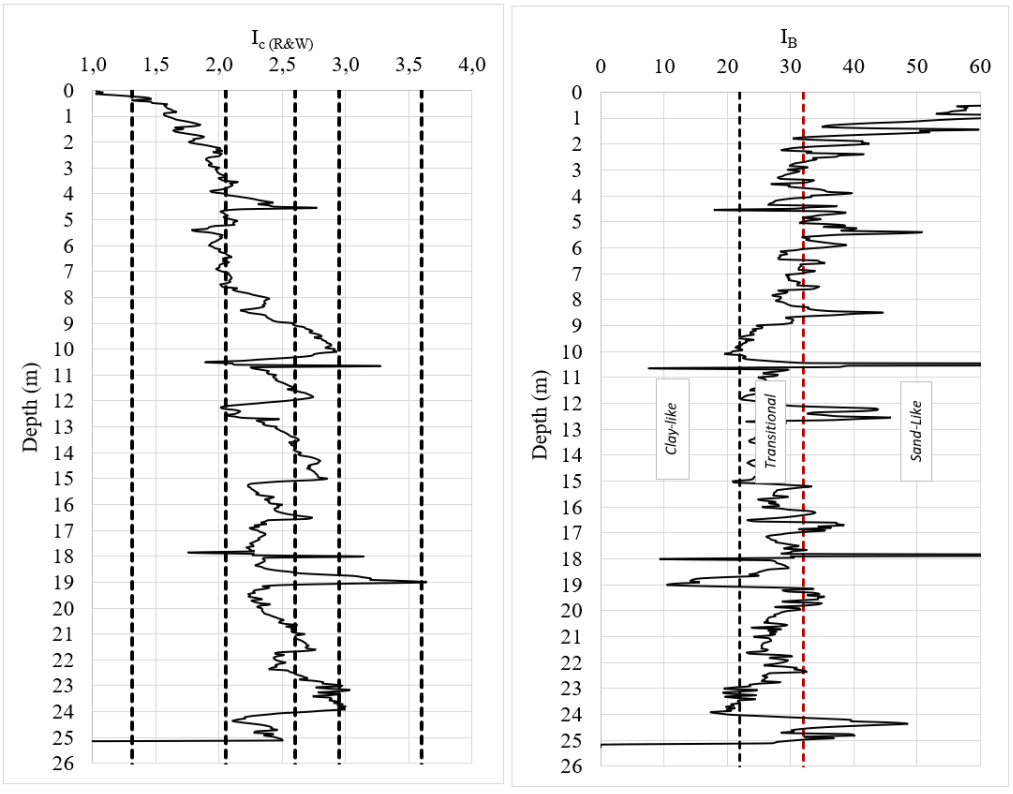

Figure 3: Soil behavior type suggested by Robertson and Wride (1998), modified soil behavior type index (I_B) suggested by Robertson (2016)

Table 2 shows the results of the five dissipation tests (DPP) performed in depth. As can be seen, all tests resulted in a $t_{50} < 45$ s, which indicates a drained penetration condition, since the values did not reach the interval of $t_{50} > 60$ s as suggested by DeJong and Randolph (2012) for undrained behavior.

Table 2: t_{50} in the dissipation tests performed in depth

Dissipation Depth (m)	t_{50} (s)
6.35	35
10.45	30
15.30	35
15.55	45
23.95	10

Microstructure

The evaluation of the microstructure in the iron ore tailings was performed using the shear wave velocity from the SCPTu. Almost all depths were tested, using the methodology suggested by Robertson (2016).

As shown in Figure 4, the results showed that the tailings classify as an ideal material (no microstructure) for most of the evaluations, with seven elevations in the structure region.

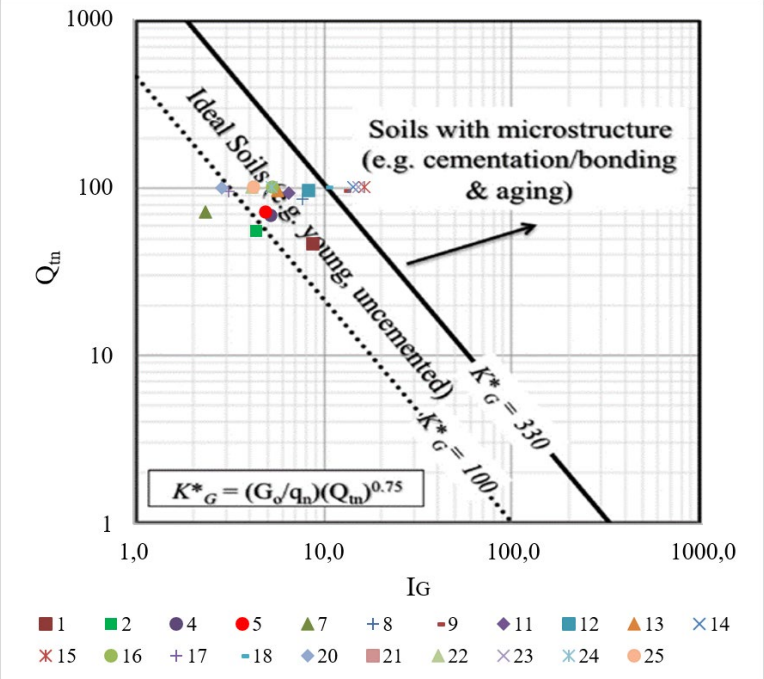

Figure 4: Microstructure evaluation (Robertson, 2016)

Results – susceptibility to flow liquefaction

The evaluation of the susceptibility to flow liquefaction of the tailings using the screening level methods of Mayne and Sharp (2019), Smith et al. (2021) and Robertson (2021) are shown in Figure 5.

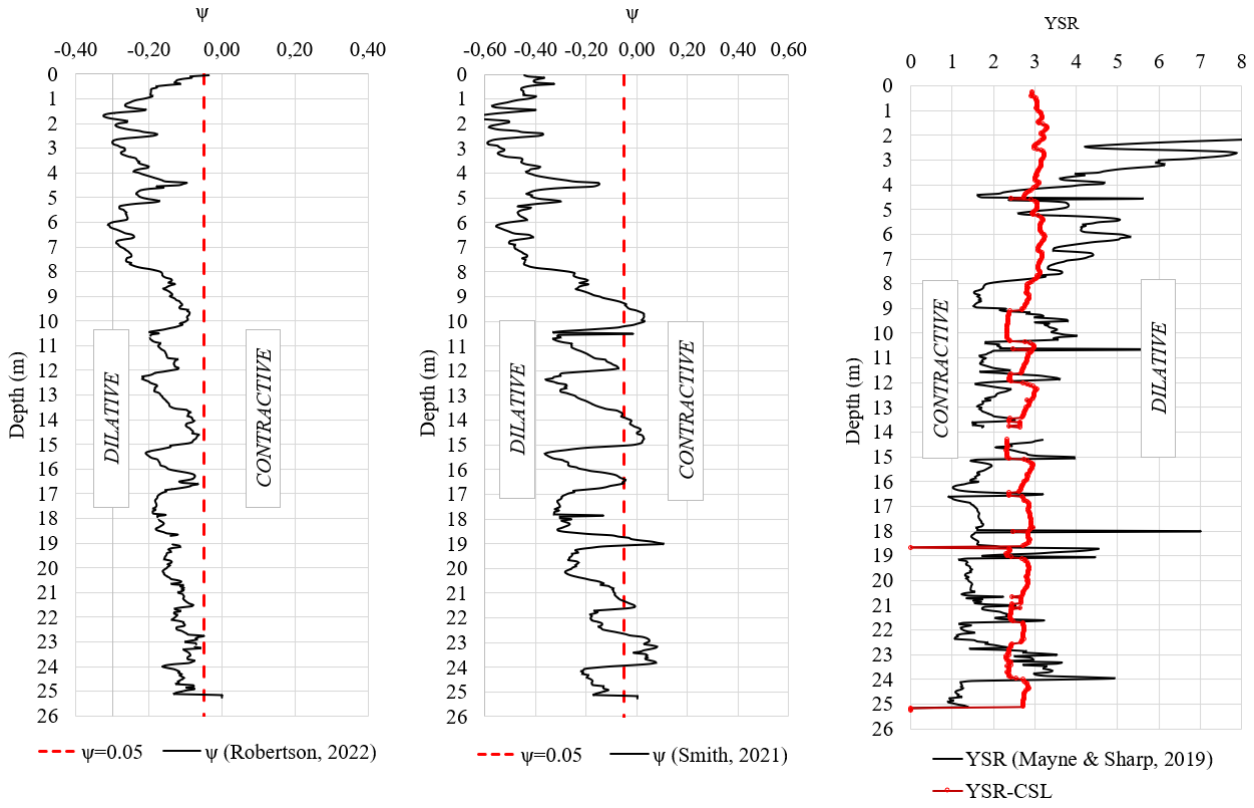

Figure 5: Evaluation of flow susceptibility based on (a) Robertson (2021), (b) Smith (2021) and (c) Mayne and Sharp (2019)

The drained inversion equations of Smith et al. (2021) were applied, because all the regions along the borehole resulted at $|B_q| < 0.02$ and $t_{50} < 60$.

Analyzing Figure 5 and considering the three methodologies, Region I (0.00 – 8.00 m) presented dilative behavior in the filtered tailings. This behavior indicates that the tailings deposited in this region were highly compacted and stacked at the optimum moisture content, according to the design. Also, we can observe a very small layer of contractive behavior at a depth of 4.00 m depth using the Mayne and Sharp method. At depth, Region II (8.00 – 25.25 m) presented a predominantly dilative behavior according to the Robertson (2021) and Smith (2021) methodologies. Also, we observed some small layers of contractive behavior at depths of 9.00 m, 14.00 m, 19.00 m and 23.00 m, using the Smith (2021) methodology. However, the yield stress ratio (YSR) used for the Mayne and Sharp method (2019) showed predominantly contractive behavior in this material, with YSR < 3.

Considering the three methods evaluated, there is a good convergence of tailings behavior in the methods that considered the evaluation of state parameter, Robertson (2021) and Smith (2021), with the dilative behavior along the borehole. For the methodology that considers the evaluation of YSR, Mayne and Sharp (2019), it is possible to confirm the contractive behavior of the excavated tailings from a reservoir of a TSF between 8.00 and 25.25 m, diverging from the other two methodologies.

Conclusion

This paper presented a case study of the susceptibility of IOTs to flow liquefaction using the screening level methods of i) Mayne and Sharp; (2019), ii) Smith et al. (2021); and iii) Robertson (2021).

The geotechnical characterization of the IOTs was conducted by performing: i) the grain size distribution curve, ii) the water content, iii) the specific gravity of soils solids (G_s), iv) the liquid limit (LL), and v) the plastic limit (PL). The classification of the tailings using the Unified Soil Classification System (ASTM D2487) showed that the IOTs are predominantly classified as silt (group symbol ML) with no plasticity.

A SCPTu with five dissipation tests was performed inside stacked dry tailings to evaluate the susceptibility of the tailings to flow liquefaction. Based on the behavioral characteristics, and on the geotechnical characterization and on the origin of tailings, two distinct regions were identified in depth. A predominant drained behavior during cone penetration was observed, and the results from the shear wave velocity indicated that in general the tailings classify as an ideal material (no microstructure).

The results obtained from the evaluation of the susceptibility to flow liquefaction indicated a good convergence between the three methodologies used in Region I between 0.00 and 8.00 m. In this region the filtered tailings presented a predominantly dilative behavior. With the methodology that evaluates the YSR (Mayne and Sharp, 2019), it is possible to confirm the contractive behavior of the excavated tailings from a reservoir of a TSF (Region II) between 8.00 a 25.25 m, diverging from Robertson (2021) and Smith (2021) methodologies in this region, that indicates dilative behavior. This behavior can be related to the compaction thickness realized in the Region II and air-drying process of this material.

It is noted that the methodologies used in this paper are initial screening tools to evaluate the susceptibility to flow liquefaction, and that they alone are insufficient to determine whether the tailings under evaluation present strain-softening and brittle behavior in undrained shear.

Abstract

The integration of photonics technology, particularly hyperspectral sensing and high-resolution imaging, with piezocone penetration tests (CPTu) offers a transformative approach to soil and tailings characterization. This paper presents preliminary work on the assessment of hyperspectral data combined with CPTu data for tailings characterization through analyzing a large dataset of paired hyperspectral, CPTu, and laboratory results using machine learning models. Additionally, it presents discussion on initial findings on particle size estimation employing a machine learning based approach to analyze high-resolution imaging acquired from reference samples and in-situ tests. The results demonstrate that incorporating hyperspectral and CPTu data significantly enhances tailings characterization, and the particle size determination using high-resolution images is promising.

Introduction

In geotechnical and geoenvironmental site investigations, characterization of soil and soil-like properties is essential. This often requires a combination of in-situ testing and sampling methods. Traditionally, laboratory testing and piezocone penetration testing (CPTu) have been the common techniques for soil characterization. While laboratory testing offers a comprehensive analysis of various soil properties, from constitutive, to geotechnical, to chemical, it involves drilling, sampling, and subsequent transportation, which is costly, carbon-intensive (Purdy et al., 2021), and more hazardous than CPTu operations. In-situ collection of soil hyperspectral data and high-resolution images coupled with CPTu or Seismic CPTu (SCPTu) offers promise for reducing cost, time, and environmental impacts associated with sampling and laboratory testing.

Building upon the foundation of CPTu technology, advancements are being made in incorporating hyperspectral sensors and high-resolution cameras into modules that can be placed in-line with the CPTu. The hyperspectral module enables real-time and continuous spectral data collection across an extended wavelength spectrum during CPTu operations. The vision module, designed for RGB imaging, facilitates the acquisition of high-resolution photographs in real-time during the CPTu push.

The hyperspectral module provides valuable insights into the chemical composition and crystal structure of geomaterials by measuring reflected light across different wavelengths. This capability allows for the identification and quantification of minerals (Clark, 1999; Entezari et al., 2017; Debaene et al., 2023), estimation of water content (Fabre et al, 2015; Entezari et al., 2016), detection and quantification of contaminants (Schwartz et al., 2011; Shi et al., 2014), and assessment of chemical composition (Cozzolino and Moron, 2003; McBride, 2022). The vision module provides detailed texture and color information about the geomaterial, aiding in the estimation of particle size distribution and identification of soil types (Hryciw et al., 2009 and 2015; Ventola and Hryciw, 2023).

This paper presents preliminary work on the analysis and interpretation of hyperspectral data coupled with CPTu data for tailings characterization. This assessment is conducted through the analysis of a dataset of paired hyperspectral and CPTu data, alongside tailings properties from laboratory testing. In our previous studies, we have developed machine learning models for the estimation of tailings constituents using hyperspectral data (Entezari et al., 2022a) and using Gamma-CPTu (GCPTu) data (Entezari et al., 2022b). In this paper, we evaluate the potential of combining hyperspectral and CPTu data for improved tailings characterization. Additionally, we present initial pilot results on particle size estimation using high-resolution benchtop and in-situ images analyzed with a machine learning based algorithm.

Background

Hyperspectral module

The hyperspectral module (patent pending) is configured with spectrometers capable of collecting reflectance spectra in the spectral ranges of 400-850 nm and 950-1700 nm. Alternate configurations can be used to collect different spectral ranges. To collect the reflectance spectra during CPTu operations, the hyperspectral module contains a light source to illuminate the soil through a window. The reflected light is then transferred to a spectrometer(s) that transmits a digitized signal to the CPTu data acquisition system (DAS). Figure 1 illustrates sample data obtained from a wet and a dry tailings sample using a benchtop setup of the hyperspectral module.

By measuring reflected light across different wavelengths, spectral sensors provide information about chemical composition and crystal structure (Clark, 1999). This versatile method enables both qualitative and quantitative assessments of various materials and substances.

Reflectance spectroscopy facilitates quantitative assessments of soil properties by correlating spectral signatures with specific parameters of interest. Through empirical relationships established between spectral features and target properties, quantitative estimations with high accuracy can be derived. By calibrating spectral data against reference measurements obtained from laboratory analyses, robust quantitative models can be constructed for diverse soil properties, including mineral content, organic carbon content, and contamination levels.

In qualitative analysis, reflectance spectroscopy can help identify and characterize different components present in the soil. By analyzing the spectral signature (the unique pattern of light absorption and reflection across various wavelengths) the presence of minerals, organic matter, and contaminants can be identified (Clark, 1999; Schwartz et al., 2011). Each component exhibits distinct spectral features, allowing for their identification without the need for physical extraction or laboratory testing.

The integration of hyperspectral sensors into CPTu modules allows for real-time, continuous hyperspectral reflectance data collection during CPTu or SCPTu operations. The synergistic integration of hyperspectral data with CPTu data (or SCPTu), correlated and analyzed by machine learning algorithms, can produce new methods to estimate soil properties such as plasticity, fines content, water content, degree of saturation, mineralogy, and contaminants.

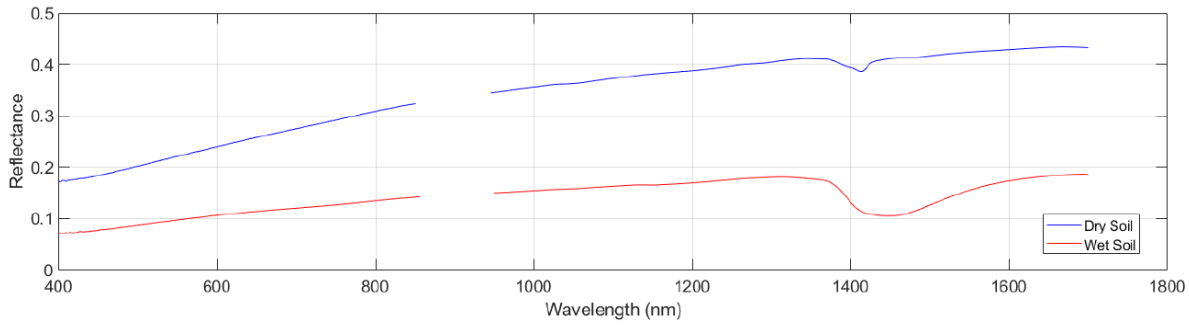

Figure 1: Example hyperspectral data from hyperspectral module

Vision module

The vision module is equipped with an 18 MP high-resolution image sensor which captures photographs through a 16 mm diameter window. With the present configuration, each pixel of the image corresponds to an area of approximately 4µm × 4µm. Figures 2a and 2b show example images acquired from two soil samples with particle diameters ranging from150-250 µm and 105-150 µm, respectively.

Vision module offers numerous advantages for geotechnical and geo-environmental site characterization. The ability to perform visual inspections using in-situ images reduces the need for visual assessment by physical soil sampling and complements soil behaviour type (SBT) derived soil stratigraphy. Additionally, it facilitates a thorough quality check of CPTu data by pairing images with the data, allowing for the identification of anomalies through supplementary visual evidence. This technology can also enable

the estimation of particle size distribution through textural analyses or machine learning modelling (Buscombe, 2019; Ventola and Hryciw, 2023). Furthermore, the detailed insights gained from analyzing particle size and colors enhance soil classification and characterization, making vision CPTu a valuable tool in site assessment and analysis.

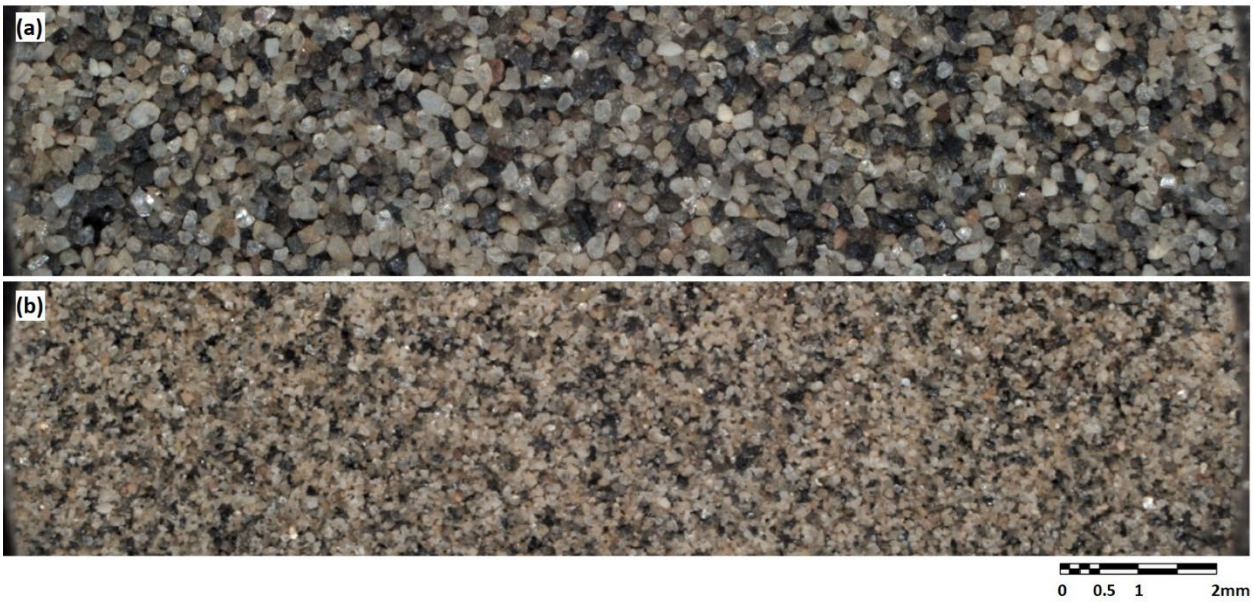

Figure 2: Example vision module data from samples with particle size of (a) 150-250 µm and (b) 105-150 µm

Data and methods

Hyperspectral GCPTu dataset

To explore the potential synergy between hyperspectral and CPTu data, a dataset combining hyperspectral and GCPTu data from the oil sands region in Canada was compiled. ConeTec's oil sands tailings dataset (Entezari et al., 2022a), originally collected in the 350-2500 nm range from ex-situ samples, was limited to the spectral ranges of 400-850 nm and 950-1700 nm, corresponding to the spectral ranges of the hyperspectral module.

To pair hyperspectral data with GCPTu data, our geospatial database was queried to identify GCPT soundings in proximity (within 10 m radially, 3 months temporally) of the hyperspectral data samples. The GCPT parameters, including gamma counts, undrained shear strength, and the slope and linearity of porewater pressure (Entezari et al., 2022b), were averaged over the sample length and paired with hyperspectral data. This process resulted in a dataset comprised of hyperspectral data, GCPTu data, and corresponding laboratory results. The final dataset included 4723 data pairs, providing a large dataset for analyzing the combined utility of hyperspectral and CPTu data in tailings characterization. The dataset was split into training and test sets, through random selection of ~10% of the data points as the test set. Four

models were trained using four different sets of input features including: (1) hyperspectral and GCPTu parameters, (2) hyperspectral and CPTu parameters (no gamma), (3) only hyperspectral parameters, and (4) only GCPTu parameters. Consistent with previous work (Entezari et al. 2022a and 2022b), the models of this study were trained using the training set and an ensemble of neural networks using bootstrap aggregation (Bagging) technique (Sollich and Krogh 1996, Breiman 1996). The models were trained to predict the contents of bitumen, solids, water, total fines, fines/(fines+water) (FFW) as well as methylene blue index (MBI). The performance of the models was evaluated using the cumulative distribution function (CDF) of errors on the test set (Error = Lab -predicted). The bias of the prediction was determined at the 50th percentile in the CDF. Assuming normal distribution of errors, the CDF values at 15.9% and 84.1% correspond to ±1 standard deviation and the average of these CDF values was adopted as the comprehensive error measure for the model.

High resolution images

To assess the use of vision module images to determine particle size distribution in coarse grained soils, the Segment Every Grain machine learning procedure (Sylvester, 2023) was applied to two images: one from a benchtop study, and one from in-situ imaging. The Segment Every Grain algorithm detects particles in images and provides estimates of particle diameter by identifying boundaries and determining the major and minor axis length of particles. The algorithm first identifies particles, then allows the user to delete improperly detected particles and add new particles. This combined machine-user approach allows for quick refinement of modeled results.

Imagery was first captured on the reference sample with particles ranging from 105 -150 μm (Figure 2b). The algorithm was then applied to the image and results were refined by the user. A field demonstration was also conducted using the vision CPTu to collect imagery and CPTu data up to a depth of 12 meters in oil sands tailings. During the CPTu test, the probe was stopped at 10 cm increments to capture images. Data collected from in-situ tests were compiled and a sample image of a predominantly sandy material was selected to assess the performance of the Segment Every Grain algorithm for the particle size estimation of the in-situ images.

Results

Tailings characterization using hyperspectral and CPTu data

The results of the trained models developed using different sets of input features are presented in Figures 3-6. These figures include scatter plots that depict the relationship between lab measured constituents and the predicted results for the test set. The model architecture and training parameters were consistent across all four models to facilitate a comparative analysis. As shown, models incorporating both hyperspectral and

GCPTu/CPTu parameters as input features outperformed those trained solely with hyperspectral parameters or solely with GCPTu parameters across all tailings characterizations. The summary of the error analysis is provided in Table 1.

The application of the developed models on in-situ data faces two challenges. First, collecting hyperspectral data in oil sands fluid tailings is impractical due to bitumen smearing and the lack of a self-cleaning mechanism, limiting the application of the model to soil-like materials in the oil sands where data collection is feasible. However, this limitation does not apply to non-hydrocarbon deposits. An error analysis was therefore conducted exclusively on soil-like material where in-situ hyperspectral data collection would be feasible (Table 1). The soil-like material was identified based on a pore pressure linearity of less than 0.8.

Second, variations between the spectrometers used during model development and those in the hyperspectral module may require calibration transfer to ensure accurate data interpretation. Future efforts will evaluate the need for calibration transfer methods to align data from different spectrometers, thereby enhancing the model's reliability and applicability to in-situ data.

PSD analysis using images

Figure 7a presents a benchtop image of a reference sample captured by the vision module, with the highlighted area enlarged in Figure 7b. The particle detection results are shown in Figure 7c, where the algorithm successfully detected most particles. The PSD results from machine learning are displayed in Figure 7d. Most particles fall within the 105-150 µm range (#100-140 sieve), though sizes below 105 µm and above 150 µm are also observed (Figure 7d). A close examination of Figure 7c, compared with the grains in Figure 7b, indicates that some adjacent grains were detected as larger agglomerated particles, leading to sizes over 150 µm. Additionally, overlapping particles sometimes resulted in only the uncovered part of a particle being detected, accounting for sizes under 105 µm.

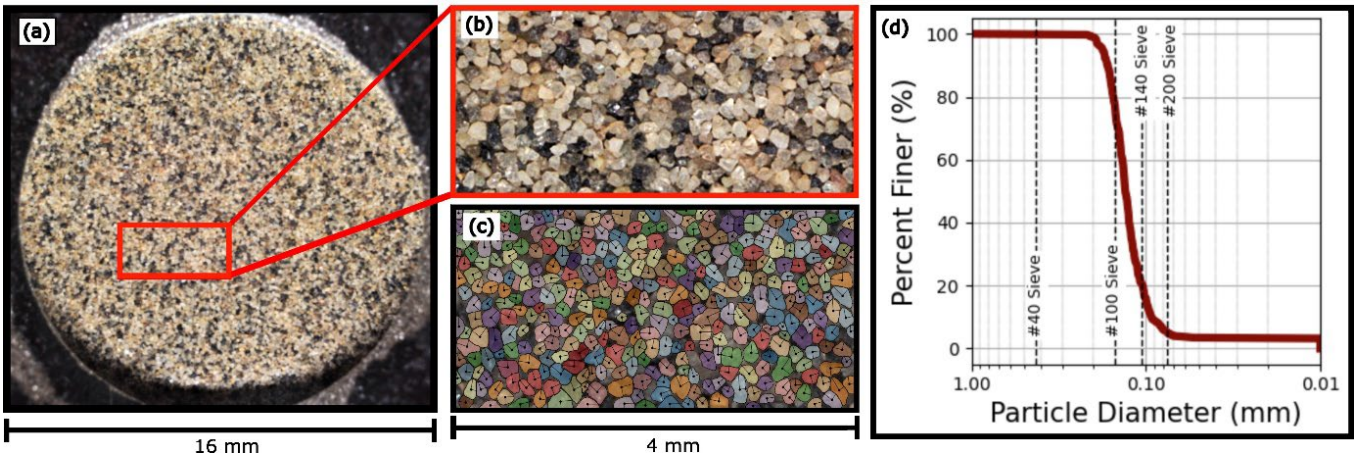

Figure 7: Results from benchtop imaging including (a) the image of the reference sample, (b) the cropped section used in analysis, (c) results from machine learning segmentation, and (d) the particle size distribution curve for detected particles

Figure 8 presents the results from in-situ field testing using the vision module, showcasing cone tip resistance (qt), sleeve friction (fs), stacked incremental images compiled from cropped thin sections from the imagery, and enlarged image sections at selected depths. As shown in Figure 8, a transition in qt is observed near a depth of 7 m, which corresponds to a transition from predominantly sandy material to fine grained mixtures. When cross referencing this information with in-situ images, a color change in the tailings profile is observed. Additionally, a visual change in moisture condition above and below the water table at 0.6 m depth is observed based on the enlarged images.

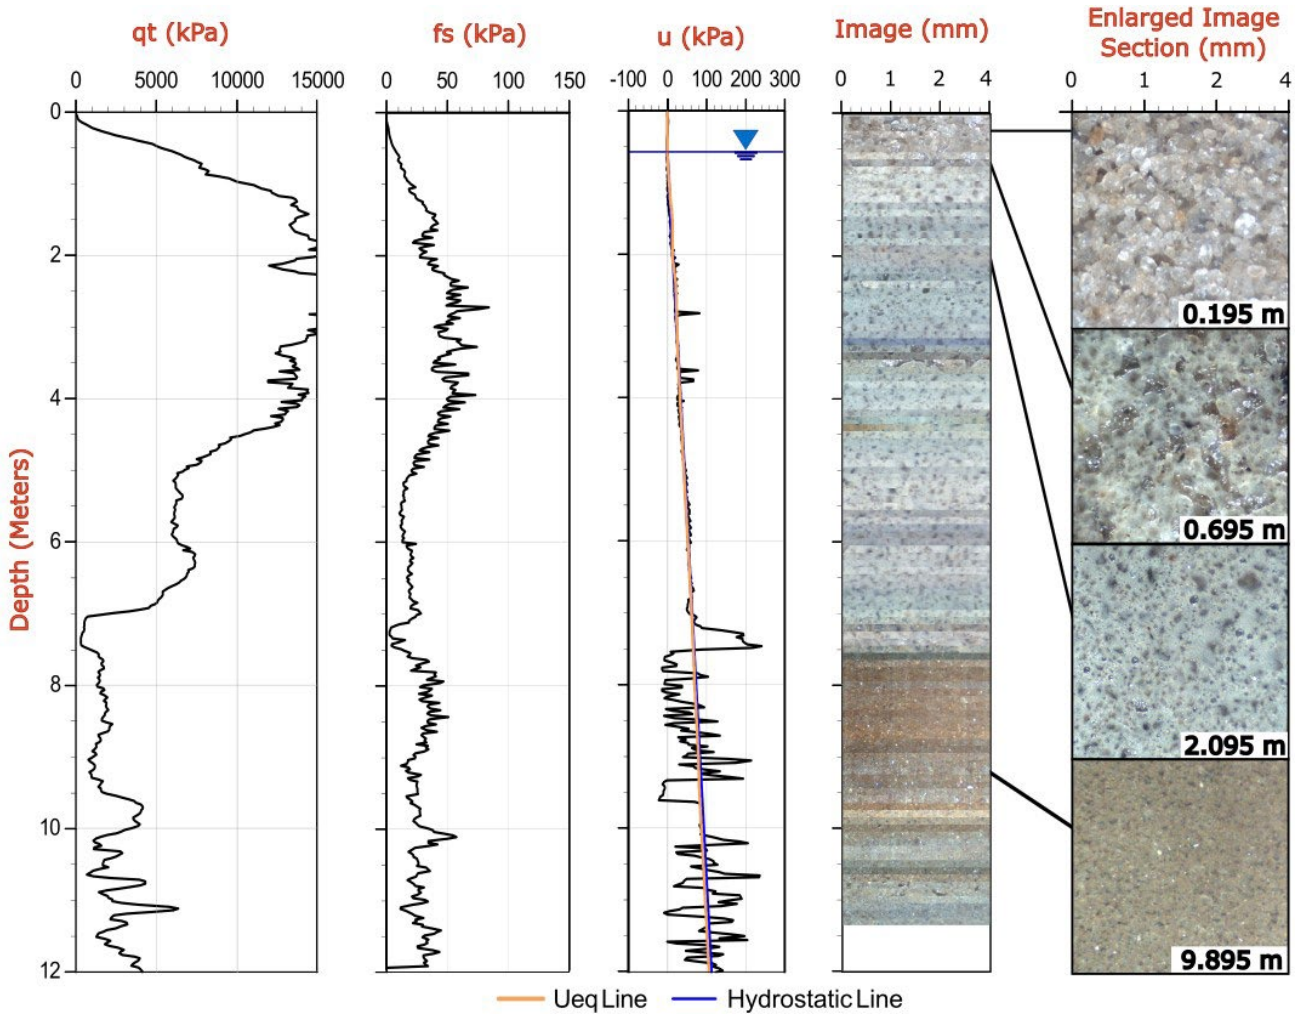

Figure 8: CPTu data and associated images including the cone tip resistance (qt), sleeve friction (fs), dynamic pore pressure (u), cropped image at each imaging depth, and enlarged image sections at selected depths

Figure 9 illustrates the results of the Segment Every Grain algorithm applied to an in-situ image from sand-dominated tailings. Visual interpretation suggests that the algorithm successfully identified the majority of particles in the image. However, due to the similar color of the particles, its performance is limited. While laboratory data are required to thoroughly evaluate the accuracy of the results, the preliminary PSD analysis indicates that most particles are larger than 75 µm, which is typical for such tailings. This initial assessment shows promise for predicting particle size distribution from in-situ images.

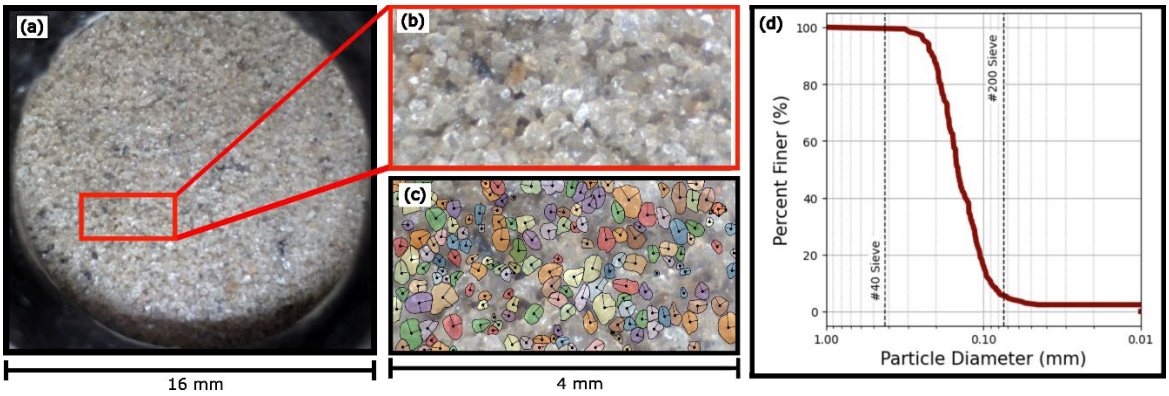

Figure 9: Results from in-situ imaging including (a) the image of the sand-dominated tailings, (b) the cropped section used in analysis, (c) results from machine learning segmentation, and (d) the particle size distribution curve for detected particles

Conclusion

This paper introduced initial research on the integration of advanced photonics technologies, including hyperspectral sensing and high-resolution imaging, into CPTu modules. Results show that the synergistic fusion of hyperspectral data with CPTu data, empowered by machine learning algorithms, improves the accuracy and reliability of predicting tailings properties. Analysis of a dataset containing hyperspectral, CPTu, and laboratory data demonstrates that modeling procedures that incorporate both hyperspectral and GCPTu/CPTu data outperform models that only use hyperspectral or CPTu data. Additionally, the use of the high-resolution images and machine learning-based analysis shows promise for the estimation of particle size distribution for coarse grained materials. Although the application of optical technologies and machine learning for soil and tailings characterization is still a developing field, this study, among others, highlights the potential of these technologies to enhance the speed, cost-efficiency, and resolution of site characterization.

Hydraulic Dewatered Stacking Demonstration – Approaching Operational Completion

Phil Newman, Anglo American, UK
Mark Bruton, WSP, UK
James Purrington, WSP, UK
Alireza Nickman, WSP, UK
Andrea López, Anglo American, Chile

Abstract

Hydraulic dewatered stacking (HDS) is an engineered co-disposal approach that uses a fines-free sand, derived from the tailings themselves, to deliver robust and effective omnipresent drainage channels throughout the tailings facility, accelerating consolidation and dewatering.

Since its inception in 2019, Anglo American have rapidly developed the science behind the new tailings system and designed, built, and commissioned a bespoke 150,000 m^3 capacity greenfield tailings facility at the El Soldado Mine in Chile.

This paper presents the results to date of the trial, encompassing two of the planned three stages of tailings and sand drainage layer deposition and the construction of drainage channels. A review of the efficacy of the technology will be presented and a comparison between two different methods of co-disposal and placement of sands will be considered.

Key parameters associated with the desaturation and resaturation of the facility will be presented based on the review of in-situ data collected from an extensive array of instrumentation and, where available, follow-on intrusive investigations and laboratory testing.

The industry appears ready to embrace the benefits of the technology, which include:

- enhanced water recovery delivering real value and increasing the resilience of operations in water-scarce regions;
- limited capital expenditure while delivering many of the performance benefits of filtered tailings stacking;
- a final tailings facility footprint suitable for re-purposing, reducing long-term liabilities; and
- an instrumentation solution that can deliver on enhanced transparency for stakeholders, helping owners to move towards GISTM compliance.

Introduction

Hydraulic dewatered stacking (HDS) is a novel tailings management approach developed by Anglo American that utilizes fines-free, rapidly draining sand to create a 3-dimensional drainage structure to deliver a predominantly desaturated tailings storage facility (TSF).

The sand is derived from the tailings themselves, which in most cases, assures compatibility as a robust and long-lasting filter medium (Terzaghi and Peck, 1948). Suction pressures are developed rapidly in the tailings, which drain both vertically and horizontally thanks to spigotted tailings possessing a K_h that is 10x K_v. This anisotropy in permeability is exploited well by the engineering design of HDS and although results remain preliminary, the data generated from the 150,000 m^3 demonstration facility at the El Soldado Mine in Chile supports the initial hypothesis. The dewatering and consolidation performance measured to date has been excellent and an extensive site investigation planned for Q4 2024 will provide the final calibration of the data collected to date.

The trial was constructed in 2021 after initial laboratory testing (Newman et al., 2022) indicated that a desaturated stack was feasible. As with all pilots, operational learnings and data generated has led to design changes during the trial. Significant data has been generated, and lessons learned regarding in-situ instrumentation to monitor tailings facilities. Data is presented below, with interpretation and reference to the ongoing concurrent modeling of the facility. The work completed has fed directly into studies for full-scale implementation of HDS both within and outside of Anglo American's assets. Cost estimates have confirmed that HDS is more expensive to operate than conventional wet tailings disposal, but highly water generative (with associated safety, expansion optionality, and closure benefits). When assessed using a Net Present Cost (NPC) approach, the results are dependent on i) water costs/constraints; ii) time to closure; and iii) estimated closure costs. When compared to filtered tailings, both capital and operating cost savings are significant and the approach can deliver an unsaturated stack where the net present cost of implementation is between one third and one half (Newman et al., 2024).

Demonstration design and operation

Concurrent modeling of the proposed trial led to a variation in design with the trial facility split into two cells testing two different approaches to HDS execution (see Figure 1).

The design in Cell A was varied to exclude sand blankets and only sand channels were utilized; modeling had shown that thin layers of tailings separated by sand blankets could increase the rate of consolidation. However, the development of suction pressures would be hindered such that air entry might not be achieved. Cell B was left with sand blankets so that a comparison could be made between the two approaches.

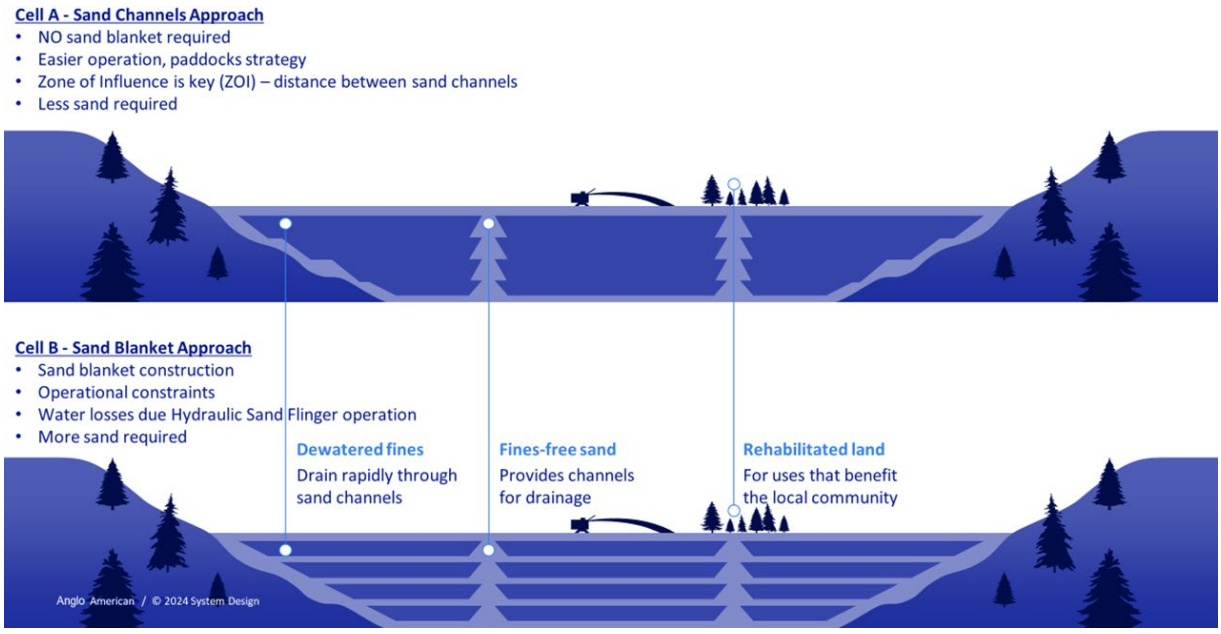

Figure 1: Sand blankets (Cell B) vs. sand channels (Cell A)

An important artefact of this change in design (of cell A) is that the sand channels are not physically continuous with the basal drain layer since a 2 m thick layer of tailings had already been placed in the cell. It was considered that this would limit the ability of the sand channel approach to drain and hence would have a conservative impact on the performance. A greenfield application of the HDS system would include such a connection – modeling of the two approaches is proposed and will be reported on in due course.

Lessons learned and impact on future commercial applications

The change in placement approach also has operational implications; the placement of the sand blankets was considered problematic. Working with the contractor, a Hydraulic Sand Flinger (HSF) was developed to place the sand blanket; the approach worked although getting an even layer was difficult, resulting in higher consumption of sand than expected. However, at larger scale applications (wherein most of the value for HDS exists for the mining industry) the placement of these blankets would likely involve the machine moving across recently placed tailings – adding another degree of operational uncertainty. In addition, the loss of water through evaporation also reduced the attractiveness of the sand blanket approach. Alternative sand blanket options investigated included open pipe placement, creating large cones of deposited sand about 600 to 800 mm high and 20 m in diameter; simple and effective.

The drainage channels have been built hydraulically with an SPCU (Self Propelled Cyclone Unit), which has performed well at approximately 80-90 tph. Higher placement capacity is feasible but the demonstration was limited by the size of the fluidizer plant. The SPCU was originally developed to classify

a conventional slurry. Hence, optimization of the system is required when the duty is changed to dewatering a fines-free sand.

Design work is ongoing with an Original Equipment Manufacturer (OEM) looking at other sand placement techniques, with a target of achieving >250 tph sand placement. At these placement rates, larger scale operations become easier to implement with a small number of "berm-builders." The constraint going forward will be the pipeline management for the delivery of the sand slurry given that the discharge point is continuously moving. Innovations developed on large scale conveying and stacking (i.e., the tripper conveyor) do not exist at this time for slurry transport. Hence, further innovation is required to fully automate the sand placement process.

Water recovery has been strong, and of good quality. Under steady state conditions, the water quality in terms of suspended solids is the same or better than conventional tailings return water. Geochemically, the water quality was similar.

Instrumentation

Designing a demonstration tailings facility provides an unparalleled opportunity to generate data on the settlement and consolidation behavior of tailings. Lining the facility was not a permitting requirement but was a decision taken to facilitate water balance calculations and monitoring.

The HDS contains an array of geotechnical instrumentation to allow designers and operators to monitor the desaturation of the facility through operations and into closure. Vibrating Wire Piezometers (VWPs), Moisture Content (MC) probes, Suction Transducers (ST) and Fiber Optic cabling have all been installed within the facility raises. Lidar surveys are conducted daily to monitor consolidation.

Following the development of two alternative construction approaches (Cell A and Cell B), the two approaches can be quantitatively compared. At the time of writing this paper the facility has been operated through Phase 1 and 2 of the trial. For the placement of the first 2 m layer of tailings in Phase 1 both cells were operated in the same approach, subsequent to this, two alternative approaches were implemented.

MC probes record Volumetric Water Content (Volume of water compared to volume of solid); laboratory calibration has been used to convert this to a gravimetric moisture content, but this is a function of the density of the tailings, so these values provide a relative gauge rather than absolute value. This can be seen in the data set when presenting the degree of saturation (Sr) based on a constant assumed voids ratio (Figure 2), where the consistently flat sections of the data correspond to the tailings in the location of the instrument being fully submerged by the supernatant pond.

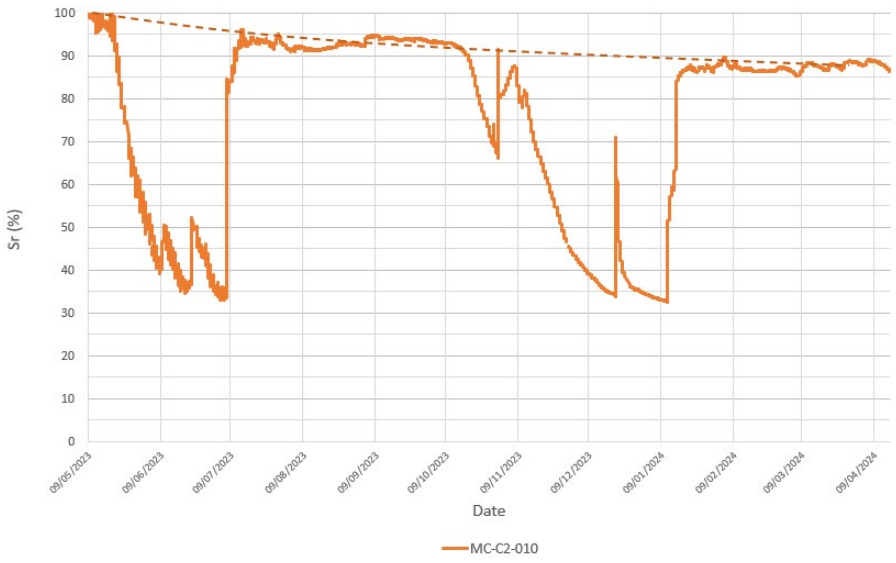

Figure 2: Change in voids ratio

The data acquisition system (DAS) at the demonstration has worked well. The permitted facility was built on top of an existing tailings facility and piezometers measure the development of excess pore pressure within the supporting tailings mass, and inclinometers in slopes that surround the facility monitor deformation that could adversely affect the safety of the staff working on the trial. The integrated satellite DAS connects directly to a user-friendly dashboard accessible globally through an internet connection. Alerts as required can be generated, resulting in direct communication with relevant personnel and linked to the Operations and Surveillance Manual (OMS) and trigger action response plan (TARP).

On-line site cameras covering the trial allows daily interaction with the facility from designers and stakeholders located thousands of miles from the site and it has provided unexpected insight. For example, a 1:10 year rain event experienced on site in June 2024 was an unscheduled (but valuable) test on the sand channels' capacity to remove excess water. Time lapse photography shows that as fast as water was entering the facility, it was being removed through the drainage system. Operational data shows that water removal through the drains rose steadily delivering clean water to the concentrator from unhindered flow through the sand channels at the demonstration site.

Lessons learned from instrumentation experience

The instrumentation installed in the facility has provided valuable insight into the performance of the facility. However, the discrete nature of the data points offer only part of the picture and it is evident that coupling moisture content and suction transducers at each location would offer greater insight. The attempt to create a broader spatial understanding of the facility using self-heating (active) fiber optics has proven elusive, with no significant data capture due to numerous failings in the system.

Discrete instruments have, in general, delivered a robust solution. Selecting suction transducers, not ideally suited to the intended use, has led to a few data gaps. In Phase 3 the addition of a different type of soil water potential sensor at each of the suction transducer locations has been included.

In addition to the instrumentation data the trial will be supplemented from a dense array of intrusive investigation holes, in-situ test work and laboratory testing, to increase the overall understanding of the performance of the facility.

Data and discussion

Some insights from the data obtained during Phase 1 and 2 of the trial are presented below. It is noted that instrumentation measures performance of the facility at discrete locations and the data is indicative of trends rather than absolute values. This is particularly important where data is interpreted using assumed constants (e.g. voids ratio assumptions used to interpret gravimetric moisture content or degree of saturation). Artifacts of the trial such as the large pond size relative to the tailings storage cell volume must be carefully considered when assessing and reporting on performance of the stack.

Phase 1

Results from Phase 1 of the trial have shown that through the construction of a substantial basal drain across the facility the tailings achieved an estimated degrees of saturation (Sr) of approximately 75-80 %. See Figure 3.

During Phase 1 high suction pressures were recorded in the instruments installed 1 m above the basal drain resulting in an initially low degree of saturation (Sr) from 75 to 80 %. However, with repeated wetting fronts from tailings and sand channel deposition, the tailings immediately above the basal drain became effectively fully saturated. It is likely that the initial high suction pressures were a result of desiccation at the surface of the tailings rather than downward flow into the basal drain, and as further layers of material are placed above, the influence of suction generated by desiccation, and the resultant finger flow evaporation, is lost. Figure 3 shows this general trend of reducing suction pressure development in the lower layer as more tailings are deposited. The data also indicates that air entry of the tailings occurs at around -11 kPa.

It is again noted that the apparent reduction in the degree of saturation is a function of an assumed constant voids ratio where in fact the materials have continued to consolidate. Where the suction transducer ST-C1-001 shows positive pore pressure (or even suctions less than the air entry value), it would suggest fully saturated conditions and as such Sr should be 100 %. Cell A and B showed a similar trend in the results through Phase 1. Since the instruments are in discrete locations from one another and are influenced

by operational factors such as pond migration, tailings deposition and wetting fronts, correlations between suction and moisture need to be considered with a degree of judgement.

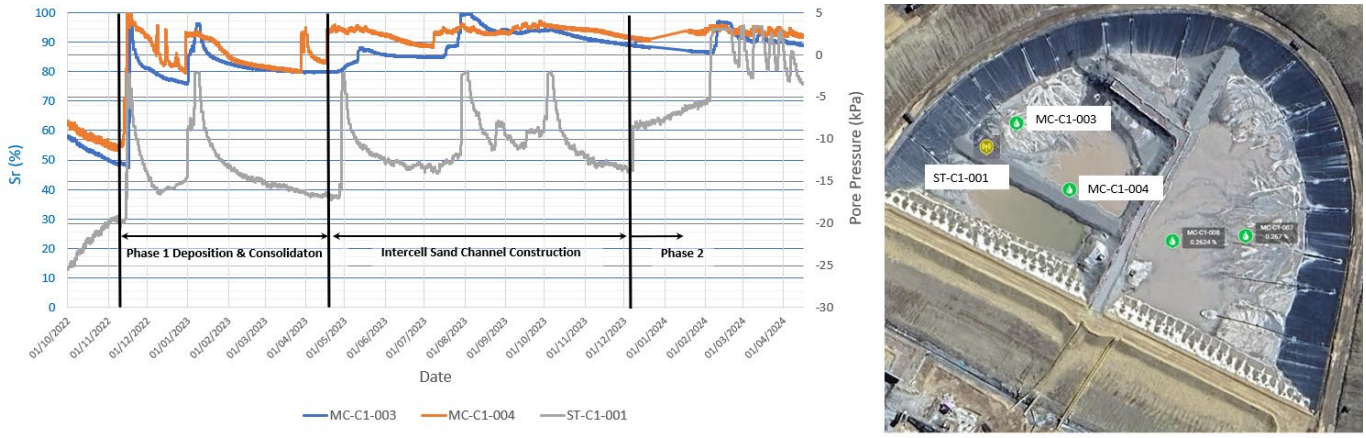

Figure 3: Phase 1 saturation of lower tailings layers (Cell A)

Phase 2

The Phase 2 tailings deposition occurs in Cell A as a continuation of tailings deposited on top of the already placed Phase 1 tailings. However, the cell is now subdivided into three sections with intercell sand channels that connect directly to the central sand channel separating the two cells (Cell A and Cell B), Figure 4. Cell B had a circa. 1 m thick sand blanket layer placed on the tailings surface prior to the next 2 m layer of tailings being deposited into the cell.

In Cell A the lower instruments clearly observed wetting fronts passing through the bottom layer of tailings and into the basal drain, as observed from instruments MC-C1-003 and MC-C1-004 shown in Figure 3. Instruments MC-C2-009 and MC-C2-010 installed 1 m into the next layer of tailings, circa 3 m above the basal drain. In this layer suction pressures were maintained even with 2 m of tailings placed above the instruments, Figure 5. In this instance the data has been plotted as the raw volumetric moisture content values reported by the instrument to avoid further ambiguity relating to computed Sr values, but the trends are obvious, and clearly result in very low Sr values which are estimated in the range from about 50 % in MC-C2-009 to 80 % in MC-C2-010 at the end of the data set presented. Further desaturation is expected after deposition ceases since suction pressures were beginning to approach the apparent air entry point of around -11 kPa as the supernatant pond receded.

The results for the second layer of tailings in Cell B show similar results to the lower layer. Since the instruments are approximately 1 m above the placed sand blanket, development of suction pressure is initially high due to desiccation that occurs due to rapid drainage of supernatant water as the tailings consolidate quickly. However, as seen in the lower layer, successive material deposition and wetting fronts reduce the ability for the tailings layers to generate suction in this way, thus trending towards high degrees of saturation.

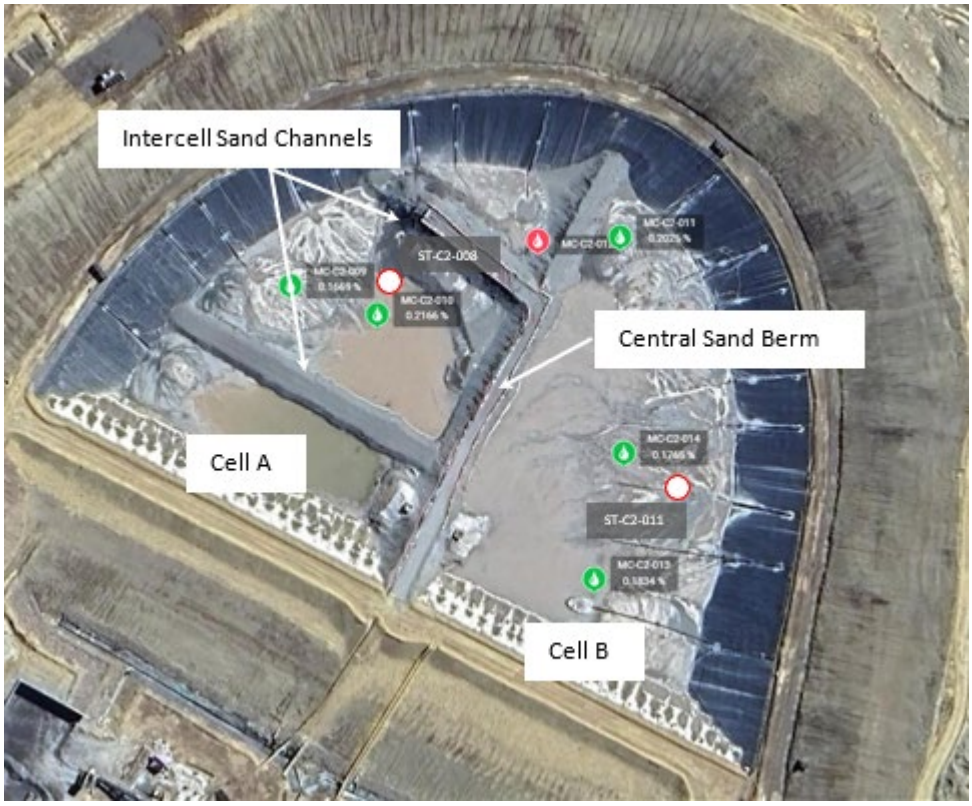

Figure 4: Phase 2 cell layout

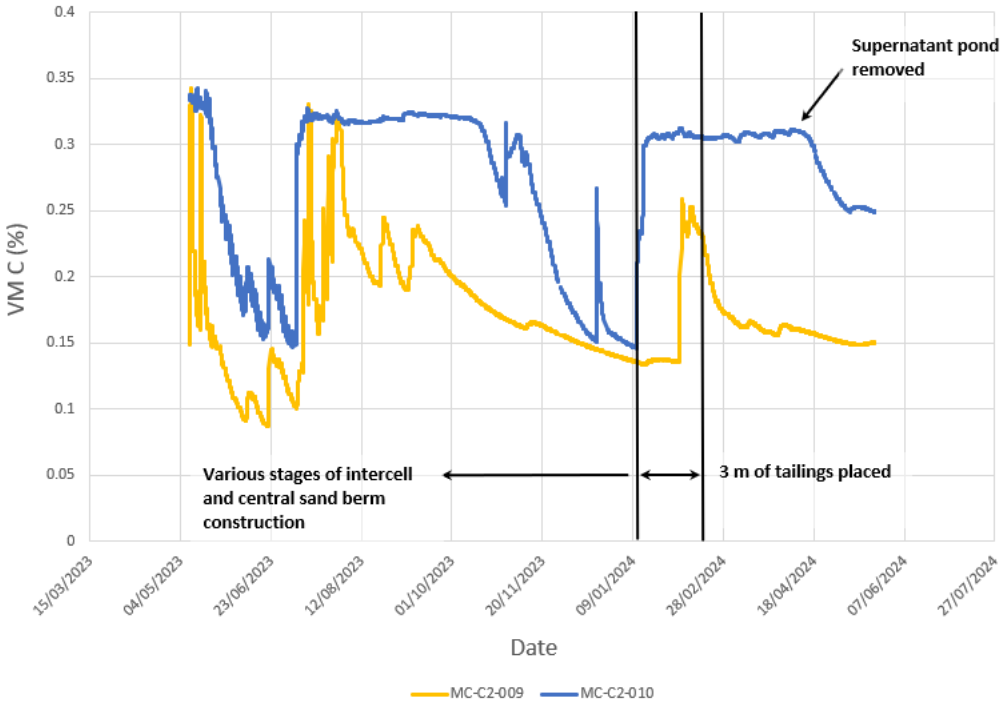

Figure 5: Moisture trends in Phase 2 tailings layers (Cell A)

Results suggest that interbedding layers of tailings with sands aids consolidation but also reduces the ability to generate ongoing gravitational desaturation (i.e., development of matric suction). This is only true where the range of suction pressures generated fall below the air entry value; hence, thicker layers of tailings between sand blankets may ultimately deliver both desaturation and accelerated consolidation. Further analyses would be required to ascertain the optimum conditions for a given tailings material and could ultimately be modeled in proprietary software.

The extent to which the sand channels are aiding the desaturation of the tailings is hard to assess based on the limited discrete instrument data points we have. However, extensive geotechnical investigations are planned to take place upon completion of the trial including 42 no. CPTs, 6 boreholes, and extensive sampling for laboratory analyses.

Moving from trials to simulations

Alongside the real time data collection and in preparation for the extensive geotechnical investigation, the demonstration facility is being modeled using Seep/W. The team have conducted an initial model for Phase 1 of the trial in Cell B. This will be extended to Phase 2 and will cover both Cell A and Cell B. Furthermore, the development of a 3D model is intended.

Soil water content characteristics

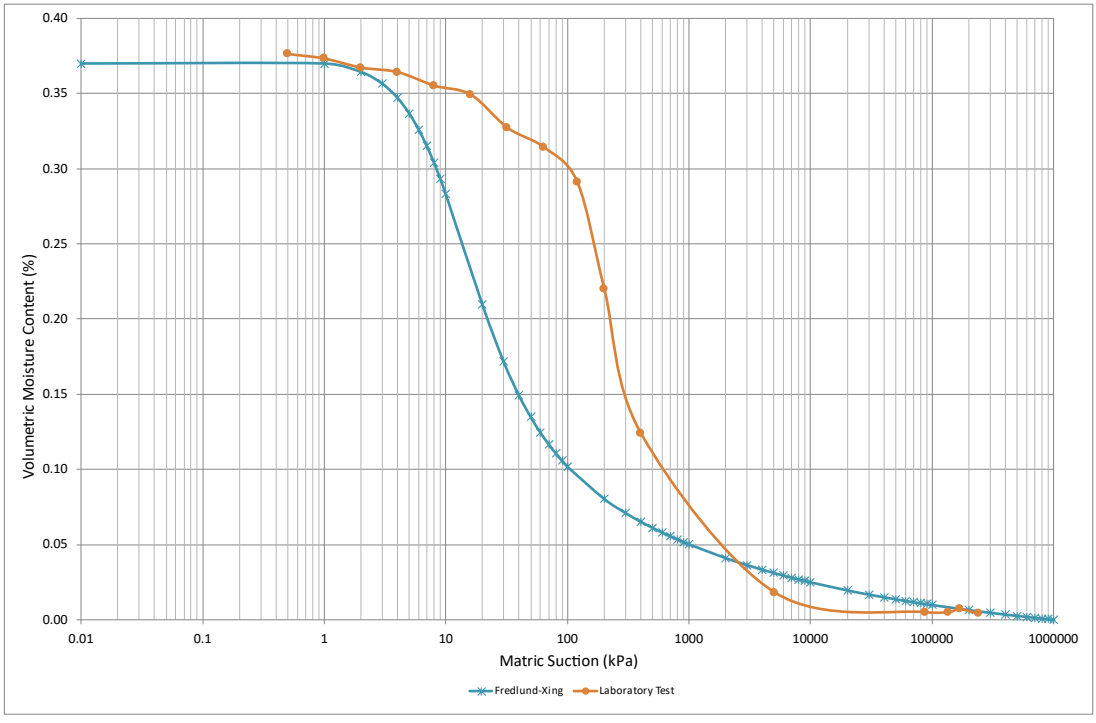

Figure 6: Comparison of matric suctions against volumetric water content for in-situ measurements (blue line) against laboratory measurements (orange line)

The soil water content parameters including the soil water content curves (SWCC) were initially established based on the results of the laboratory test results. The predicted air entry value of circa 40 kPa was not observed in the field. The approach by Fredlund and Xing (1994) was adopted, which is available as a built-in function within the modeling software used (Seep/W).

The comparison between the two resultant SWCC plots is shown in Figure 6. Fredlund and Xing (1994) provides a better correlation of the air entry value to that observed in the field. The specific reasons for the variance are being explored further as part of the ongoing work to build confidence in these modeling tools.

Boundary conditions

Boundary conditions were derived from field data using real-time on-site photos. Images from the cameras indicated the periods of expansion and contraction of the temporary ponds, and site records of tailings and sand deposition were also used. These are crucial factors in numerical modeling, as they influence the available moisture in the tailings. Additionally, the rate of rise of the gradually increasing tailings levels and the thickness of each modeled layer was found to be critical in achieving comparable results between the models and the field observations.

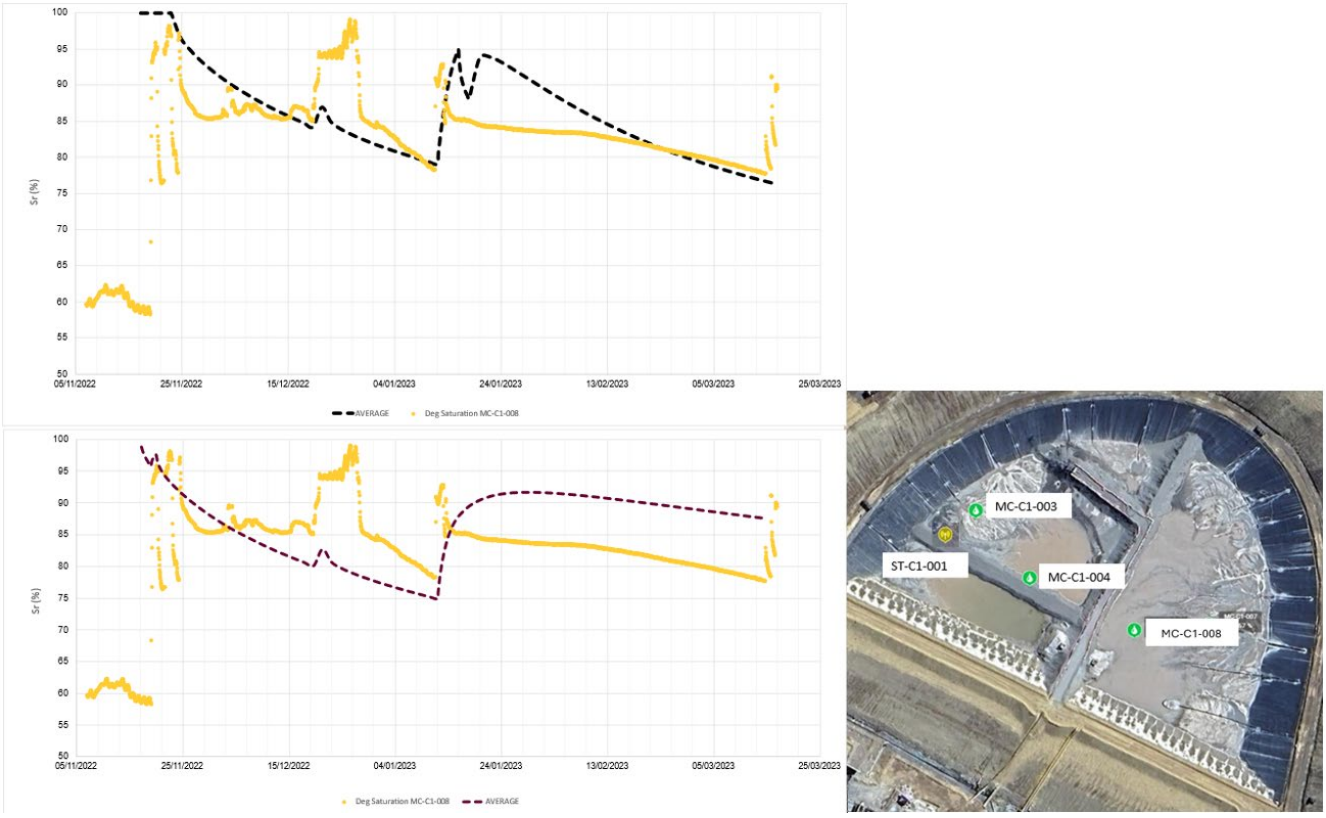

Figure 7: Variation in model calibration due to boundary conditions

The variation in the results, and particularly the steady-state conditions, between models and field results, for varying modeled layer thickness can be seen in Figure 7. For Cell B, this is considered likely associated with the desaturation due to desiccation, and as such may be less critical to the approach being taken in Cell A. This will be explored further as modeling works continue.

Calibration process

During the calibration process, various parameters were evaluated to identify the most relevant for optimizing the numerical model's performance. A few parameters were found to significantly impact the calibration, and they are detailed in the following sub-sections.

Saturated hydraulic conductivity

The saturated hydraulic conductivity of the tailings was analyzed to identify the optimal performance ranges. The study considered two relevant phases of the tailings in relation to field conditions: fully saturated tailings during deposition and partially saturated tailings during consolidation. The modifications to the saturated hydraulic conductivities are detailed in Table 1.

Table 1: Calibrated saturated hydraulic conductivity parameters

Saturated Hydraulic Conductivity	Original Values	Calibrated Values
Wet Tailings	5e-09 (m/s)	1e-08 (m/s)
Consolidated Tailings	1e-09 (m/s)	5e-08 (m/s)

Saturated hydraulic conductivity anisotropy

A review of images from the field cameras revealed that dewatered tailings desiccate and form cracks. This phenomenon enhances vertical flow in the form of finger flow. Therefore, the anisotropy of saturated conductivity was adjusted to find the optimal range, and a value of 1.1 was found to work better than 1. It is noted that this phenomenon is transient and appears to be more significant than the horizontal drainage for Cell B since the drainage paths to lateral drains are much greater than the vertical drainage paths. It is anticipated that anisotropy will have a more significant impact on the calibration process for Cell A, where anisotropy may be closer to a factor of 10.

Phase 1 Cell A seep model results

Simulation results were extracted, compared with the measured data, and are presented in Figure 8.

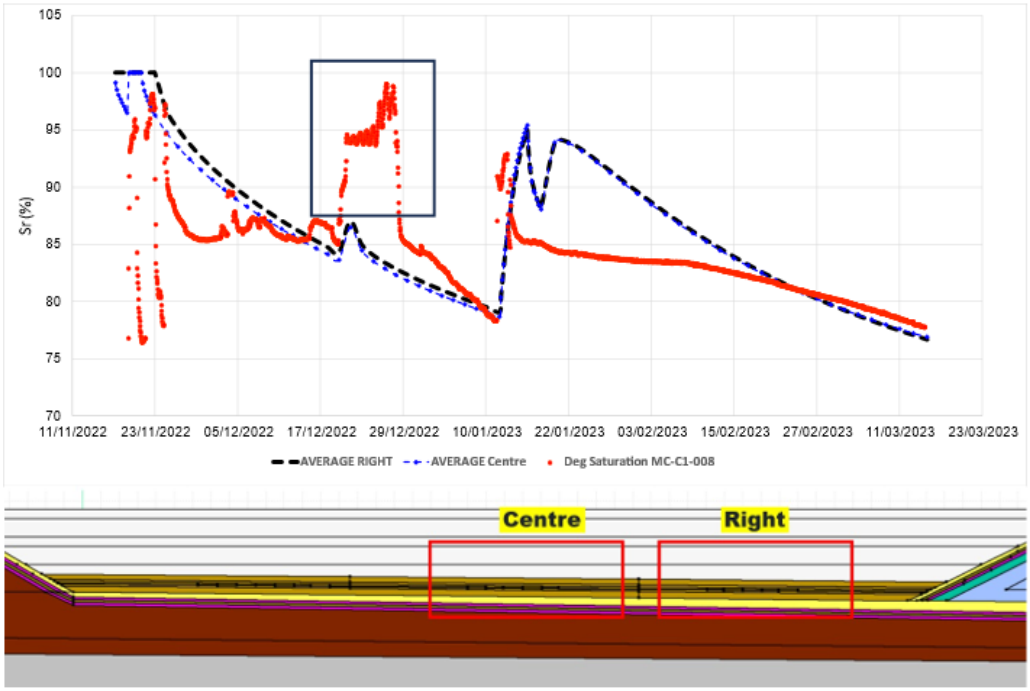

Figure 8: Phase 1 Cell B calibration results

The results indicate a good fit for the calibrated model, both in terms of trends and the steady-state condition of tailings during the consolidation period. During a specific period in December 2022, a high degree of saturation was observed, related to cyclone operation, with the overflow creating a significant pond area on Cell B. This was ignored in the modeling. During this period there is a significant deviation between the model results and field observation. This is highlighted with boxes in Figure 8. The calibrated model does not fully represent the measured data during deposition phases and wetting phases, and this discrepancy is attributed to the limitations of the numerical model in simulating finger flow due to surface desiccation and the transient nature of these characteristics. Importantly, steady-state conditions show a reasonable degree of alignment.

Conclusion

The HDS trial has exceeded expectations and much of the data has supported the hypothesis that a robust basal drainage layer, coupled with horizontal drainage channels, accelerates consolidation and delivers desaturated tailings.

As the demonstration extends vertically, the impacts of the horizontal drainage channels vs. sand blankets are becoming more apparent. The generation of matric suction is noted and the impact of discrepancies between laboratory-tested SWCC parameters and field data needs to be understood further.

The prevalence of drainage paths within a tailings facility will, intuitively, reduce the saturation levels in the co-disposed tailings. Finding the optimum engineering approach is the primary goal of the HDS demonstration team going forward, and modeling results show good correlation to date.

Tailings facilities are not currently designed for closure – the ability for HDS to offer a low-cost route to prevalent drainage offers a pathway to a hydraulically placed, yet rapidly desaturated tailings facility. Phase 2 and 3 modeling will allow prediction of in-situ tailings properties that can then be tested during the proposed extensive site investigation planned for Q4 2024. Water will be continually removed through operational stages of the facility. With the development of a robust cover and upon closure, drawdown to steady state seepage flows will be rapid and long-term water management will be significantly reduced. As operational experience continues to develop and additional laboratory and proof of concept testing generates more data, it is hoped that the HDS Working Group (a community of practice for geotechnical consultants) will facilitate data sharing and accelerate the implementation opportunities for this exciting tailings storage approach.

Acknowledgements

The authors wish to thank Anglo American Sur and the El Soldado Mine for their support. All contractors are also acknowledged for their excellent safety commitment in delivering an LTI-free project (3.5 years in April 2024).

In-pond Mixing of Fine and Coarse Tailings – Results from a Commercial-scale Pilot in Canada's Oil Sands

Evan Davison, Canadian Natural Resources Ltd, Canada

Bobby Hutchinson, Canadian Natural Resources Ltd, Canada
Peter House, Canadian Natural Resources Ltd, Canada

Abstract

Fluid fine tailings are a low-strength suspension of silts and clays formed during the extraction of bitumen in Canada's minable oil sands. These fluid fine tailings require treatment to support reclamation in a terrestrial landscape. In-pond mixing of treated fluid fine tailings with hydraulically deposited coarse sand tailings has proven to be an effective means of sequestering treated fluid fine tailings and creating a mixed or interlayered deposit with geotechnical properties conducive to terrestrial reclamation. Canadian Natural Resources Limited (Canadian Natural) is evaluating the potential use of in-line flocculation (ILF) as a means of creating a treated tailings material with approximately 45 to 50 wt.% solids content, capable of mixing with coarse sand tailings in an active tailings facility. This work supports Canadian Natural's "end-in-mind" tailings management strategy, in which closure considerations are integrated into mine and tailings planning processes.

Canadian Natural has conducted a multi-year pilot program studying the mixing of ILF-treated fluid fine tailings with hydraulically deposited coarse sand tailings. Building on ILF experience gained from atmospheric fines drying operations, the pilot program consisted of bench-scale proof of concept testing, development of a conceptual model for in-pond mixing, and execution of a commercial-scale mixing pilot over two successive summer seasons with different depositional configurations. Site investigations were conducted throughout the program to characterize the tailings deposits. This paper presents results from the pilot program. The presented results include the index properties and strength of the dewatered fluid tailings prior to sand addition, as well as the geometry, composition, strength, and consolidation properties of the resulting mixed deposit.

Introduction

Stabilization of fluid fine tailings (FT) produced during the aqueous extraction of bitumen is a key

consideration for mine reclamation and closure in the Athabasca oil sands in Alberta, Canada. Mine operators in the region aim to reclaim disturbed areas to form self-sustaining boreal forest ecosystems following mine closure, incorporating both terrestrial and aquatic elements into the closure landscape.

Challenges associated with reclamation of FT in a terrestrial landscape are well documented (COSIA, 2012 and 2014) and extensive research has been developed in this area over the past two decades. The addition of sand to FT to form a fines enriched sand or mixed deposit is a concept with the potential to improve the geotechnical performance of FT, resulting in deposits with strength conducive to capping and consolidation properties that can be accommodated in practical landform designs. Canadian Natural is evaluating the use of in-line flocculation (ILF) to form a treated FT product that can be mixed with coarse sand tailings (CST) to form a fines-enriched sand deposit. This paper presents the results from laboratory testing and field-scale piloting of various ILF FT/CST mixing techniques.

Background

Canadian Natural has observed the mixing and bedding of centrifuged FT (CFFT) and CST in the Jackpine Mine (JPM) External Tailings Facility (ETF), creating deposits that satisfy regulatory and technical performance criteria (Canadian Natural, 2022). Building on the observed CFFT/CST mixing behavior, it was hypothesized that ILF could be used to create a product similar to CFFT, which could be subsequently mixed with CST to achieve similar deposit performance.

Flocculation is a well-established means of treating and dewatering tailings slurries; however, flocculants are usually added into relatively dilute slurries. Recently a number of processes were developed for flocculation of relatively dense slurries, including Canadian Natural's Atmospheric Fines Drying (AFD) process. In the AFD process, high molecular weight anionic polyacrylamide (aPAM) is added as a bridging flocculant via jet mixing to FT at greater than 12 vol.% solids. A highly turbulent environment creates good conditions for rapid mixing of the polyacrylamide solution with FT; however, poor conditions for building large flocs are critical to the AFD process. So, exposure to high turbulence is brief (< 1 s), and the momentum of the stream is rapidly dissipated to transition to an environment more ideal for flocculation (low shear rate).

The resulting product is typically high yield stress (> 200 Pa) and/or very high permeability – capillary suction times are essentially unmeasurable as the rate of water release is too fast. The high yield stress is indicative of the formation of very large flocs (un-flocculated FT will typically have a yield stress 100× lower than AFD product). When this is achieved, FT will typically dewater from circa. 30 wt.% solids to 45 to 50 wt.% solids within a 24-hour period – comparable to CFFT, but stronger due to a high extent of residual flocculation. This similarity to centrifuge properties was the driver to attempt the ILF FT/CST

mixing process, in which the AFD flocculation process was used to form large sub-aqueous deposits of ILF FT for subsequent mixing with CST.

Pilot development

Conceptual model

Based on the observed CFFT/CST mixing behaviors, and incorporating learnings from commercial AFD operations, pilot work was developed with a focus on in-pond mixing of ILF FT and CST. In support of this objective, a laboratory-scale tailings mixing research project was carried out to characterize the mixing behavior of CST deposited into ILF FT in-pond. The work involved a desktop study, a series of jet (jar) tests, and physical model tests (flumes with length, width, and height of 240, 10, and 40 mm, respectively).

Eight jar tests were conducted to qualitatively assess the mixing behavior for different tailings types and CST addition methods. Approximately 2 L of treated FT was placed in 12×12×40 cm (length, width, and height) jars before fluidized CST was added by dropping from height. Three types of treated FT samples were tested, including ILF FT, CFFT, and shear-thinned CFFT. Each sample was tested with two CST velocities, controlled by drop heights of 0.1 and 1 m. An additional two tests were conducted on the shear-thinned CFFT using a constant drop height of 0.5 m and with the CST added in 20% (vol.) increments. It was observed that the ILF FT had the least sand penetration, followed by CFFT and shear-thinned CFFT. The higher drop height and higher CST addition frequency resulted in more penetration of CST into the treated FT.

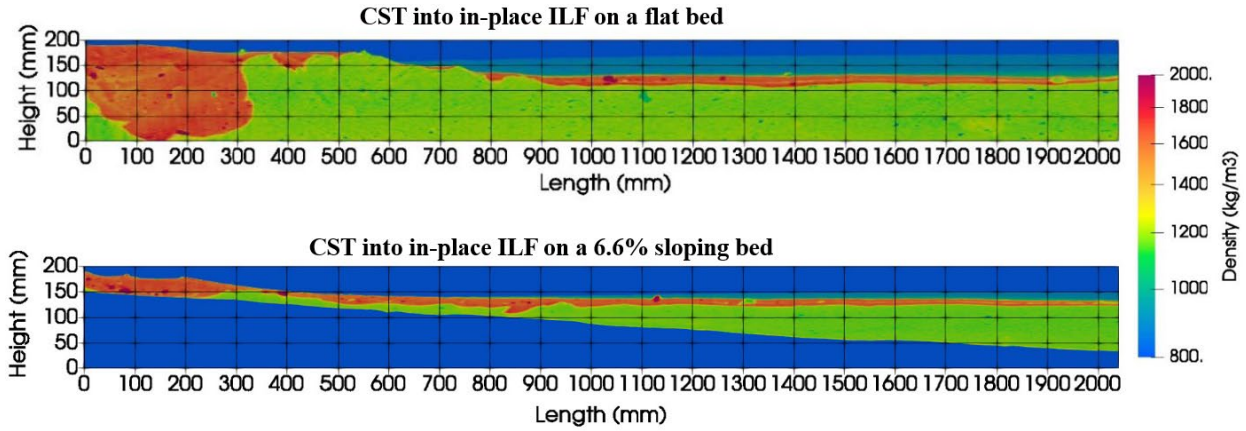

Figure 1: Density profiles of flume test deposits

The flume tests used ILF FT samples collected during the 2022 pilot. The geometry of the flume was based on a 1:100 scale of the expected field conditions and the tests were conducted with and without a 6.6% base slope. The ILF FT material was poured at the deposition end of the flumes and the top surfaces were levelled using a plastic plate. Prior to CST addition, ILF FT in the sloped-bed flume was present 20 mm thick on the first half of the slope, increasing in thickness up to 90 mm at the distal end of the flume.

ILF FT thickness in the flat-bed flume was 100 mm prior to CST addition. Fluidized CST with 55 wt.% solids content was discharged from height into the ILF FT. The resulting deposit was scanned using a computed tomography scanner. The density profiles of the deposits from the flat bed and sloped-bed flume tests are shown in Figure 1.

In both flume tests, CST formed a block near the discharge point and started to form a thin layer on top of the ILF FT. It was noted that more ILF FT was displaced by CST in the flat-bed flume. Figure 2 provides a conceptual model for the CST and ILF FT mixing behavior based on the observations and data collected during the jar and flume tests. At various points along the profile of a deposit, the ILF FT could be subject to erosion, entrapment, entrainment, and/or displacement, with behavior dependent on a number of variables. In the conceptual model, erosion occurs as CST slurry flows in parallel with the ILF FT deposit on the slope. Eroded ILF FT are incorporated into the CST slurry and degree or depth of erosion may be numerically represented by the entrainment ratio presented by Cenedese and Adduce (2010), which increases with Froude and Reynolds numbers.

Specifically, erosion increases with velocity and density of the CST slurry and decreases with density of the ILF FT. Entrapment occurs when the ILF FT or ILF FT/CST mixed material have sufficient strength to support the load of CST. Newton's second law in the vertical direction was used to describe the entrainment and displacement behaviors. Parameters governing entrainment and displacement behavior include mass rate and velocity of CST slurry and density and yield stress of ILF FT. Additional work is ongoing to investigate the relationship between ILF FT yield stress, shear rate, and consolidation pressure in order to further characterize in-pond mixing of ILF FT and CST.

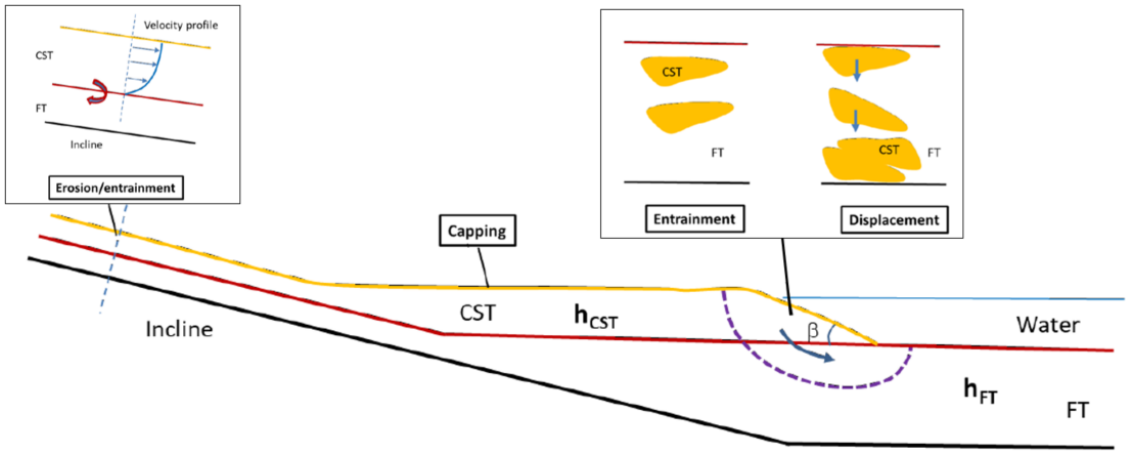

Figure 2: Illustration of CST and ILF FT mixing mechanisms

Trial location and setup

Fluid Cell 1 (FC 1) at JPM was chosen as the location for the field trial based on several factors including access to both CST and raw FT feed lines, relatively little previous deposition, and the ability to divert

production-related tailings to other cells during the trial period. This configuration ensured acquisition of the most accurate and clean data possible by minimizing variables that could impact the study outcomes.

The polymer used to treat the raw FT was received dry at site and required hydration prior to in-line injection for FT treatment. A skid-based hydration system and associated infrastructure were installed in an existing laydown roughly 500 m from the trial area in FC 1. The raw FT and hydrated polymer pipelines were piped to the deposition location on the south shoreline of FC 1 where the hydrated polymer was injected into the raw FT pipeline 3 m from the end of the pipe, forming ILF FT.

The injection header was setup to generate turbulent conditions immediately upon injection of the polymer solution to maximize contact between the polymer and the fines within the FT and then reduce turbulence shortly thereafter to minimize shearing of the flocculated FT. Turbulent conditions were generated by a reduction in piping diameter at the injection location and the subsequent dissipation of energy was accomplished by submerging the discharge of the ILF FT line in the treated tailings plunge pool. Figure 3 shows the configuration of the polymer injection header and discharge during ILF FT production.

Figure 3: Photograph showing ILF FT flocculant injection spool and submerged discharge line

Piping was installed to facilitate the deposition of CST on the north and south sides of the existing CST beach in FC 1. During the 2022 pilot, CST was deposited from both locations to confine the ILF FT in the southern half of FC 1 and promote mixing. During the 2023 pilot, the north CST deposition location was not used and CST was only deposited from the south deposition location. During both pilot seasons,

ILF FT was deposited from the south deposition location. Figure 4 shows the general layout and setup for the 2022 and 2023 pilots in JPM FC 1.

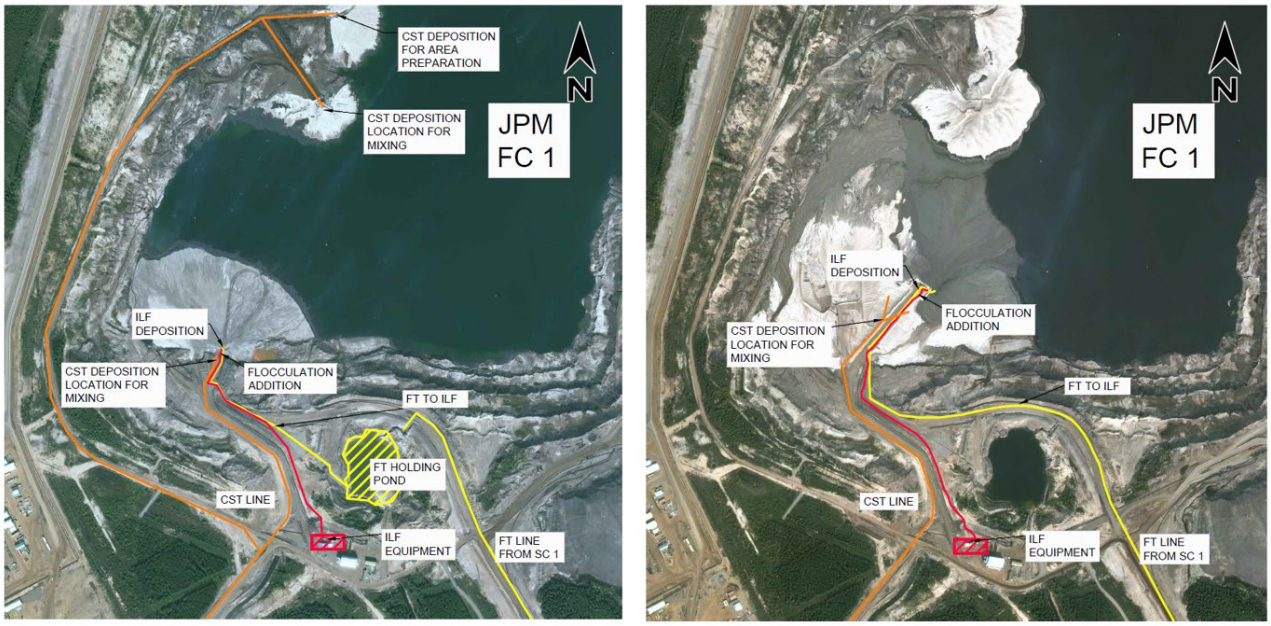

Figure 4: Infrastructure layout for 2022 (left) and 2023 (right) ILF FT/CST mixing pilots

Material properties

Raw FT was supplied to the pilot from a dredge located on the JPM external tailings facility at a design flow rate ranging between 800 to 1,000 m^3/hr. The average solids content of the raw FT was 26 wt.%, the fines content (<44 µm) was typically greater than 90 wt.%, and the residual bitumen was approximately 1.5 wt.%. Properties of the ILF FT prior to CST addition were variable due to the progressive dewatering of the material over time in the pond. The solids content of the ILF FT ranged from 40 to 50 wt.%, the dry density ranged from 1,300 to 1,450 kg/m^3, and the average yield stress was approximately 200 Pa. The CST stream deposited into the ILF FT had an average flow rate of approximately 7,500 m^3/hr and an average dry density of 1,510 kg/m^3. Mineral solids in the CST slurry are comprised of predominantly sand-sized particles.

In-pond mixing pilot program

The following sections summarize the activities undertaken during the two-year ILF FT/CST in-pond mixing pilot program. The 2022 and 2023 pilot results represent mixing performance following in-situ dewatering of ILF and deposition of CST under confined and unconfined beach below water (BBW) conditions, respectively.

Deposition activities

2022 Pilot – confined mixing conditions

The ILF FT produced during the 2022 pilot was deposited in the southwest corner of FC 1 and accumulated adjacent to the discharge on the beach above water (BAW) and on the slope of the pre-existing CST BBW. Over the course of the Phase 1 pilot, 1.4 Mm^3 of raw FT was treated, forming 0.65 Mm^3 of dewatered ILF FT in the trial area. 2.95 Mm^3 of CST was deposited into the ILF FT from the two locations shown in Figure 4, with 1.6 Mm^3 deposited into the ILF FT from the north deposition location and 1.35 Mm^3 deposited from the south location. This deposition resulted in the formation of 1.3 Mm^3 of ILF FT/CST mixed deposits during the 2022 pilot.

Sand deposition from 2022–2023

Following completion of the final 2022 pilot site investigation, and prior to the start of the 2023 pilot, approximately 0.95 Mm^3 of CST was deposited into FC 1 during normal operations of the tailings cell. This CST deposition resulted in the formation of an additional 0.6 Mm^3 of mixed ILF FT/CST deposit as residual ILF FT leftover from the Phase 1 pilot was captured. The deposit formed during this period was sandier than the deposit formed during the Phase 1 pilot due to the reduced volume of ILF FT available for mixing.

2023 Pilot – unconfined mixing conditions

The 2023 ILF FT/CST mixing pilot was set up to test mixing performance with limited downstream confinement at the toe of the BBW. ILF FT was deposited across the beach formed during the phase 1 pilot from the south deposition location. During the Phase 2 pilot, 1.4 Mm^3 of raw FT was treated, forming 0.68 Mm^3 of dewatered ILF FT in the trial area. The produced ILF FT accumulated on the BAW and BBW slopes downstream of the discharge location and was allowed to flow through a central unconfined central channel into the pond. Confinement of the ILF FT during the 2023 pilot was limited to the southeast corner of the BBW where a submerged dyke slope was present. Following the completion of ILF FT production, 1.7 Mm^3 of CST was deposited into the ILF FT from the south deposition location, in the same direction as ILF FT deposition. This deposition resulted in the formation of 0.9 Mm^3 of ILF FT/CST mixed deposit during the 2023 pilot.

Results

Site investigations were completed at various points throughout pilot program to validate performance of the ILF FT treatment system, measure properties and geometry of the ILF FT prior to sand addition, and to characterize the ILF FT/CST mixed deposits. In total, over 100 in-situ tests (cone penetration test (CPT), ball penetration test, electric vane shear test) were completed and over 1,500 tailings samples were collected

and tested to support the assessment of ILF FT/CST mixing performance over the two-year period.

Observations

The post-CST deposition site investigations highlighted regions within the trial area that demonstrated the behaviors of erosion, entrapment, entrainment, and displacement, similar to those hypothesized in the conceptual model. Figure 5 shows the observed regions within the 2022 (left) and 2023 (right) trial deposits.

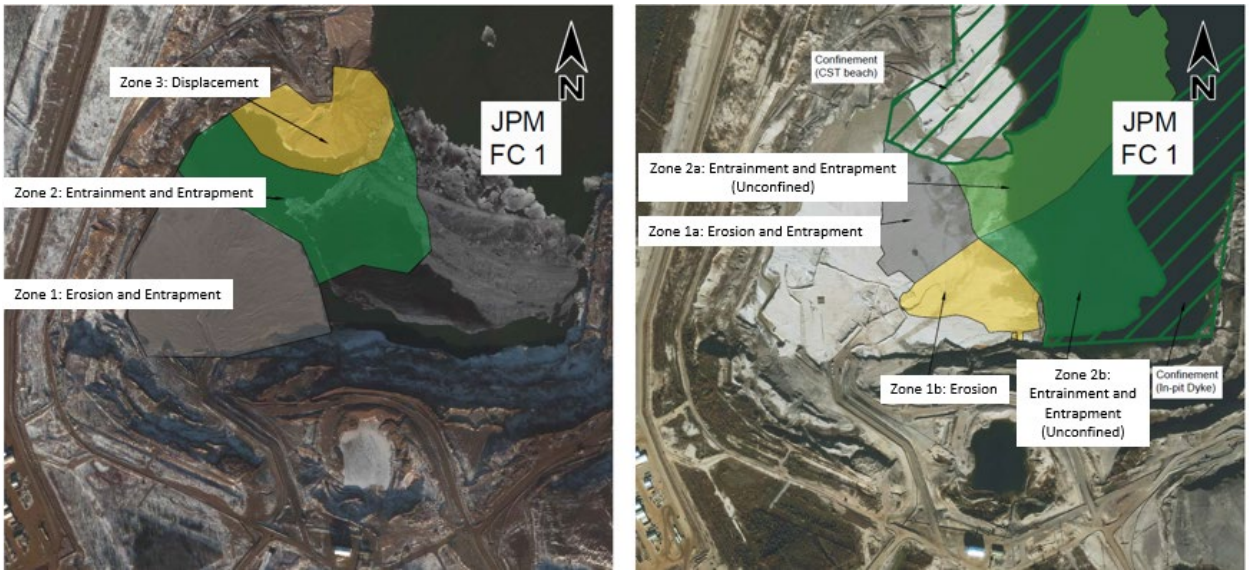

Figure 5: Behavioral regions observed following 2022 (left) and 2023 (right) ILF FT/CST mixing pilots

During the 2022 pilot, the in-pond ILF adjacent to the pit wall was generally displaced by the high-energy CST stream from the north deposition location. In the region located on the BAW immediately downstream of the south CST deposition location, a portion of the ILF FT present on the BAW was eroded by the CST and a portion of the ILF FT was capped (or entrapped) in place. In this region a CST-capped bed of ILF FT, generally 0.5 m thick, was observed at several BAW testing locations at the base of the deposit. The third region, located in-pond on the BBW slope downstream of the south CST deposition location, was characterized by entrainment and entrapment of the ILF FT into the trial beach. Fines incorporated into the beach in this region were comprised of eroded ILF FT from the BAW upstream as well as the in-pond ILF FT present on the BBW slope at the time of CST deposition. At the conclusion of the Phase 1 pilot, out of the 0.65 Mm^3 dewatered ILF FT, approximately 0.2 Mm^3 remained unmixed in the pond. This residual ILF FT was captured by CST deposition that occurred between the two pilot seasons.

During the 2023 pilot, the ILF FT present on the BAW prior to CST deposition was predominantly eroded, with only limited observations of a capped ILF FT bed on the BAW. This behavior differed from the frequent observations of capped ILF FT observed during the 2022 pilot, and was attributed to the

reduced aging time of the BAW ILF FT prior to CST addition. The observed behaviors on the BBW slopes differed depending on the degree of confinement at the toe, with more entrainment and entrapment observed in the confined region of the deposit than in the unconfined region. At the conclusion of the 2022 pilot, approximately 0.35 Mm^3 of unmixed ILF FT remained in the pond out of the 0.68 Mm^3 that was available for mixing. Based on observations following the 2022 pilot, this residual ILF FT is expected to be captured with additional CST deposition into FC 1.

Mixed deposit composition

The sampling data were used to generate a 3D block model of the ILF FT/CST mixed deposit. Figure 6 shows the modeled geometry and sand fines ratio (SFR, wt% of mineral solids larger than 44 µm over the wt% of mineral solids smaller than 44 µm) of the deposits formed during the 2022 and 2023 ILF FT/CST mixing pilots. In both pilot seasons, ILF FT/CST mixed deposits were successfully formed in the trial area. Incorporation of fines in the BAW and BBW was limited in areas where high-energy CST contacted unconfined ILF FT, evidenced by high SFR regions within the deposit. ILF FT which was eroded upstream, tended to be entrained or entrapped within the beach at lower elevations along the BBW slope as deposition energy decreased. In areas where the deposit was confined, increased entrainment and entrapment of ILF FT within the beach was observed.

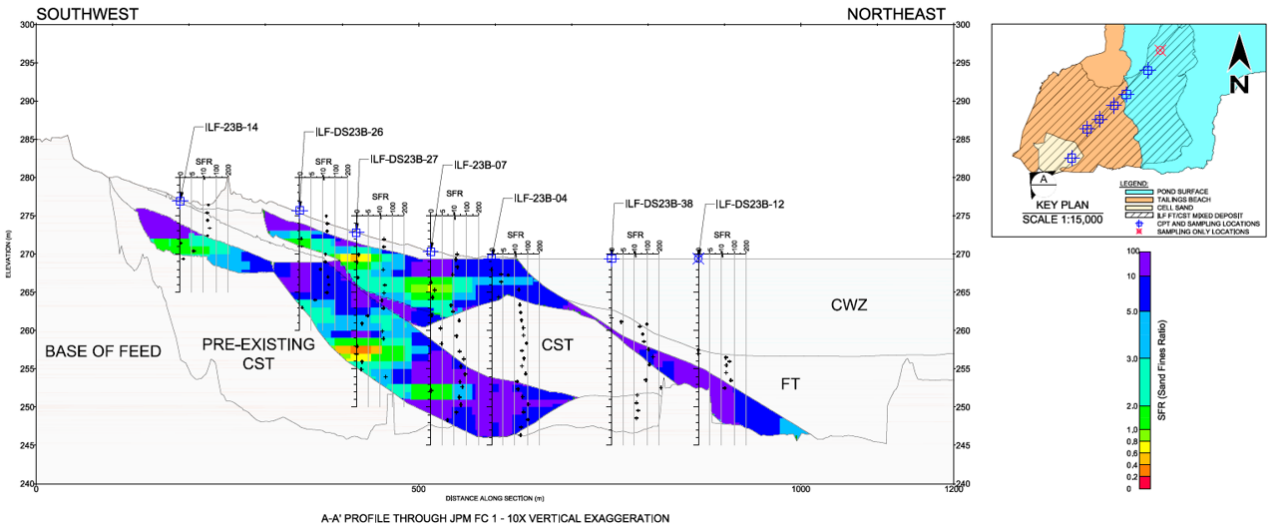

Figure 6: Geometry and composition of ILF FT/CST mixed deposits (adapted from Canadian Natural, 2024)

The block modeled properties of the deposit formed during the pilot program are presented in Table 1. The total estimated volume of the mixed deposit produced during the trial was 2.8 Mm^3, including the sandier mixed material formed via sand deposition between the 2022 and 2023 pilots, and not including

clean CST cap present on top of the mixed deposit. The modelled average solids content of the ILF FT/CST mixed deposit was 73.3 wt.%, ranging from 53 to 88 wt.%. The modeled average SFR was 3.9.

Table 1: ILF FT/CST mixed deposit properties

Deposit Zones	Estimated Deposit Volume (Mm³)	Modeled Solids Content and Range (wt.%)	Modeled SFR
2022 ILF FT/CST mixed deposit	1.3	75.2 (66–88)	3.2
2022-2023 ILF FT/CST mixed deposit	0.6	73.9 (53–78)	5.5
2023 ILF FT/CST mixed deposit	0.9	72.3 (54–87)	4.3

Laboratory testing data for ILF FT/CST mixed deposit samples used to populate the block model are shown on a ternary diagram (Figure 6). Regions illustrating the potential range of CST and ILF FT slurry and deposit properties are provided for reference. The data on the figure represent tailings samples collected following the 2023 pilot season and classified as ILF FT/CST mixed deposit. Note that the geometry of the pre-CST ILF FT deposit was considered when defining the extents of the mixed deposit in FC 1 in order to assess the efficiency of fines capture during the pilot program. As such, regions dominated by displacement are included in the data set in some cases. These sand-dominated regions are apparent in Figures 6 and 7.

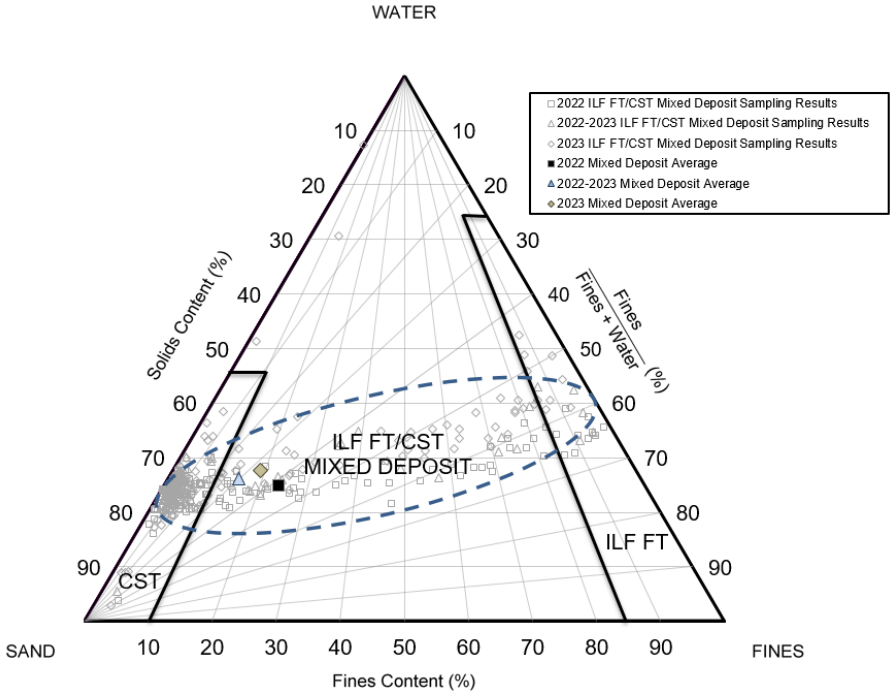

Figure 7: ILF FT/CST mixed deposit properties

Mixed deposit strength and heterogeneity

The in-situ testing programs completed at various points during the 2022 and 2023 pilots helped to inform the results and analyses presented above and provide insights into the characteristics of the ILF FT/CST mixed deposit. Given the multi-stage deposition approach and the nature of the fluvial deposition environment, the ILF FT/CST mixed deposit formed as a heterogeneous blend of entrapped high-fines beds, regions of entrained fines, and coarser low-fines zones. The development of this interlayered deposit in a commercial-scale field pilot supports the concept of enhanced fines capture through comingling of fine and coarse tailings streams hypothesized by BGC Engineering (2017).

Figure 8 shows a representative profile through the ILF FT/CST mixed deposit, including both sampling and CPT data, illustrating the complex inter-bedding of coarse and fine tailings throughout the profile. The measured undrained shear strengths consistently exceed 10 kPa. High-fines beds are typically less than 5 m thick, and are regularly overlain, or entrapped, by coarse tailings as the deposit is formed. This configuration is expected to result in more rapid consolidation of the fine tailings when compared with a homogeneous high-fines deposit because of the relatively short drainage paths and overall increase in coarse material present within the interlayered deposit. At this location, the deposit has been successfully capped with up to 4 m of CST at surface and any fine tailings present below the cap are expected to remain sequestered in place.

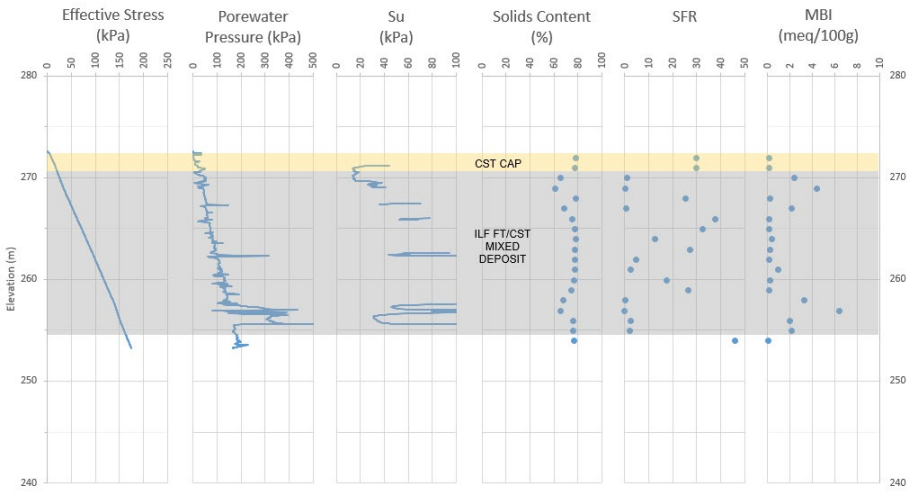

Figure 8: Example of heterogeneous ILF FT/CST mixed deposit profile

Mixed deposit consolidation properties

A series of consolidation tests were completed on samples collected following the 2022 pilot, selected to reflect a range of properties within the ILF FT/CST mixed deposit. Results from selected consolidation tests on samples with SFRs near the average of the ILF FT/CST mixed deposit are provided in Figure 9. Previously published consolidation testing data from CFFT/CST mixed deposits at similar SFRs are

included for comparison. The results show that ILF FT/CST mixed deposits and CFFT/CST mixed deposits have similar compressibility, evidenced by the convergence of the void ratio vs effective stress curves at anticipated in-situ effective stresses > 100 kPa. This suggests that ILF FT/CST and CFFT/CST mixed deposits are expected to undergo a similar magnitude of ultimate settlement if a similar initial void ratio (or solids content) is developed within the deposit. At comparable void ratios and SFRs, the hydraulic conductivity of ILF FT/CST material was found to be typically 0.5 orders of magnitude greater than that of CFFT/CST, indicating that consolidation of ILF FT/CST mixed deposits is expected to progress faster than consolidation of CFFT/CST deposits.

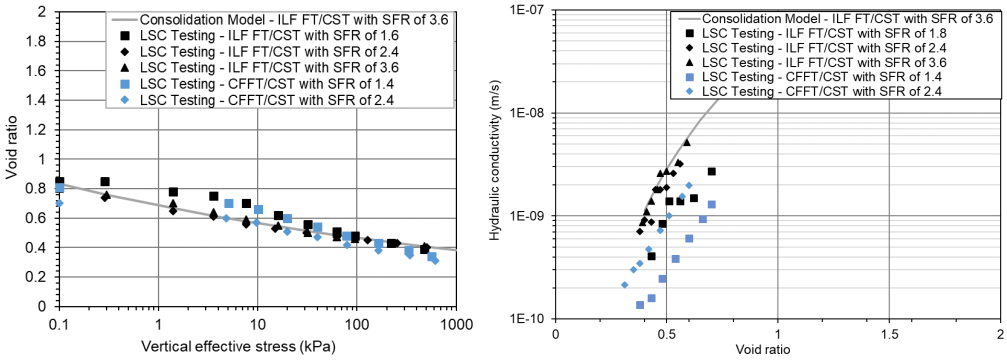

Figure 9: Large strain consolidation test results for ILF FT/CST and CFFT/CST mixed deposits

Conclusion

Results from the ILF FT/CST mixed deposit testing demonstrated the behaviors of erosion, entrainment, entrapment, and displacement identified in the conceptual model. The complex depositional environment resulted in a heterogeneous deposit with erosion and displacement tending to be more prevalent on the BAW and upper BBW slopes, entrainment and entrapment tending to be more prevalent on the lower BBW slopes, and displacement occurring in areas where high-energy CST was deposited into unconfined ILF FT. Based on the results from the pilot, the dominant drivers influencing fines-coarse mixing are hypothesized to be the density and strength of the ILF FT prior to CST addition, which increase with dewatering of the ILF FT in-situ, and the energy of the incoming CST, which decreases with distance from the discharge location.

Confinement at the toe of the ILF FT deposit also served to increase the entrainment/entrapment of fines into the trial beach. The ILF FT/CST mixed deposits were found to have strengths sufficient to support the development of a hydraulically placed sand cap both within the deposits, entrapping bedded high-fines layers, and at the surface. Consolidation testing results suggest that the magnitude of ILF FT/CST mixed deposit settlement will be similar to published values for CFFT/CST mixed deposits and that the rate of consolidation will be faster.

Overall, the pilot program demonstrated that in-pond mixing of ILF FT with CST is a viable means of producing a mixed sandy-fine deposit under the conditions tested. Potential next steps for the research program include:

- continued laboratory study to develop quantitative metrics that govern mixing behavior;
- development of 1D consolidation models based on the consolidation testing data and validation against field-measured settlement; and
- continued piloting to optimize and balance the metrics governing mixing behavior with operational constraints in an active tailings cell.

Abstract

Tailings dams are among the biggest structures ever constructed. Managing and operating these structures is an arduous task that demands a deep understanding of tailings and mining processes. The lifecycle of tailings dams includes conception, construction, operation, and closure. Especially in Brazil, new legislation has demanded the closure of upstream raised tailings dams and prohibited the construction of dams by this method after recent incidents. Closing a tailings dam requires decommissioning the structure (it no longer receives material nor operates as a dam) and then rehabilitation of the dam area. However, closure operations pose several challenges – e.g., tailings variability, lack of records for the structure, changes occurring in the material over the deposition period, and insufficient safety for closure work. The tailings' variability can come from their natural variability, effects of uneven sedimentation and deposition, and changes in the beneficiation processes during the years (e.g., increasing mineral recovery with new technology).

This paper aims to evaluate the tailings variability in a dam that will be decommissioned soon. Hence, piezocone penetration tests were evaluated, and samples were collected at different points of the dam. The results were evaluated, and the response of different tailings was verified through in-situ testing and laboratory testing. The results demonstrated a stratified profile of tailings with variable particle size distribution. Regarding the laboratory tests, the finer tailings generally were more compressive than coarser tailings. Nonetheless, the strength mobilization for distinct tailings was similar, probably due to the common nature of the tailings in the dam.

Introduction

Sustainable mining principles require planning and designing all facilities in ore exploitation to deal with the distinct phases of this industrial operation. Regarding tailings storage facilities, it is necessary to evaluate several aspects during their lifecycle, such as the conception, construction, operation, and closure (Spitz and Trudinger, 2019). Among the viable options for tailings disposal, dams are the most common and cost-effective, although they are also the most challenging structures to operate (Santamarina et al., 2019; Yin et al., 2011). In upstream-raised dams, the dam storage capacity is expanded by raising the starting dyke over the previously stored material. Hence, the new dykes are supported by tailings themselves, usually in a loose and saturated state.

In Brazil, recent disasters motivated changes in legislation, requiring the closure of existing upstream raised tailings dams and prohibiting their construction. At the time, around sixty upstream raised tailings dams existed in Brazil, of which 3 were classified as stage 3 risk obligating immediate closure (ANM, 2023). However, tailings dam closure operations are challenging environmentally, economically, and in terms of safety, besides being very site-specific and despite there being few reports of successful cases. One aspect that makes closure operations intricate is the tailings' spatial variability inside the structure. Variability can come from uneven sedimentation and deposition effects, evolution in beneficiation processes over the years aiming for greater ore recovery, and the natural variability of the ore's deposit.

Tailings' characteristics can vary significantly inside a dam depending on their position. For example, tailings nearer to the deposition point usually are coarser, while those further from the deposition point are usually finer since finer particles take more time to sediment and thus are carried further (Consoli and Sills, 2000). Furthermore, tailings are generally mixed mineralogy geomaterials, and can be composed of minerals with very different specific gravities, resulting in complex sedimentation patterns. Li and Coop (2019) investigated the behavior of tailings from different locations of an impoundment and reported differences arising since particle size distribution (PSD) to constitutive parameters. The effects of grading and mineralogy on the behavior of tailings have been thoroughly investigated and demonstrated to highly influence their mechanical response (e.g., Consoli et al., 2024; Wagner et al., 2023).

The effects of fabric on tailings have also drawn the attention of researchers (Carrera et al., 2011; Carvalho et al., 2024; Chang et al., 2011). However, sampling undisturbed tailings at dam sites is still unresolved (Shuttle and Jefferies, 2016). Obtaining representative samples of tailings from impoundments is rather challenging due to their cohesionless nature and the usually loose state in which they are found. Although developments are currently being pursued in this sense (e.g., Dominguez-Quintans et al., 2023; Reid and Fanni, 2022), the use of in-situ tests remains the viable option to characterize tailings in dams and investigate their variability. The cone penetration test (CPTu) has long been used to determine the

geotechnical profile of tailings impoundments, as well as to estimate tailings properties and their state at the dam (Ayala et al., 2022; Shuttle and Jefferies, 2016; Shuttle and Cunning, 2007).

Therefore, this paper aims to investigate tailings variability inside a dam to be closed through in-situ and laboratory tests. The profile of tailings at two distinct points was determined by CPTu and representative tailings samples were selected for laboratory testing. Triaxial tests on reconstituted samples were conducted to investigate the differences arising from the distinct PSD and mineralogy of tailings on constitutive parameters necessary for properly designing closure operations.

Methodology

In-situ testing

The field investigation comprised piezocone tests executed according to ASTM 5778 (ASTM, 2020). The tests were performed with 10 cm² piezocones, a penetration velocity of 2 cm/s, and data acquisition with a resolution of 2 cm. The tests were performed at two locations in the same structure: one point is closer to the original tailings' deposition point, and the other is further away. Also, the typical profiles obtained from CPTu were used to identify the tailings characteristics along the depth.

Laboratory characterization

Based on the field tests, three samples of different materials were collected for laboratory characterization. The tailings were subjected to physical and mineralogical characterization tests. Also, consolidated drained triaxial (CID) tests were performed on a fully automated triaxial apparatus, in three main stages: saturation, consolidation, and shearing. The saturation stage consisted of CO_2 percolation, de-aired water flushing, and incrementing the backpressure until a B-value greater than 0.95 was obtained. After saturation, specimens were consolidated under hydrostatic conditions and then were sheared in a strain-controlled condition at 1 mm/hr. The specimens for triaxial tests were molded using the moist tamping method, and the confining pressures used were 100, 200, and 400 kPa. The experimental program focused on determining the extent of the variability of tailings properties, rather than simulating their in-situ fabric. Therefore, moist tamping was selected as the standard procedure because it enables obtaining mostly uniform specimens over a broad range of void ratios. Dense specimens were targeted (around 80% of relative density) to enable the evaluation of strength and dilatancy parameters usually adopted in conventional constitutive models.

Results

In-situ testing

Two piezocone tests were conducted at different locations inside the dam. CPTu-01 was conducted further from the deposition point, while CPTu-02 was nearer. Figure 1 presents the results of these tests. Both

CPTu profiles are stratified and present large portions with small tip resistance. Moreover, marked pore pressure generation occurred during piezocone penetration, indicating possible effects of partial drainage or completely undrained behavior. The main difference in the CPTu profiles is that CPTu-02 had a thick sandy layer below 6 m depth, clearly shown by the increase in tip strength q_t and the drop in pore pressure generation, remaining close to the equilibrium pore pressure.

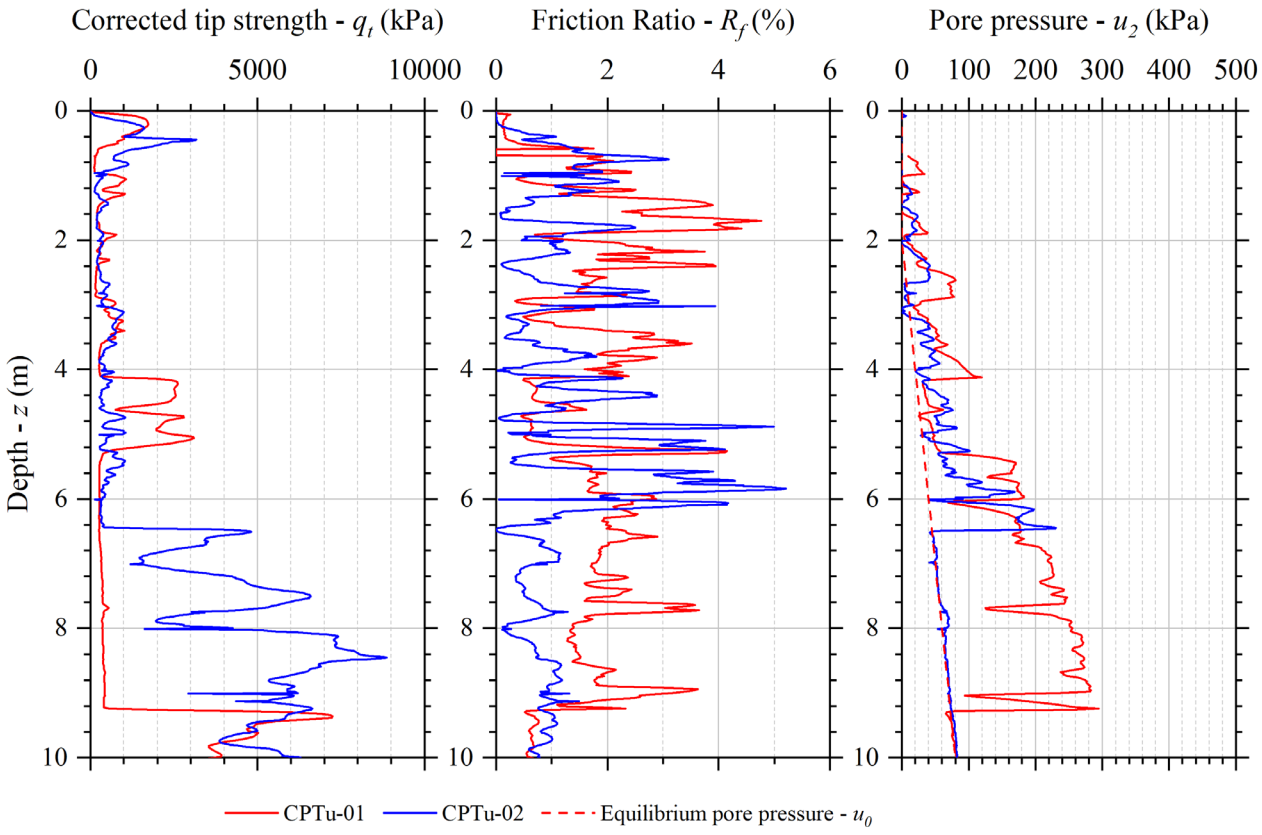

Figure 1: Results of piezocone testing

The results were also analyzed using the normalized tip strength and friction ratio framework. Figure 2 plots the CPTu data in a space where three large groups of tailings could be identified: one was finer tailings, another was a silty one referred to as intermediate tailings, and the third demonstrated sandy-like behavior. Although somewhat diverse, these groups were identified based on expected behavior from CPTu results. The data was classified over the depth and organized into clusters where the most data on this depth range lie on the graph. This procedure enabled the identification of similar tailings and the determination of the stratigraphy of tailings in the dam.

Figure 3 presents the CPTu profiles plotted according to the corresponding Soil Classification Index (I_c) (Jefferies and Davies, 1993). Figures 2 and 3 show that, although three large subgroups could be identified, the profiles are highly stratified with alternate layers of tailings, especially CPTu-01. Thus, the

stratigraphy of tailings was interpreted as composed of tailings from these three groups, as shown in Figure 3. The main difference between the two piezocone tests lies in the presence of a thick layer of finer tailings in CPTu-01 at greater depths and a layer of fine tailings at shallower depths. Figure 2 also indicates the state of the tailings in the field. The intermediate and fine tailings are predominantly contractive, while the coarse tailings are more dilative. This condition is related to the tailings' grain size distribution and depth. The dilative tailings were present mostly at shallower depths, which may be related to the seasonal variation of the water level. In addition, as the water level was found to be around 2 m, the tailings are considered fully saturated below this.

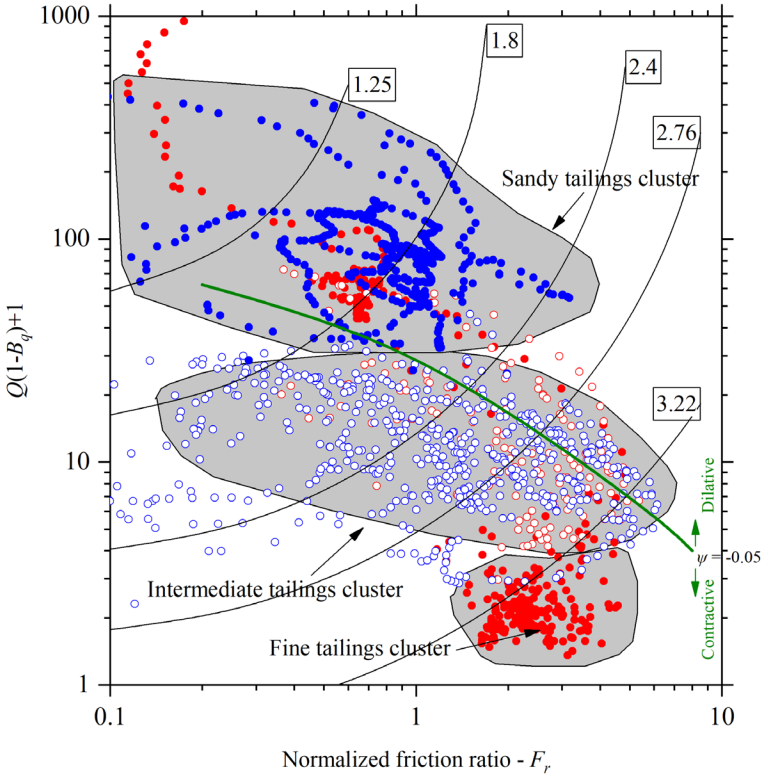

Figure 2: Normalized results of piezocone testing

Geotechnical characterization

Three characteristic groups of tailings were identified from the in-situ testing campaign. Then, representative samples of these groups were identified and collected for laboratory testing. It is important to note that the piezocone tests considered in this research are a portion of a much larger set of tests, conducted for characterizing the whole dam for closure planning, which enabled the identification of locations for collecting the representative samples of fine, intermediate, and sandy tailings. Figures 4 to 6 present the characteristics of tailings considered in the laboratory testing.

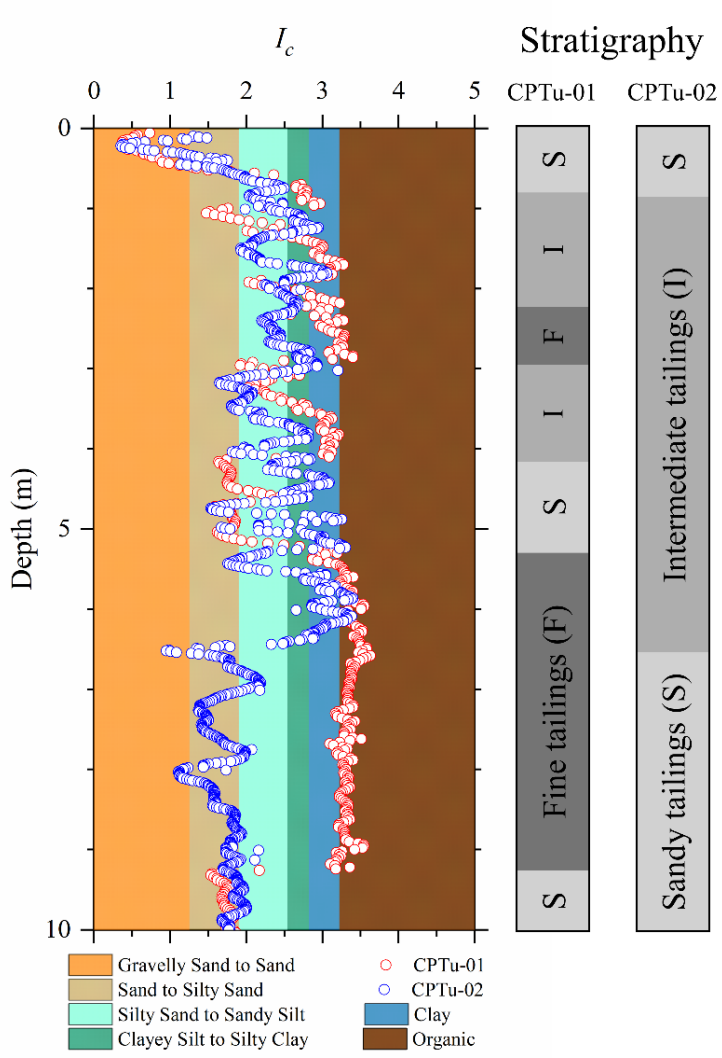

Figure 3: Tailings profile interpreted from CPTu

The PSD shown in Figure 4 and the calculated indices in Figure 5 demonstrate that the three collected tailings have distinct grading characteristics. The higher the fines content, the more well-graded are the tailings (higher values of C_u). Beyond the differences in fines content, the distribution and arrangements change throughout the tailings structure.

Hence, the tailings collected present distinct PSDs and mineralogy. The finer tailings present higher iron oxides content (Figure 6a) compared to sandy and intermediate tailings. Regarding the quartz content (Figure 6b), intermediate and sandy tailings have similar amounts. However, intermediate tailings appear to have another mineral in their composition, while sandy tailings are mainly composed of iron oxides and quartz. Regarding the specific gravity of tailings, they do not differ significantly (3.58-3.71) because all tailings present considerable amounts of iron oxides, which usually are heavier than other minerals in their composition (Souza et al., 2021).

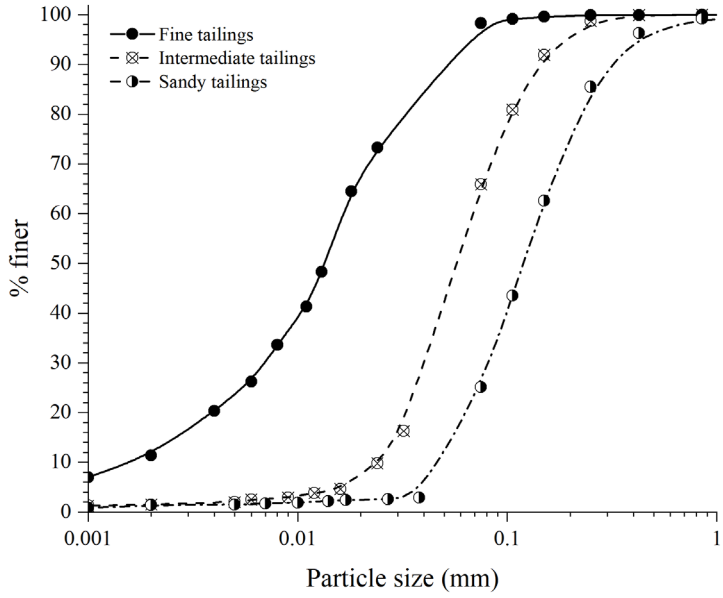

Figure 4: Particle size distribution of representative tailings samples

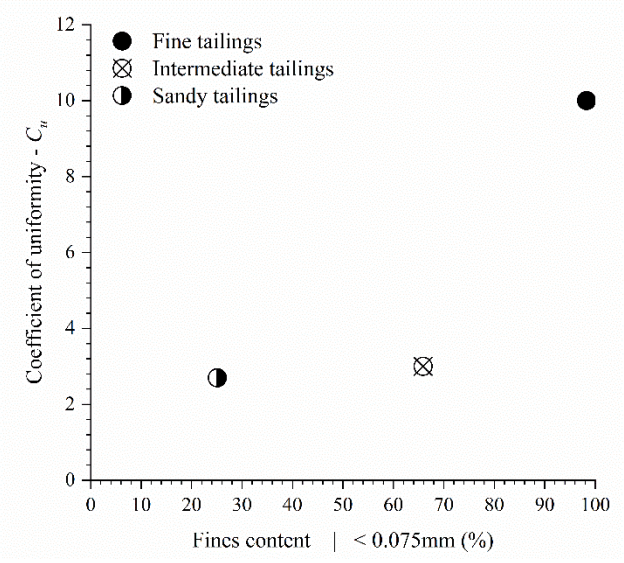

Figure 5: Distribution characteristics of tailings according to their fines content

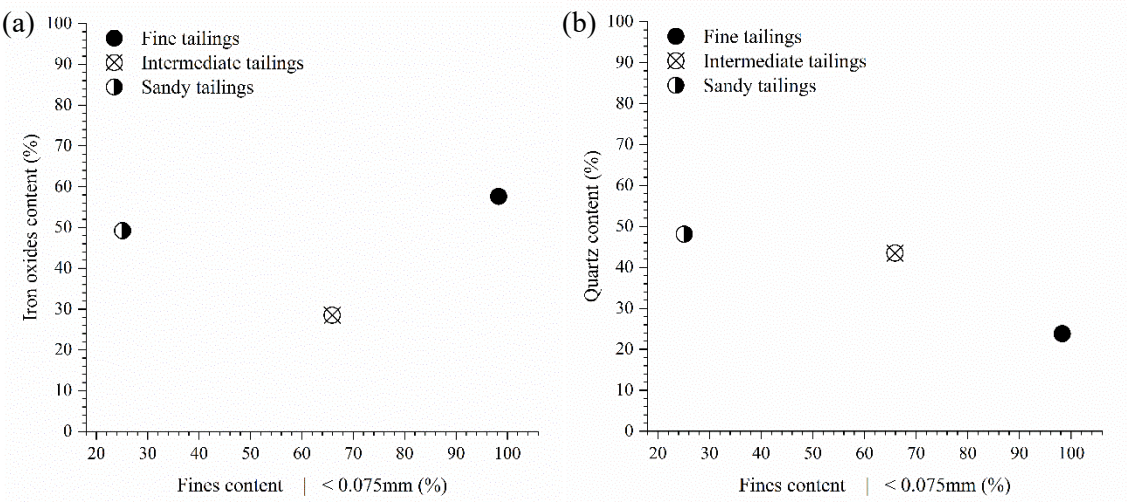

Figure 6: (a) Iron oxides content and (B) quartz content of tailings according to the fines content

Triaxial testing

Figure 7 depicts the stress-strain results of conventional triaxial tests conducted on tailings. Overall, sandy and intermediate tailings presented similar responses with brittle behavior indicated by marked peak strength followed by a loss of strength. The volumetric response was also similar, with slight compression followed by a dilative trend. On the other hand, fine tailings presented a ductile behavior up to large strains without loss of strength. The volumetric response of fine tailings was much more compressive than the other two, with a slight tendency to dilation at larger strains.

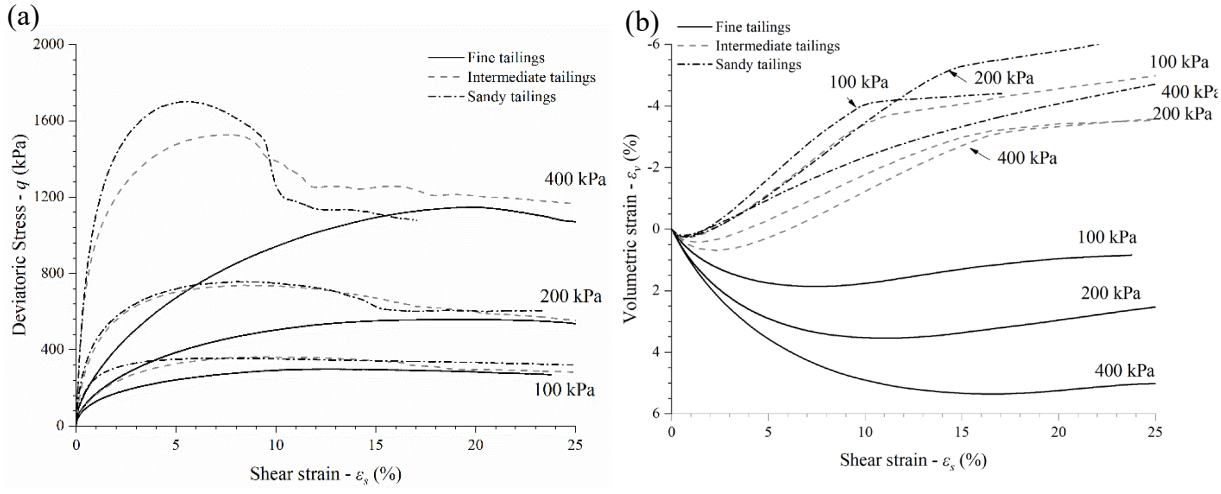

Figure 7: (a) Stress-strain results and (b) volumetric response of conventional triaxial testing

Since all specimens presented dilative behavior associated with dense states, it is difficult to estimate the critical state strength of the materials. This is because dense specimens generally suffer from localization effects, which can be detected in Figure 7 by the plateaus in the volumetric response of

intermediate and sandy tailings, as well as in the loss of strength after peak. However, dense specimens were selected to determine important parameters of tailings behavior, regardless of their actual condition in the field. Then, the triaxial results were analyzed under a stress-dilatancy framework (Figures 8 to 9), aiming to estimate critical state strength with higher confidence and to investigate other constitutive parameters relevant to the design of tailings structures.

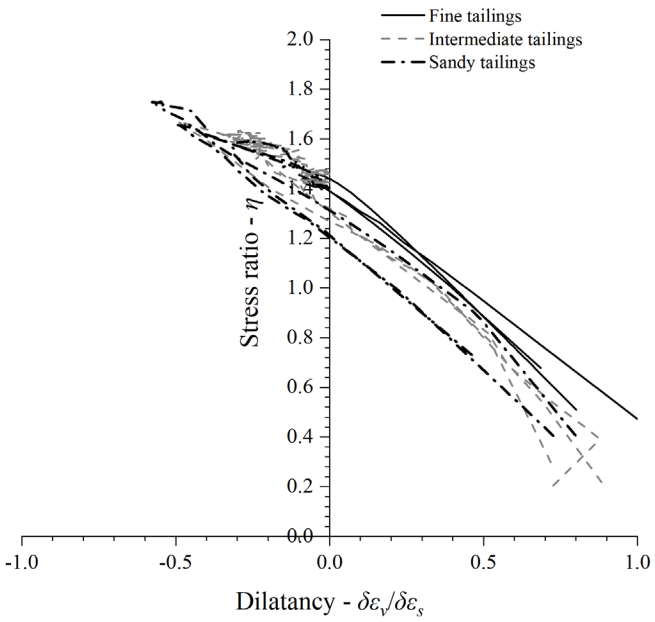

Figure 8: Stress-dilatancy of tailings

The results in Figure 8 demonstrate a trend of all tailings achieving a unique final stress ratio ($\eta = q/p'$) of approximately 1.4 ($\varphi = 34.6°$). Furthermore, the more dilative response of intermediate and sandy tailings can be clearly observed. Thus, although clear differences in volumetric response during shearing are observed, the differences in PSD and mineralogy of tailings do not influence their strength mobilization much. However, dilatancy depends on both the stress level and the density at which the samples were sheared (Been and Jefferies, 1985; Muir Wood and Belkheir, 1994; Silva et al., 2024; Wagner et al., 2023). The relationship between dilatancy and peak strength comes from the energy dissipation principles and defines a fundamental relationship from which other constitutive relations can be derived.

Figure 9 shows that a unique relationship between peak strength and minimum dilatancy could be obtained for all tailings, although they have distinct geological and geotechnical characteristics. This is an important finding since it can simplify the analysis by allowing us to adopt a single set of parameters regarding the stress-dilatancy behavior, for the distinct tailings present in the same structure.

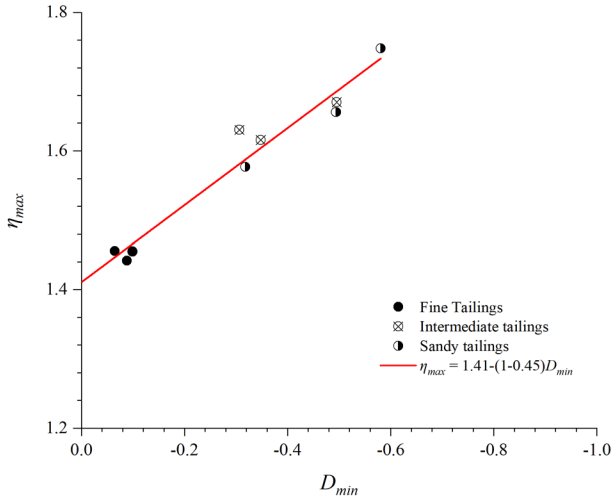

Figure 9: Peak states analysis of tailings

Conclusion

This paper investigated the variability of tailings in a dam to be closed using a set of in-situ and laboratory tests. Dam closure, especially that of upstream raised dams, is an operation that usually involves high-risk operations demanding appropriate design and planning, which can only be achieved through a deep understanding of tailings' behavior. One aspect to be considered in planning and designing for safe closure is the tailings' variability inside the impoundment and how engineers and practitioners can deal with it. The results obtained here demonstrated the existence of highly stratified tailings profiles inside a dam, composed of tailings with distinct geotechnical characteristics. However, although the volumetric response of the tailings differed greatly, the strength mobilization was similar, probably due to the common nature of the tailings in the dam. This characteristic can simplify design aspects by allowing the use of a single set of strength parameters for the tailings, reducing the effects of spatial variability.

Solar-powered Electrokinetic Tailings Dewatering

Ed Hanna, ElectroKinetic Solutions Inc., Canada
John Vandersleen, ElectroKinetic Solutions Inc., Canada

Abstract

The global inventory of tailings is currently >50 billion m^3 and continues to grow. Costs associated with these tailings include construction and maintenance of tailings storage facilities (TSFs), liability of catastrophic releases of tailings, and erosion of social license. Much effort has been spent innovating new, and improving existing, tailings management practices. The use of electrokinetics (EK) has been extensively researched for tailings dewatering. However, multiple efforts to commercialize EK technologies have failed. One of the major obstacles is high energy consumption. The EKS Dewatering Tailings (DT) Technology dewaters tailings in situ. The development of the DT Technology has spanned 14 years, overcoming past obstacles to EK commercialization, including the high energy consumption. A 19-month commercial demonstration was successfully completed in 2021, proving the performance of the technology. The energy consumption of the commercial demonstration was 15 kWh/m^3 of water released.

EKS is continuing to improve the DT Technology. A recent innovation is the exclusive use of solar energy to power commercial installations. Floating solar panels rest on the surface with the electrodes suspended below. DC power is sent directly from the solar panels to the underlying electrodes. Solar power has proven feasible even in areas with high levels of cloud cover and low incident solar radiation. Using solar power offers significant economic and environmental benefits. The use of solar power can reduce the energy consumption of the DT Technology by >50%. Solar power effectively eliminates operating costs. The technology involves no moving parts, no additives, and no onsite operator. At the end of dewatering operations, the solar panels can continue to produce energy for mining operations. This paper will describe the results of the commercial demonstration and the supporting data and analysis, demonstrating the feasibility and benefits of solar-powered electrokinetic dewatering.

Introduction

The mining industry is facing significant pressure from investors, governments, and the public to address the environmental liability associated with the large inventories of unstable tailings and the continuing increase in this inventory. The costs incurred by the mining industry for tailings management, including

tailings storage facility (TSF) construction, material transport, and tailings dewatering, are significant (Baker et al., 2020). In addition, the water trapped in the tailings is unable to be used for ore processing, requiring more freshwater to be imported into the mining process. This water demand can be difficult to source and costly in arid regions (Ghorbani and Kuan, 2017; Nasirov and Agostini, 2018). Another major safety and environmental liability is the risk of dam failure and resulting catastrophic release of fluid tailings. This liability can be reduced by strengthening the tailings dams, but is only removed when the tailings are dewatered and made geotechnically stable (Owen et al., 2020; Roche et al., 2017).

The EKS Tailings Dewatering Technology, developed by ElectroKinetic Solutions Inc. (EKS), can rapidly dewater the tailings in a TSF, addressing the liability posed by the tailings. The DT Technology consists of many parallel pairs of electrodes deployed inside a TSF. For TSFs with a water cap or fluid tailings surface layer, the electrodes are horizontal. Each installation consists of one or more independent modules, each occupying an area of ~50 × 25 m. The maximum size of a horizontal electrode EKS installation is limited by the number of modules that can be deployed in the fluid tailings portion of a TSF. Where the tailings' surface is covered by a solid "crust," vertical electrodes can be used.

Figure 1 is an end view schematic of horizontal EKS electrodes below the tailings' surface in a TSF. Direct current (DC) is passed between the electrodes. The electrochemical reaction at the cathodes is hydrogen evolution. At the anodes, the two primary electrochemical reactions are oxygen evolution and/or anode corrosion.

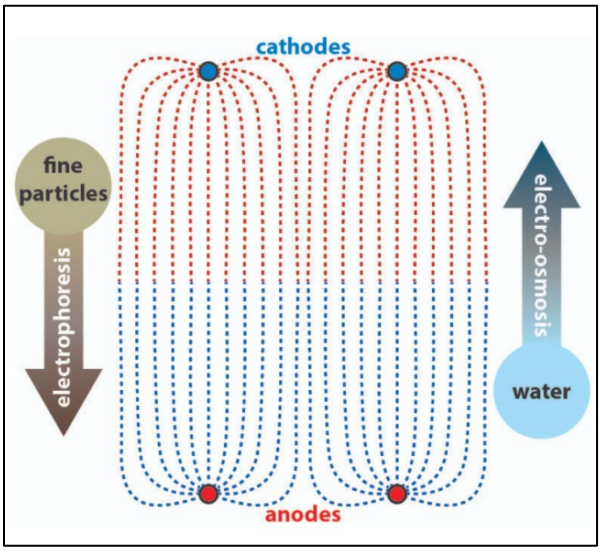

Figure 1: End view schematic of two DT electrode pairs, below the tailings' surface in a TSF

As current passes through the tailings, an electric field is created, resulting in rapid tailings dewatering via electroosmosis and electrophoresis. These electrokinetic (EK) processes have been studied extensively for decades (Casagrande, 1949; Dixit et al., 1975; Islam, 2014; Lockhart, 1983; Shang, 1997). EKS

previously presented a desktop case study quantifying the cost savings that can be achieved with the EKS Technology compared to current tailings management practices. The forecast net present value was $274 million, corresponding to an annual rate of return >90% on the EKS capital costs. The cost of water recovered by the EKS installation was forecast to be $1.11 per m^3 (Vandersleen and Hanna, 2023). In comparison, costs of $1.62 per m^3 of recovered water have been reported for tailings dry stacking (Zamorano et al., 2020).

The DT Technology has been progressively and reliably scaled up through laboratory and field research. EKS has recently proven the technology through a commercial demonstration in Alberta, Canada. This demonstration successfully operated continuously, year-round, from November 2019 to May 2021. The first purpose of this paper is to describe the dewatering performance achieved during the demonstration.

The commercial demonstration of the technology was powered by grid electricity. A recent innovation is the use of solar panels, floating on the surface of a TSF to power the technology. Laboratory experiments have been completed to quantify the impact of the use of solar power on the technology's dewatering performance. The second purpose of this paper is to describe these results.

Methodology

Commercial demonstration

A commercial demonstration of the DT Technology was carried out to prove that the technology scales as expected and that EKS can accurately forecast the performance of the technology. To determine whether these objectives were achieved, several key performance indicators (KPIs) were set for the commercial demonstration of the DT Technology. The target KPIs and the results are shown in Table 1. The results for these KPIs are described in more detail elsewhere (Vandersleen and Hanna, 2023).

Table 1: Key Performance Indicators for the DT commercial demonstration

Metric	Target	Result	Achieved?
Water released	1,000 m^3	1,100 m^3	✓
Released water quality	Suitable for reuse	Achieved goal!	✓
Increased tailings storage capacity	+58%	+63%	✓
Maximum solids content between electrodes	>60% (kg/kg)	>60% (kg/kg)	✓
Energy consumption	<30 kWh/m^3 water released	15 kWh/ m^3 water released	✓
Year-round operation	Successful winter operation	Achieved goal!	✓

The commercial demonstration occurred at InnoTech Alberta's research facility at Vegreville, Alberta, Canada. An inactive sewage lagoon was excavated to create a test cell. The dimensions of the top

of the test cell were 20 m × 25 m and its depth was 6 m; the walls of the test cell had a 1:1 slope. An impermeable liner was installed and over 1,700 m^3 of oil sands tailings were pumped into the test cell.

The average solids content of the tailings was 18% by weight. The tailings solids were primarily fine particles; the particle size distribution is shown in Figure 2. The average particle size is about 6 microns and over 25% is <2 microns. These fine-grained tailings are very difficult to dewater with current tailings management practices (McKenna and van Zyl, 2020).

The electrode array consisted of 16 electrode pairs, each 10 m long. A custom retrofitted sea container was designed to house the power supply and the central control system. Communication with the control system was via the internet. The primary purpose of the commercial test was to understand how the technology functions at scale and under field conditions. To support this objective, in situ sensors were installed in the test cell (e.g., sensors to measure the electric field pattern in the tailings).

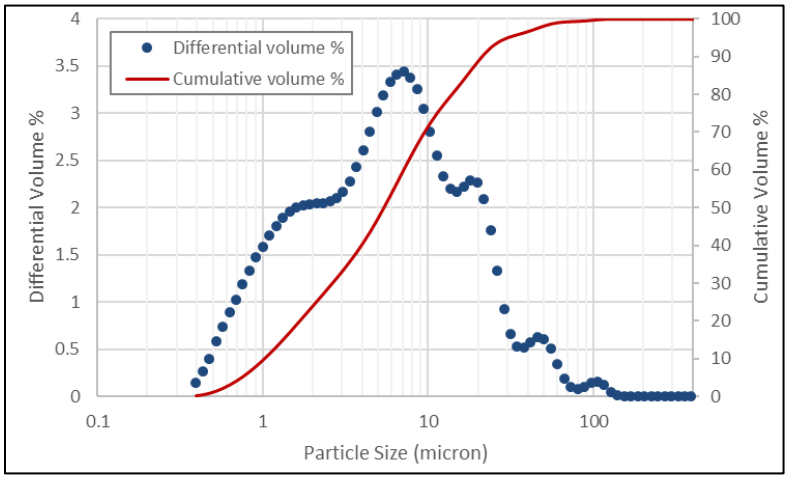

Figure 2: Particle size distribution (PSD) for the tailings dewatered during the DT commercial demonstration

Once the electrodes, sensors, and power supply and control systems were deployed, the operation of the commercial demonstration was initiated. During operations, the control system communicated with the rectifier which applied power continuously to the electrodes. The voltage and current applied to each individual electrode were monitored and recorded by the control system. Based on the measured dewatering performance, the control system adjusted the power applied to individual electrodes.

In addition to the continuous data recorded, physical sampling occurred approximately every six weeks. On each sample date, the water level within the test cell and the mudline depth at multiple locations within the test cell were measured. Core samples of tailings were also collected from multiple locations within the test cell using a custom-fabricated sampling device.

Each core was divided into sections and samples of each section were collected. For each section, including the sections that were above the mudline, the pH, electrolytic conductivity and solids content

were measured. Other analyses, including particle size distribution and ionic concentrations were measured for select sample sections.

The continuous data recorded by the sensors as well as the physical samples collected from the test cell were used to quantify the performance of the technology and to compare that performance to the KPIs set for the commercial demonstration (Table 1). In addition, the performance of the commercial demonstration was forecast using the EKS Model, proprietary software developed by EKS. This model has been developed through extensive laboratory research and is a critical tool used by EKS to design and optimize commercial EKS installations. The commercial demonstration results were also used to demonstrate the accuracy of the EKS Model and that EKS can accurately forecast the technology's performance.

Solar-powered dewatering

A recent EKS innovation, introducing another design variable, is the use of solar panels, floating on a TSF to power an EKS installation. There is significant synergy that can be achieved by powering the DT Technology with solar power. The DC power produced by the solar panels can be provided directly to the electrodes, without conversion to AC power. The DT Technology does not require a constant or reliable power source; the dewatering rate simply increases or decreases according to the power available. Finally, dewatering "pauses" at night (i.e., when no solar energy is available), and resumes in the morning without any operator intervention. As a result, no energy storage is required.

Large-scale laboratory tests were conducted to prove the performance of the DT Technology when powered by solar energy. Each experiment was conducted using a custom fabricated apparatus (Figure 3). 12 vertical electrodes were installed in a 500-L polycarbonate tank. The distance between each anode-cathode pair was 28 cm. The distance between adjacent cathodes was 14 cm. At the start of each experiment, 300 L of oil sands tailings were added to the tank. The initial solids content of the tailings was 42% by weight and the particle size distribution (PSD) is shown in Figure 2.

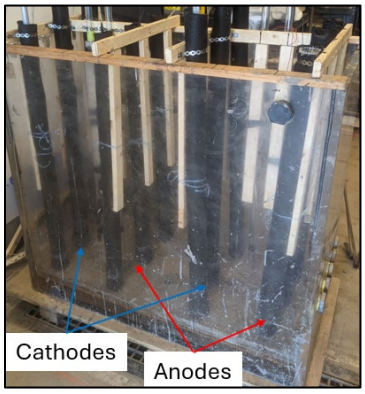

Figure 3: Experimental apparatus for GP and SP experiments

The electrodes were connected to a DC power supply which provided a specific power signature to the electrodes. The use of pulsed power (i.e., alternating periods of constant voltage and zero voltage) has been shown to maximize the efficiency of EK dewatering. (Kim et al., 2020) The automated control system for the DT Technology adjusts the power signature based on the measured properties of the tailings and the installation's objectives. The first experiment simulated the use of grid power (GP) for dewatering. As a result, a continuous power signature was applied (i.e., the voltage did not vary throughout the day). The second experiment simulated the use of solar power (SP). The applied voltage was varied over each 24-hour period according to the available solar radiation.

Each test was operated for five months. As the tailings were dewatered, the voltage applied for each experiment was increased. The recovered water was removed from the surface of the tailings. The volume of water recovered was measured by recording the height of tailings remaining in the tank. Core samples of tailings were also extracted periodically. The solids content was measured for each core and used to confirm the volume of water recovered.

Results and discussion

Commercial demonstration

The following sections summarize the key results achieved by the EKS commercial demonstration. In summary, the commercial demonstration met or exceeded each of the KPIs specified in Table 1, demonstrating that the technology functions well in the field, at scale.

Water release

The DT Technology released water from the tailings during the commercial demonstration. The released water was left in place as a "water cap" on top of the tailings. As water was released, the tailings depth decreased, and the water cap depth increased over time. By periodically measuring the depth of the mudline, the volume of water released from the tailings was determined. In addition, core samples were periodically collected from the test cell. The volume of water released from the tailings was also determined based on the solids contents of the core samples. The water released over time, expressed as a fraction of the initial tailings volume is shown in Figure 4.

The mudline-derived and the sample-derived water release estimates are similar. In addition, the water release estimated by the EKS Model was consistent with the measured water release, demonstrating its ability to accurately forecast the performance of the DT Technology. By the end of the commercial demonstration, the volume of water released was >60% of the initial tailings volume. This exceeded the KPI set for water release (58% of the initial tailings volume) shown in Table 1. The commercial demonstration was stopped due to schedule and budget constraints, not due to technical reasons. If the

demonstration had been extended, more water would have been released. Figure 5 shows the surface of the tailings at the end of the commercial demonstration, after the recovered water had been removed.

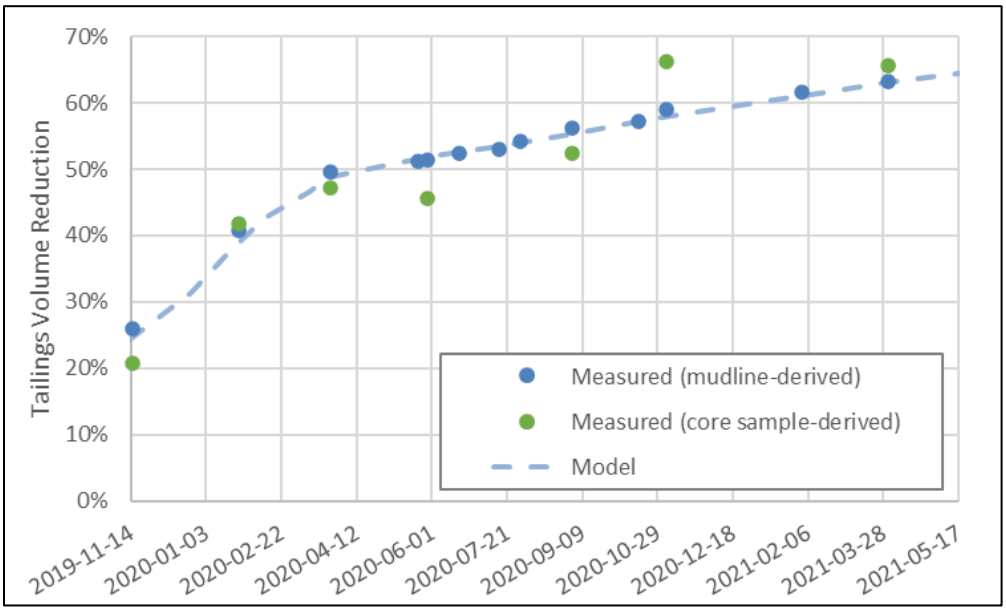

Figure 4: Forecast and measured tailings volume reduction during the commercial demonstration

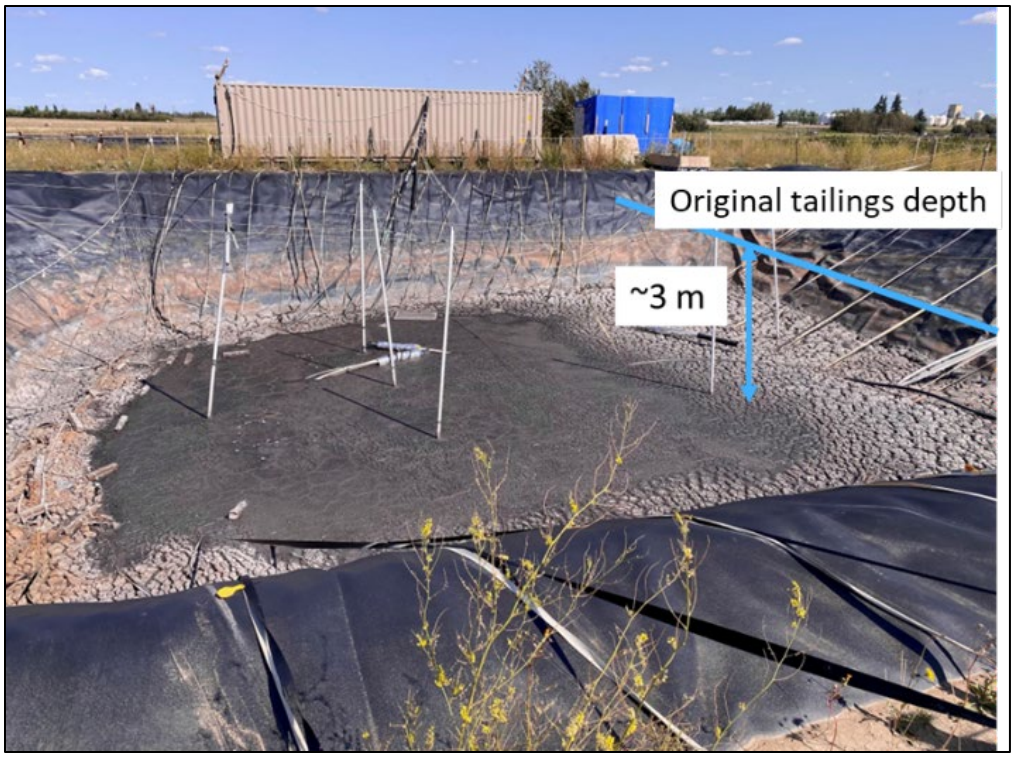

Figure 5: Surface of the tailings after the water cap was removed at the end of the commercial demonstration

For an active TSF, the released water would provide two significant benefits to the mine operator. Firstly, after the released water is recovered from the TSF, the TSF capacity would be increased by an equivalent volume. The commercial demonstration increased the capacity of the test cell by >60%. In addition, the water released from the tailings by the DT Technology is available for reuse in the mineral extraction process, reducing the amount of freshwater that is required from local waterbodies. The value of this released water varies between operations but can be quite significant in arid regions.

Solids content

The solids content at different depths and lateral locations within the test cell were determined from the core sample sections periodically collected during the commercial demonstration. This data was used to track the tailings solids content in the test cell over time, a trend shown in Figure 6. The anode solids content predicted by the EKS Model is also shown.

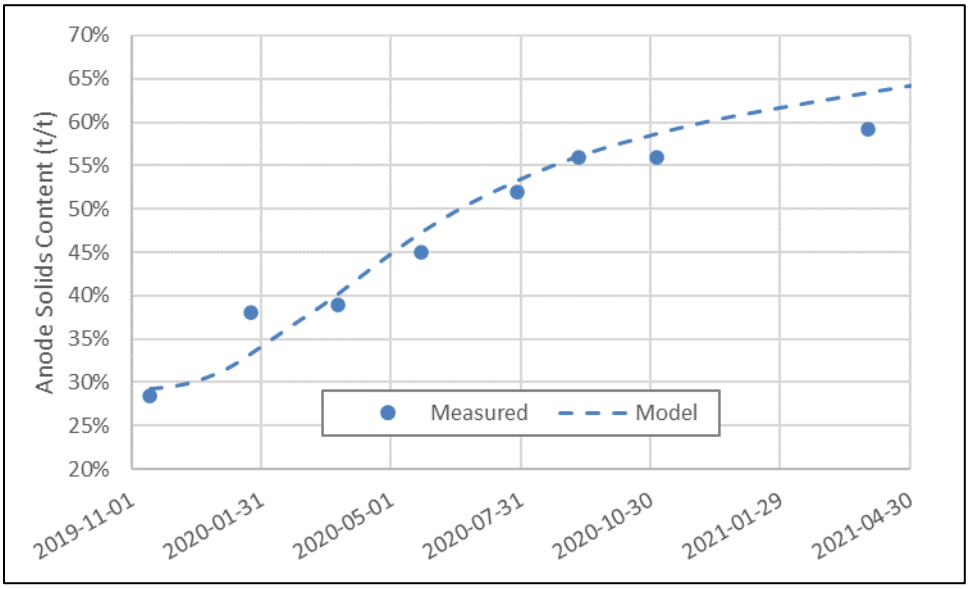

Figure 6: Forecast and measured tailings solids content near the anodes during the EKS commercial demonstration

Initially, the solids content was approximately 30% by weight near the anodes. This value increased over time and was ~60% at the end of the commercial demonstration, meeting the KPI set for solids content (Table 1). This trend was accurately forecast by the EKS Model.

Table 2 shows estimated properties for oil sands tailings at 60% solids. When the DT Technology is applied to an actual TSF and operated to produce tailings with similar properties as those shown in Table 2, the geotechnical stability of the material would be greatly increased, significantly reducing the risk of

catastrophic liquefaction of the tailings. Furthermore, the DT Technology could be used to create a stable layer on the surface of a TSF, enabling the TSF to be reclaimed sooner.

Table 2: Properties of oil sands tailings at 60% solids by weight

Property	Value	Reference
Density	1.57	Measured by EKS
Effective stress	7.7 kPa	(Jeeravipoolvarn et al. 2009)
Hydraulic conductivity	5.48 x 10^{-10} m/s	(Jeeravipoolvarn et al. 2009)

Energy consumption

The voltage and current applied to the electrodes were continuously recorded during the commercial demonstration. As the tailings were dewatered, the EKS control system was used to adjust the power signature applied to the electrodes to maximize the energy efficiency of the operation. The measured energy consumption of 14.8 kWh per m^3 of water released during the commercial demonstration was consistent with the prediction of the model of 16.2 kWh/m^3 of released water. Both values were significantly lower than the KPI of 30 kWh/m^3 set for the commercial demonstration.

Minimizing energy consumption is an important consideration for optimizing electrokinetic (EK) dewatering systems. Energy consumption is a function of the electric field pattern, the current density, the electrolytic conductivity of the pore water, and the porosity of the material being dewatered (Lo et al., 1990; Shang and Dunlap, 1996). Setting an optimal "applied voltage schedule" during the operation of an EK installation, considering the above factors, is essential to minimize energy consumption while maximizing the dewatering rate. Through its technology development program, EKS has optimized the applied voltage schedule used by the DT Technology. The low energy consumption achieved during the commercial demonstration demonstrates the result of this power signature optimization at scale.

Solar-powered dewatering

The following sections summarize the key results of EKS' large-scale experimental investigation of solar-powered EK dewatering. In summary, the use of solar power dramatically reduces the energy required for dewatering.

Energy efficiency for water recovery

Figure 7 shows the cumulative water recovery for the GP and SP experiments. The measured water release, as well as the water release forecast by the EKS Model is shown. The EKS Model was also used to forecast the water release with SWC alone.

The experiments recovered 240 to 280% more water than was forecast for SWC alone. As reported by many others (Casagrande, 1949; Islam, 2014; Lockhart, 1983; Shang, 1997), electrokinetic dewatering

is much faster than SWC, particularly for fine grained materials. In a commercial TSF, this recovered water could be reused in the mineral extraction process, reducing the need for fresh water from other sources (e.g., desalination). In addition, the recovered water increases the TSF storage capacity. The results of the GP and SP experiments correspond to 28% and 24%, respectively, increases in TSF capacity compared to SWC. This added capacity can provide significant cost savings (Vandersleen and Hanna, 2023)

The solar power experiment recovered 11% less water than with grid power. This was due to the lower levels of applied power used for the solar power experiment. Less solar power is available in the morning and evening compared to at noon, and no power is available at night (i.e., for 12 hours per day). As a result, the average applied power and resulting dewatering rate were less than for the grid power experiment.

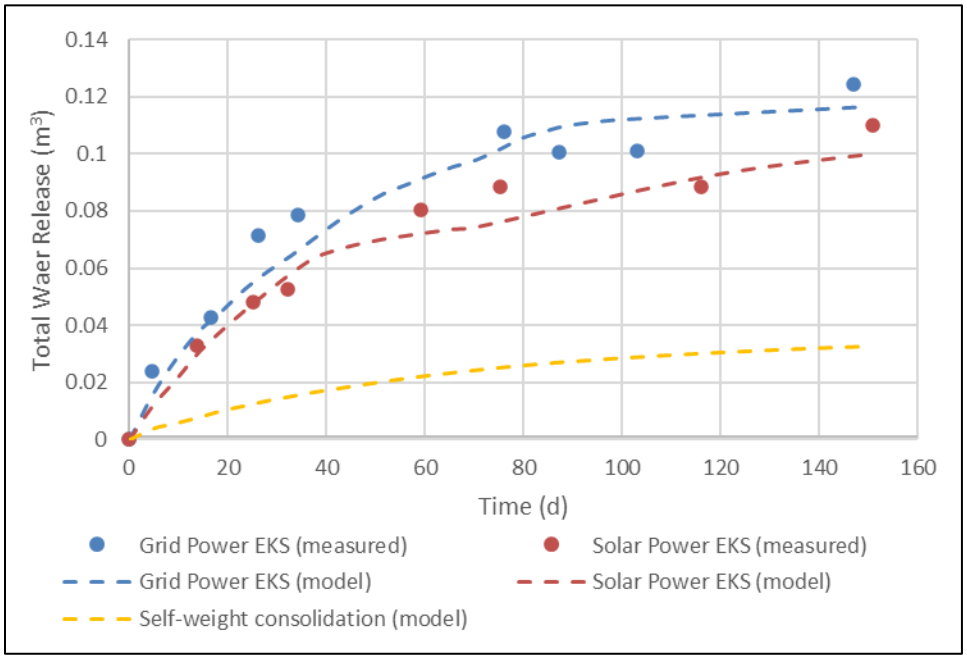

Figure 7: Volume of water released from the GP and SP experiments

Figure 8 shows the cumulative energy consumption required to dewater tailings from the initial 42% solids by weight to approximately 60% solids. The unit energy consumption per tonne of tailings solids is shown. Dewatering the tailings to 45% solids by weight required 47% less power with solar power than with grid power. To dewater the tailings to 58% solids by weight, the energy consumption of the solar power system was 77% less than for grid power.

The application of DC power signatures that vary voltage over time result in reduced energy consumption for EK dewatering. (Kim et al., 2020) The observed solar power experiment results are another example of how power signature variation can significantly improve energy efficiency.

A major barrier to the widespread commercialization of electrokinetic dewatering has been the high energy consumption associated with the technology (Fourie and Jones, 2010). The commercial

demonstration energy consumption of 14.8 kWh/m^3 shows that EKS' innovations have overcome this barrier. The SP test consumed over 47% less energy compared to the GP test. Applying this reduction to the commercial demonstration results would result in commercial-scale energy use <7.8 kWh/m^3. Further optimization of the applied power signature to minimize energy consumption continues to be a focus of EKS research.

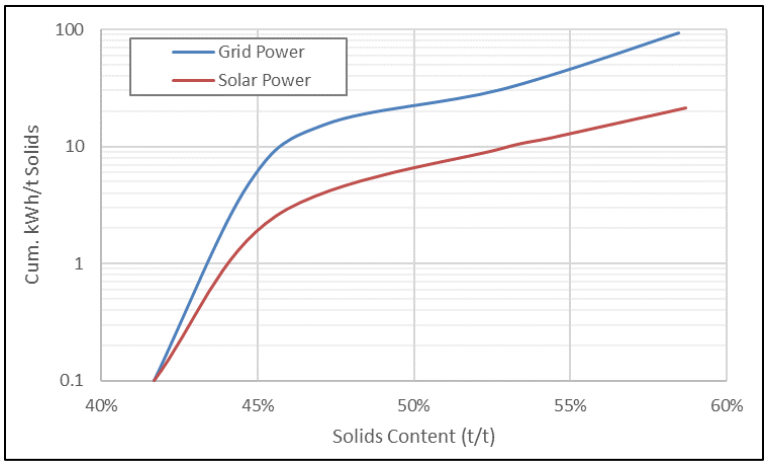

Figure 8: Unit energy consumption of the GP and SP experiments

Solids content

The initial tailings solids content for both experiments was 42% by weight. Figure 9 shows the lateral and vertical variations in solids content at the end of the experiments. These results show that the DT Technology avoids the low-density surface layer characteristic of SWC. The "soft spots" that result from the use of prefabricated vertical drains (PVDs) (Indraratna, 2009; Rixner et al., 1986) are also avoided. The greater density observed for the grid power experiment was due to the greater volume of water recovered. The density profile attainable with the DT Technology reduces reclamation costs and enables reclamation operations to commence immediately following tailings dewatering.

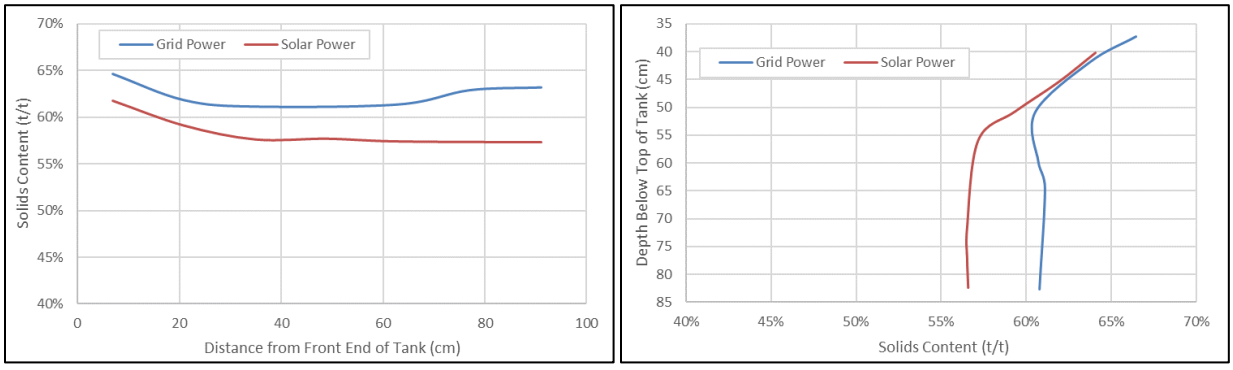

Figure 9: Final tailings density profiles for the GP and SP experiments

Conclusion

The EKS Tailings Dewatering Technology has been developed by EKS over the past 14 years to enable the mining industry to practically and economically address the liability posed by unconsolidated tailings. EKS' technology offers many opportunities to TSF operators, including increased TSF storage capacity, increased water conservation, and a reduced risk of tailings liquefaction.

A 1,700 m^3 commercial demonstration of the technology was completed in 2021 in Alberta, Canada. During the commercial demonstration, the tailings volume was reduced by >60% and the solids content near the anodes was dewatered to 60% solids by weight. The average energy consumption was <15 kWh/m^3 of water released. These results were all consistent with the estimates produced by the EKS Model, demonstrating that EKS can accurately forecast the dewatering performance of the technology. In addition, the commercial demonstration results met or exceeded all KPIs that were set for the technology, proving that the technology scales up as designed and is commercially viable.

There is significant synergy that can be achieved by powering the DT Technology with solar power. The DC power produced by the solar panels can be provided directly to the electrodes, without conversion to AC power. The DT Technology does not require a constant or reliable power source; the dewatering rate simply increases or decreases according to the power available. Dewatering "pauses" at night (i.e., when no solar energy is available), and resumes in the morning without any operator intervention. As a result, no energy storage is required.

Large-scale laboratory tests were completed to confirm the effectiveness of powering the DT Technology with solar power. Regardless of power source, the DT Technology dewaters tailings uniformly, minimizing variation in tailings' density both vertically and laterally. The tests demonstrated that the use of solar power can reduce energy consumption by over 50%, further increasing the efficiency of the technology. The DT Technology, powered by solar energy, is an attractive option for tailings operators to increase the capacity of TSFs and recover significant volumes of water for reuse.

Abstract

The International Council on Mining and Metals (ICMM) and member organizations have set ambitious targets for advancing tailings management practices, including the removal of moisture and enhancement of tailings strength through the adoption of cost-effective, scalable technologies capable of processing tailings and, ideally, reducing or eliminating tailings generation altogether. The implementation of Best Available Technology (BAT) in tailings management systems (TMS) is paramount for ensuring the cost-effective creation of safe, stable, and environmentally sound landforms during both operational and post-closure phases. Mechanical consolidation is an available technology that aligns with conventional tailings storage facility design and operation, emphasizing the key principles of maximization of tailings density and minimization of water retention – a paradigm consistent with the requirements outlined in the Global Industry Standard on Tailings Management (GISTM).

Accelerated mechanical consolidation involves the application of specialized equipment to impose controlled loads on surface deposited tailings, significantly exceeding anticipated in-situ loads and accelerating the consolidation process. This approach reduces the time required for tailings consolidation, enhancing operational efficiency and reducing operational risks, while compacting and drying material stored in the facility.

A large-scale trial conducted at a copper tailings storage facility in Chile's central region aimed to demonstrate the applicability and effectiveness of mechanical aid in consolidating and compacting copper tailings. Various geotechnical monitoring parameters – including density (both dry and bulk), undrained shear vane, moisture content, in-situ infiltration, and cone penetration resistance – were meticulously assessed on both unaltered and mechanically treated tailings. Results indicated an overall improvement in all monitored parameters for areas subjected to in-situ mechanical consolidation and compaction, while unaltered sections exhibited either minimal change or marginal improvement over the trial duration. These quantifiable benefits suggest significant potential for enhancing tailings management practices through the

application of mechanical dewatering, consolidation and compaction techniques. The findings underscore the transformative potential of accelerated mechanical consolidation as a technology in addressing key challenges associated with copper tailings management.

Introduction

The global mining industry has faced numerous tragic incidents involving tailings storage facilities (TSFs). These failures have led to significant environmental damage, loss of human life, and financial repercussions, underscoring the urgent need for improved tailings management practices. In response, the International Council on Mining and Metals, in collaboration with the United Nations Environment Program and the Principles for Responsible Investment, convened the Global Tailings Review in 2019. The objective of this initiative was to establish a comprehensive international standard for tailings management, aiming to mitigate TSF failures and prevent future environmental and humanitarian crises. The resulting Global Tailings Standard, published in August 2020, mandates that operators explore emerging and alternative options (Best Available Technology, BAT) for conventional wet TSFs.

The industry has seen substantial investment in research and development focused on alternative tailings surface storage solutions. This includes the development and refinement of paste, filtered and thickened tailings technologies, which offer promising alternatives to traditional wet TSFs. However, green-field, legacy, and operational TSFs switching to one of these alternatives as a tailings management solution are burdened with high capital and operational costs as well as operational complexity and technology limitations (Crystal et al., 2018). Accelerated Mechanical Consolidation (AMC) presents an efficient and cost-effective solution to mechanically dewater, consolidate, and compact in-situ tailings with comparable and, in some cases, superior results to filtered and stacked tailings facilities (Woolston and DiDonna, 2020; Santiago et al., 2024). The theory of AMC implies that in-situ mechanical perturbation of a deposited material accelerates its consolidation process.

In the case of suspensions, this technique overcomes the effects of hindered settlement and facilitates the exit of water from the tailings profile. When applied to highly flocculated or porous materials, it collapses the pores and rapidly increases density to levels equivalent to those achieved by filtration or centrifugation (Munro and Smirk, 2018). Reduction of interstitial pore spaces and water is by far the most important consideration for the design and operation of TSFs. Significant efforts are made to maximize the water recovered from tailings to allow continued tailings transportation and process water.

Methodology

Accelerated mechanical consolidation trial

In the interest of advancing environmental management and optimizing operational efficiency, Phibion Pty Ltd undertook a large-scale trial on an active copper mine TSF between October 2022 and March 2023. The copper mine is operated by one of the largest copper producers in the world and is located in Chile, in the Santiago Metropolitan region. A trial area was established in the south-west part of the facility in close proximity to a tailings discharge point. It was segregated into ten individual work areas covering a total area of approximately 98.5 ha (Figure 1). The work area was isolated during the trial period to minimize uncontrolled deposition on fresh tailings within the area; any fresh tailings not needed for the trial were deposited elsewhere within the facility.

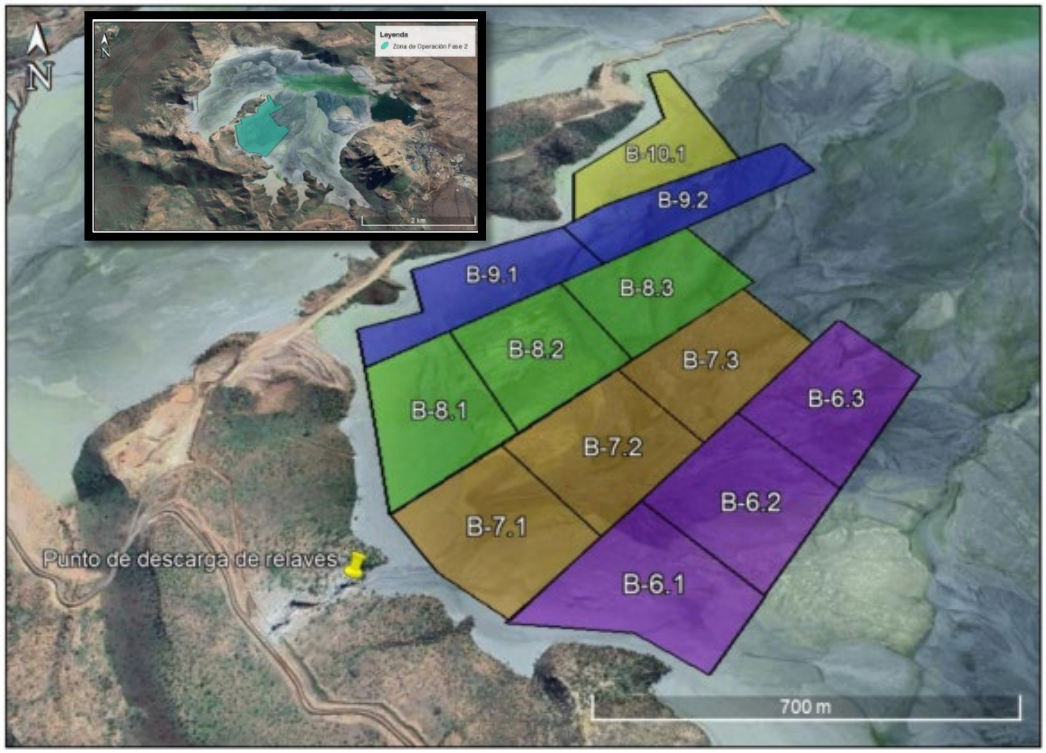

Figure 1: General location of the trial and full extent of the copper TSF

The TSF stores a mixture of copper and molybdenum tailings with a maximum tailings production storage of 180 kt per day covering an overall area of 20 km^2. Tailings generated at the outlet of the concentrator plant target a concentration of solids by weight of 54%, which is ultimately discharged at a series of outlets in upstream valleys that flow downstream towards the decant pond and return structure located in the north-east of the TSF. Prior to discharge the tailings pass through a series of hydro-cyclones on saddle dam embankments, removing the coarse fraction, which is utilized for progressive raising of

saddle dam embankments. Fresh tailings are discharged at a range of densities depending on the processing plant configuration and ore inputs; these bulk densities range from 1.23 to 1.56 t/m^3.

Over the course of the trial period Phibion operated a fleet of two MudMasters,® which are advanced amphibious machines that utilize Archimedes screws to traverse the tailings surface due to their low ground-bearing pressure. These machines employ a process known as Accelerated Mechanical Consolidation (AMC) to drive improvements in density within the tailings material, regain entrained tailings water, and consolidate and compact tailings in-situ.

The machine weight applies a concentrated load on the tailings surface, increasing surface pore pressure and effectively packing the material. Over a series of consecutive traverses this progressively increases the tailings strength through increased density and dewatering (South32, 2023; McPhail et al., 2021). Prior to deployment Phibion undertook modeling to establish the optimal machine weight (17.5 T), optimal scroll length (4.8 m), and maximum fresh tailings to achieve buoyancy requirements (1.3 m).

Figure 2: General location of the trial copper TSF and MudMaster® in action

The AMC process involves an initial period of "recovery," in which interstitial tailings water is compressed from the tailings to a point where the amphibious machine has consolidated the tailings into a dense material upon which the machine's weight is bearing. This stage is critical for operational effectiveness as machines then gain adequate traction in the consolidated tailings to traverse at greater speeds. It also creates a dense base upon which fresh tailings can be deposited and compressed against. Following the recovery phase, the operation moves into the production phase, where consolidation and dewatering are optimized. A specialized AMC plan was developed to optimally compact tailings while allowing surface water to drain freely towards the decant structure in the east of the TSF.

Critical to the AMC process is control of the deposition depth and timing of fresh tailings discharge. Throughout the trial period discharges were intermittent and not well controlled. The intent of the trial was to work the fresh tailings to understand the impact potential, rather than work within deposition sequencing. The details of subsequent deposition periods were as follows:

- Initial discharge (October 2022): fresh layer of tailings discharged across the entire surface of the trail area.
- Second discharge (end of December 2022 – beginning of January 2023): fresh discharge of tailings covering all work bays with controlled depth between 0.5 and 1.0 m maintained.
- Third discharge (end of February 2023): fresh tailings discharged over bays 6, 7, 8.1, and 8.2.

Between each discharge machines worked across the tailings surface, applying the tailored AMC operation plan.

Trial validation geotechnical testing

To investigate the effectiveness of AMC in the trial area, the TSF operator engaged an independent geotechnical testing contractor to test the tailings both in-situ and in the laboratory with representative sampling (Table 1).

Table 1: Summary of geotechnical testing

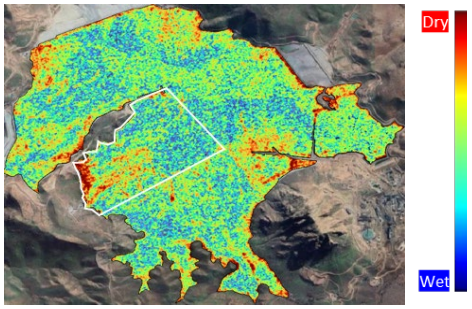
Test Type	Applied Testing Standard	Parameter	No. of Tests
Sand Cone Test	NCh 1516 (1979) ASTM D-1556-15	Dry density	15
Shear Vane Test	ASTM D 2573-15	Undrained shear strength	256
Granulometry	MC-V8 8.102.1 (Dec 2003)	Granulometric distribution – percentage fines	49
Atterberg limits	NCh 1517/1 (1979) & NCh 1517/2 (1979)	Liquid limit (LL), plastic limit (PL) and plasticity index (PI)	49
USCS Classification	–	–	38
Modified Proctor	NCh 1534/2 (1979)	Dry maximum compacted density (DMCS) and optimum moisture	1
Humidity	NCh 1515 (1979)	Percent humidity	158
Particle Density	NCh 1532 (1980)	Particle density solids – specific gravity (Gs)	49
Porchet Test	NCh 3610 (2020)	Infiltration rate	5
PANDA Test	NCh 3261 (2012)	Tip resistance	5
Unit weight	–	Dry density	3

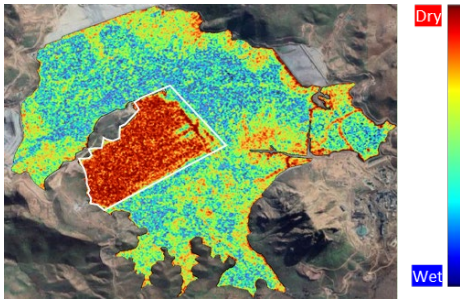
The contractor endeavored to take representative tests at a series of intervals throughout the trial period from October 2022 to March 2023. Samples were taken to reflect the unaltered tailings (no treated material with AMC) as well as altered (treated with AMC) tailings at varying intervals (2, 4, and 6 passes and final stage). Refer to Appendix Table A1 for more detailed test information and Appendix Figure A1 for sample locations. In some instances, unaltered testing was taken at the final stage of altered tailings activity to compare self-consolidation results with AMC results. Other unaltered tests were taken as baseline tests to understand the impact of AMC activity with time. The majority of testing was undertaken in situ.

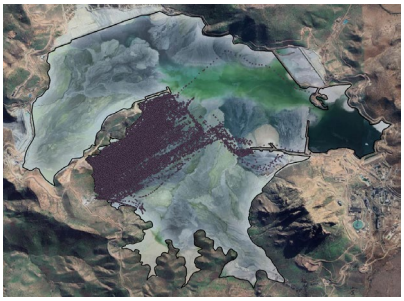
Data and discussion

Tailings classification

The results of Atterberg Limits testing determined the tailings to be classified as Non-Plastic (NP) with USCS classifications mainly as low plasticity silt (ML) with variations to silty sand (SM). The high proportion of silt reflects the effective hydro-cyclone of sands for embankment raising prior to discharge within the facility.







Visual observations

The visible tailings condition is an anecdotal indicator of the effectiveness of AMC. During the trial period there was marked improvement in the tailings surface condition, as shown in Figure 3. Fresh tailings deposited throughout the trial area in October 2022 appear wet and loose, contrasting with the post-trial image that presents a relatively dry, high strength surface. To achieve such a result required over six passes of the machines. However, there were substantial improvements in the tailings characteristics with less passes.

Figure 3: Tailings condition of the trial area prior to trial commencement 24/10/2022 (left) and approaching the completion of the trail 28/02/2023 (right)

Table 2: Variation in tailings surface moisture throughout AMC trial period, Sentinel 1 Radar Polar VV on the left in comparison to the MudMaster® tracking coverage

Date	Tailings Moisture (Radar Polar VV)	MudMaster Tracking
29/11/2022		
30/03/2023		

Tailings surface moisture is also observable through Sentinel 1 Radar Polar Moisture. This data throughout the trial period is displayed in Table 2 alongside MudMaster® GPS tracks. The rate of drying appears substantially better than unaltered areas of the TSF.

Strength and density observations

The undrained shear strength (S_u) of the tailings presents an increasing relationship with the number of passes of the equipment, due to the rapid densification and compaction of the tailings. This relationship stabilizes after four passes, reaching, for 0.5 m depth, S_u values of between 30 – 70 kPa, with an average of 48 kPa. This is ten times greater than the average S_u achieved naturally by the consolidation of the tailings in the same period of time and depth, as shown in Figure 4.

Furthermore, the decrease in S_u with depth is clear, so it is understandable to postulate that the effect of the MudMaster® and the AMC process decreases with depth, hence the need to maintain pour tailings layers to a set depth that can be worked effectively as the first 0.5 m deep. Data presented within Figures 4 to 9 represents the averaged data from all testing areas. Typically, AMC operations are analyzed in terms of number of passes of the machine as this is a quantifiable operation metric. In an active operation the number of passes to target desired performance objectives would be established.

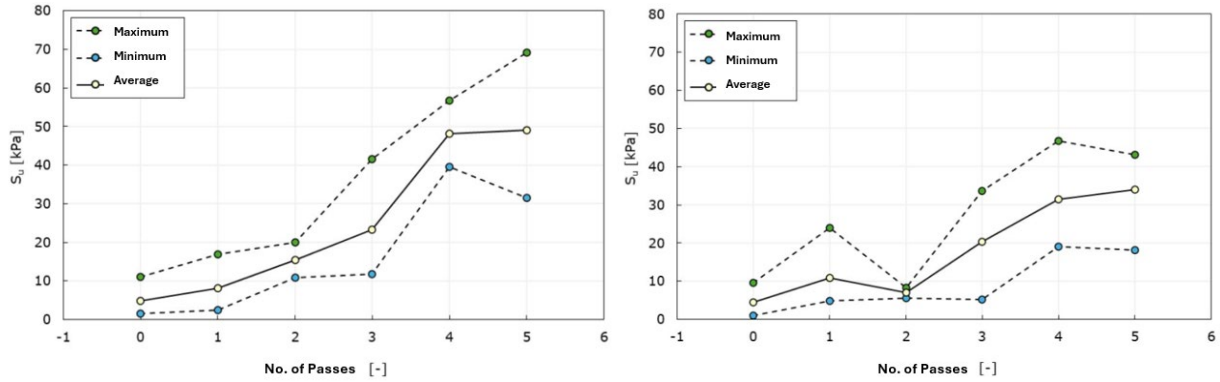


Figure 4: Undrained shear strength vs. number of passes, all data acquired October 2022 to March 2023. Left plot shows testing at 0.5 m deep and right plot shows at 1.0 m deep; data represents results across all test areas

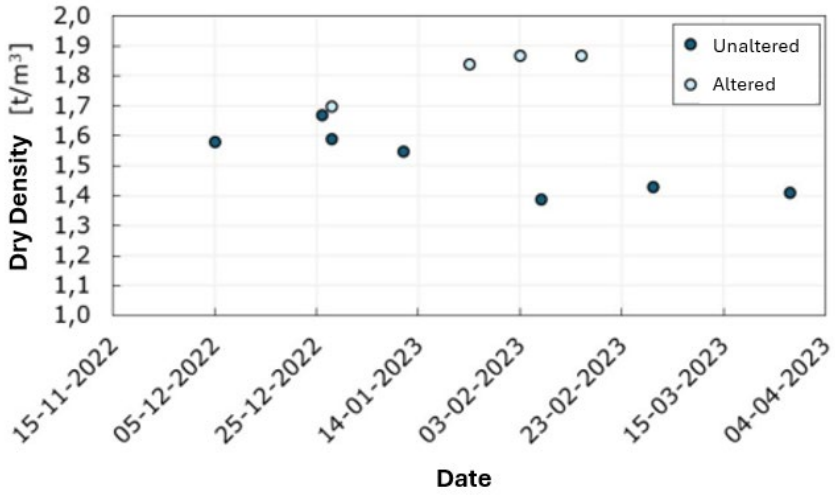

Figure 5: Dry density in unaltered and altered condition of tailings; lack of altered results within trial period due to invalid test results in February and March

A significant increase in the dry density of the tailings is evident, as shown in Figure 5, due to the action of the amphibious equipment, increasing from an average value of 1.52 t/m^3 in unchanged condition to 1.86 t/m^3 after four passes of the equipment. This has a great effect on the shear resistance parameters in drained conditions, since they are increased, especially the friction angle as there is greater interlocking between particles in a state of higher density.

An inversely proportional relationship is observed between S_u and the surface humidity of the tailings, as shown in Figure 6. This relationship arises because, by decreasing the humidity in the tailings, the amount of water stored in the interstices is reduced, which results in an increase in the effective tension between the particles, and therefore in a greater resistance to shear strength.

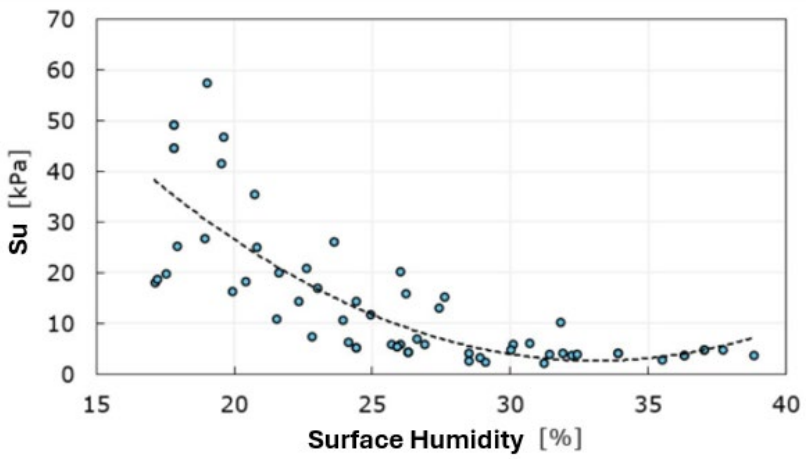

Figure 6: Correlation of undrained shear strength and surface humidity

Tailings moisture and seepage observations

A notable decrease in surface humidity is evident as the number of passes increases, until reaching a minimum value of 16% after three passes (Figure 7). To reach humidity lower than that value, the tailings should experience a suction value greater than 100 kPa (Figure 8). Additionally, the lower the humidity in the deposited tailings, the higher the yield stress and dynamic viscosity, which means the risk associated with dam failure is lower.

The reduction of the infiltration rate of the tailings deposited after the operation of the amphibious equipment is evident and contributes to the reduction of the infiltration of contacted waters in depth and towards the foundation soil, which helps reduce the risk of potential contamination of underground layers, weakening of foundation and seepage issues. Additionally, this reduction would increase the amount of water available for recovery from every wet deposition and precipitation events, which would be directed mainly toward the decant pond, except for the amount that is evaporated.

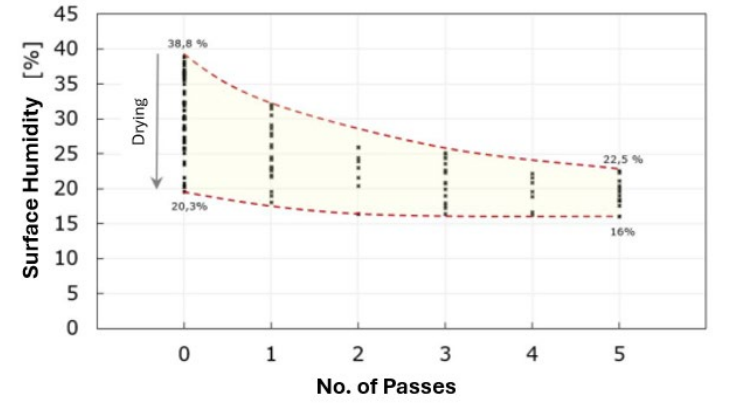

Figure 7: Surface humidity vs. number of passes

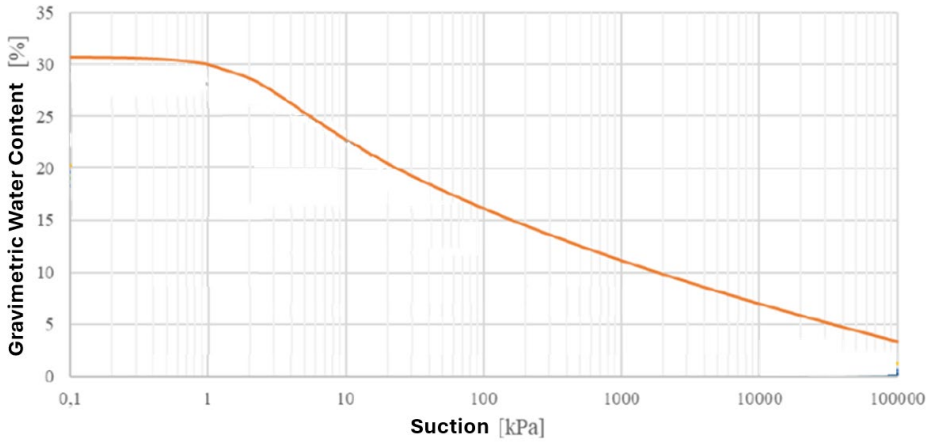

Figure 8: Tailings water retention curve

The density and compaction levels reached after four passes of the amphibious equipment indicate that the tailings experience diminishing returns in terms of infiltration rate with additional passes. This decreases the susceptibility of the tailings to static liquefaction and seepage. Furthermore, the tailings dewatering process reinforces this benefit, since the absence or scarcity of water in the interstices prevents the generation of the pore pressures necessary for liquefaction.

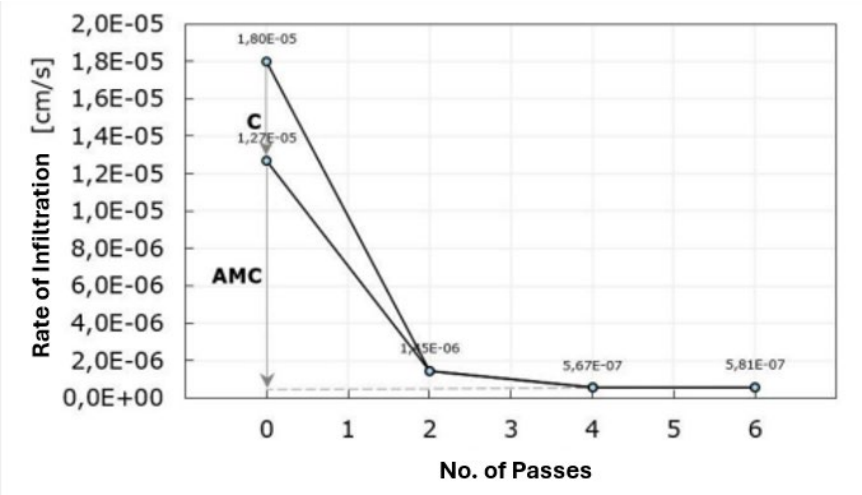

Figure 9: Infiltration rate decrease with increased number of passes of AMC in contrast to natural consolidation "C"

Impact of results on tailings operations

The operation completed effectively 66 days with two amphibious equipment and, consequently, the AMC process, to generate a net gain in the stored volume by displacing water and, therefore, in useful storage life in the TSF. In this particular case, the trial generated an estimated 3.4 days' worth of tailings deposited in the facility (4,918 m^3/day). This useful life gain, when extrapolated to the final total area of the TSF

(2,000 ha), and considering linearity and full implementation of AMC, translates into a useful life gain of over 40,000,000 m^3, which represents a total gain of 415 days' worth of storage.

The rapid reduction of the surface slopes of the basin in the areas operated by the amphibious equipment is a reflection of the rapid consolidation produced in the recently disposed tailings in the surroundings of the discharge point. Furthermore, the channels generated by the equipment's screws (scrolls) contribute to the conduction of the released water and the distribution of the tailings that are subsequently deposited.

Conclusion

The global mining industry must urgently adopt improved tailings management practices to prevent catastrophic failures of TSFs. The Global Tailings Standard, established in response to past failures, mandates the exploration of BAT alternatives to conventional wet TSFs. This study demonstrates the potential of AMC as a cost-effective and efficient method, scalable to high production rates, for enhancing tailings management compared to other methods.

The trial conducted by Phibion on an active copper mine TSF in Chile underscores the practical benefits of AMC. Over a five-month period, the use of MudMaster® machines resulted in significant improvements in tailings density and strength, reducing surface moisture and enhancing the structural integrity of the tailings. Geotechnical testing confirmed that AMC could achieve comparable, if not superior, results to traditional dewatering methods such as filtration and centrifugation.

Key findings from the trial include:

- A substantial increase in dry density and undrained shear strength (S_u) of the tailings, reaching values that significantly reduce the risk of liquefaction.
- Effective dewatering, resulting in lower surface moisture content and enhanced water recovery for processing operations.
- A reduction in infiltration rates, mitigating the potential for seepage related stability issues and contamination of underground water layers.

The AMC process not only improves the operational efficiency of TSFs but also extends their useful life, providing economic and environmental benefits. The trial's success highlights the importance of continued investment in innovative tailings management technologies. By adopting AMC and similar advanced techniques, the mining industry can better safeguard against environmental and humanitarian crises, ensuring a more sustainable future for mining operations worldwide.

Acknowledgements

Phibion would like to express our sincere gratitude to GA Consultores – Geotecnia Ambiental for their invaluable support and expertise in conducting the third-party review of this work. Their thorough analysis and insightful feedback greatly contributed to the rigor and integrity of this project.

Influence of In-situ Soil Fabric on the Critical State of a Laminated Glaciolacustrine Silty Soil

Adrian Wightman, BGC Engineering Inc., Canada

Abstract

The current state of practice for evaluating the flow liquefaction potential of a soil deposit is based on comparing its estimated in-situ state parameter (ψ_o) with a threshold value. To estimate ψ_o of a soil deposit and determine its critical state line (CSL), detailed analyses use triaxial test results on reconstituted specimens rather than undisturbed specimens. This approach implies that at critical state the influence of in-situ soil fabric on void ratios and stresses is minimal. Although this hypothesis may be generally acceptable for homogeneous fills and tailings, verification is required for naturally deposited soils that are deemed susceptible to flow liquefaction.

A series of drained and undrained triaxial compression tests were conducted on reconstituted specimens of a fine-grained glaciolacustrine soil to determine its CSL. Triaxial tests were also performed on high quality Shelby tube samples, and the results were compared to the CSL of reconstituted specimens. The testing of reconstituted specimens of glaciolacustrine soil indicated that a family of reasonably parallel CSLs rather than one single CSL existed. The tested Shelby tube specimens had initial states loose of the reconstituted specimens CSLs, and yet all tests on Shelby tube samples showed dilative behavior and moved away from the reconstituted specimens CSL. Several factors that are believed to have contributed to this observation are further investigated and discussed in this paper. The sensitivity of estimated ψ_o to a vertical shift in CSL position on the e-log p′ plane was also examined in the light of a series of spherical cavity expansion numerical simulations.

Introduction

Assessing the possibility of flow liquefaction in the foundation and construction materials of tailings dams has been an increased focus of importance within the mining sector following the failures of the Fundão

tailings dam (2015), Cadia tailings dam (2018), and Feijão tailings dam (2019). In general, geotechnical engineering practice currently relies on estimating the in-situ state parameter (ψ_o) of a soil to assess its susceptibility to flow liquefaction. The state parameter is defined as the difference between the in-situ void ratio and the void ratio at critical state for a given confining pressure (Jefferies and Been, 2016). Soils with a positive state parameter ($\psi_o > 0$) are contractive and soils with a negative state parameter ($\psi_o < 0$) are dilative. In lieu of the theoretical threshold $\psi_o = 0$, Jefferies and Been (2016) recommended adopting a practical value $\psi_o = -0.05$, where soils with $\psi_o > -0.05$ are considered contractive and prone to flow liquefaction.

Methods used to estimate ψ_o range from screening-level empirically based methods, such as those by Plewes et al. (1992) and Robertson (2010), to detailed material-specific methods like that of Jefferies and Been (2016). In the latter approach, a series of triaxial laboratory tests is conducted on a soil to define its critical state line (CSL) and calibrate the NorSand constitutive model. The NorSand model is a plasticity model developed within the critical state soil mechanics (CSSM) framework and is particularly useful for assessing the static liquefaction potential of loose strain softening cohesionless soils (Jefferies and Been, 2016). The calibrated NorSand model is then used to conduct a series of numerical cavity expansion simulations to determine CPTu inversion coefficients, which are subsequently used to calculate the ψ_o (Shuttle and Jefferies, 1998; Shuttle and Cunning, 2007).

The Jefferies and Been (2016) method uses triaxial testing of reconstituted specimens, implying that at critical state the influence of in-situ soil fabric on void ratios and stresses is minimal. Although this hypothesis may be generally acceptable for homogeneous soils and tailings, verification is required for naturally deposited materials that exhibit laminated structure. This paper presents the interpretation of the CSL for a natural laminated glaciolacustrine silt/clay based on triaxial compression tests completed on intact and reconstituted specimens. The effects of these variations on the interpretation of ψ_o are also discussed via a series of cavity expansion numerical simulations.

Tested materials

Testing was carried out on samples of a laminated glaciolacustrine (GLU) silt/clay deposit sourced from Ontario, Canada. The soils within the GLU deposit had varying amounts of silt and clay, consistencies ranging from non-plastic to low plasticity, and structure ranging from visually homogeneous to (micro) laminated, to varved. Figure 1 shows photographs of variable structures found within the GLU deposit.

Both reconstituted and intact samples of the GLU were tested. The reconstituted samples represent the average properties of the visually homogeneous non-plastic and low plastic silty parts of the GLU deposit and are referred to GLU1 and GLU2, respectively. GLU1 and GLU2 samples were created by blending and mixing Sonic core samples of similar materials to create batches of visually homogeneous

soils, from which the advanced test specimens were formed. Figure 2 compares the grain size distribution curves of GLU1 and GLU2 with those of other samples collected from the GLU deposit. GLU1 represents GLU materials with low clay content (< ~15%) and is categorized as non-plastic silt (ML) in the unified soil classification system (USCS). GLU2 represents glaciolacustrine materials with higher clay content (~25 – 40%) and is categorized as low plastic silt and clay (ML-CL) in USCS.

Intact Shelby tube samples collected from the GLU deposit were also tested to compare and assess the influence of in-situ soil fabric. The Shelby tube samples were collected from intervals within the GLU deposit where clay and silt laminations were observed. The Shelby tube samples were composed of predominantly fine-grained soils, ranging from low plastic silt and clay (ML-CL) mixtures to low plastic clay (CL).

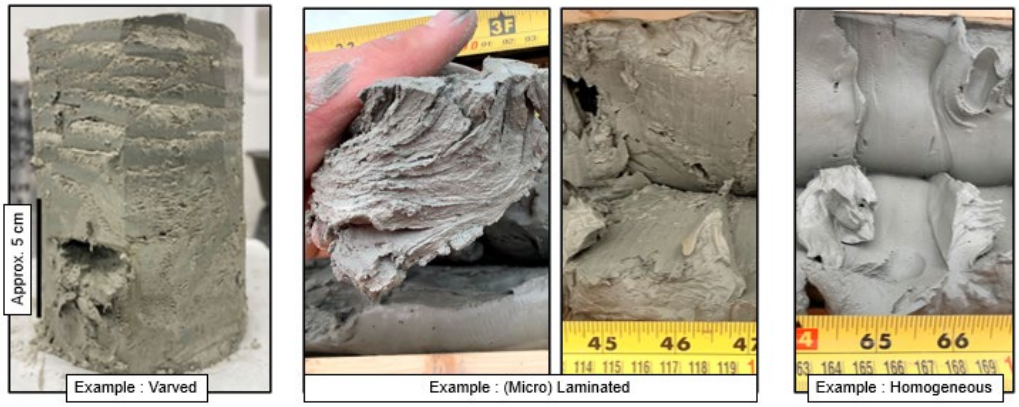

Figure 1: Photographs of variable structures found within the GLU deposit

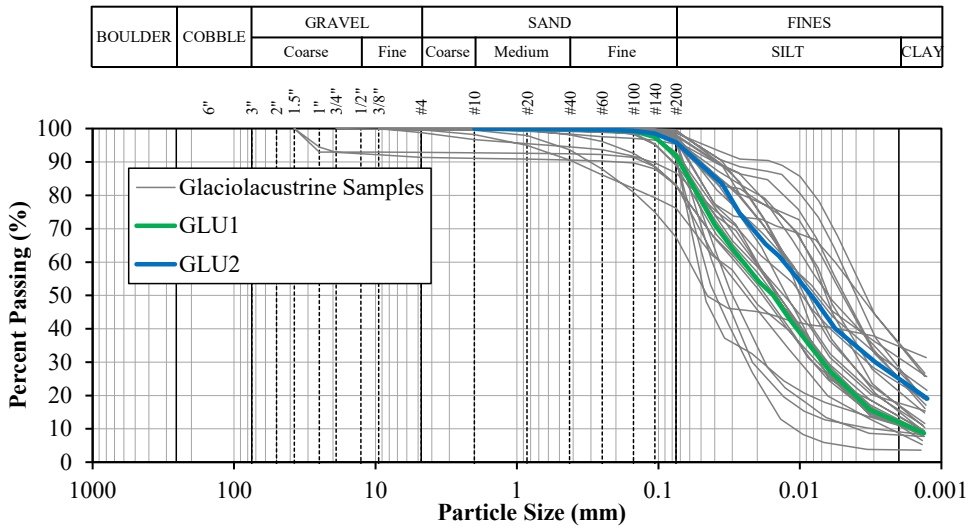

Figure 2: Gradation curves for glaciolacustrine (GLU) and blended GLU1 and GLU2 samples

Triaxial testing and NorSand calibration of GLU1 and GLU2

Triaxial tests were performed on GLU1 and GLU2 specimens to determine their CSLs and other necessary inputs for the calibration of the NorSand constitutive model. The results of these triaxial tests with emphasis on CSLs for GLU1 and GLU2 are presented first, followed by the NorSand calibration.

Triaxial testing and critical state lines

Triaxial tests were performed on GLU1 and GLU2 specimens. The triaxial specimens were prepared by reconstituting samples using the moist tamping method. The triaxial tests were completed on specimens 70mm in diameter by 140mm high with lubricated free ends, using an automated system manufactured by GDS. This servo-controlled system allows direct control of the cell pressure, testing rate, and data acquisition. The system uses an internal load cell that is placed within the cell at the end of the loading piston which eliminates the potential for piston friction. The cell pressure was controlled using GDS pressure/volume controllers. These controllers allow regulation and measurement of fluid pressures and volume changes.

A series of five isotropically consolidated drained (CID) and two isotropically consolidated undrained (CIU) tests were performed on each of GLU1 and GLU2 specimens, respectively. Of the five CID tests completed on each material, two specimens were prepared in a loose state and three were prepared in a dense state. Both CIU specimens were prepared in a loose state. The state paths of CID and CIU triaxial tests, showing variations of void ratio (e) with mean effective stress (p'), are summarized alongside CSLs for GLU1 and GLU2 in Figure 3a and Figure 3b, respectively. Figure 3c shows the comparison of CSLs for GLU1 and GLU2. Both CSLs can be defined by a semi-logarithmic equation: $e = \Gamma - \lambda \log(p')$ where Γ is the CSL intercept (altitude) at $p' = 1$ kPa and λ is the slope of the CSL. λ is associated with compressibility of soil during shear (Shuttle and Jefferies, 1996). Values of Γ and λ for GLU1 and GLU2 are summarized in Table 1, based on which GLU2 has greater compressibility and altitude than GLU1.

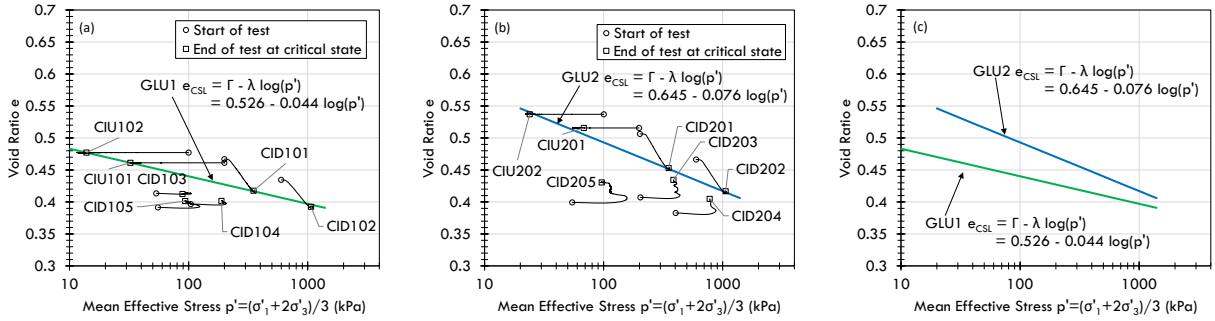

Figure 3: Triaxial test results and CSLs for (a) GLU1, (b) GLU2, and (c) both GLU1 and GLU2

Table 1: CSL parameters in e-p' plane for GLU1 and GLU2

Material	Γ	λ
GLU1	0.526	0.044
GLU2	0.645	0.076

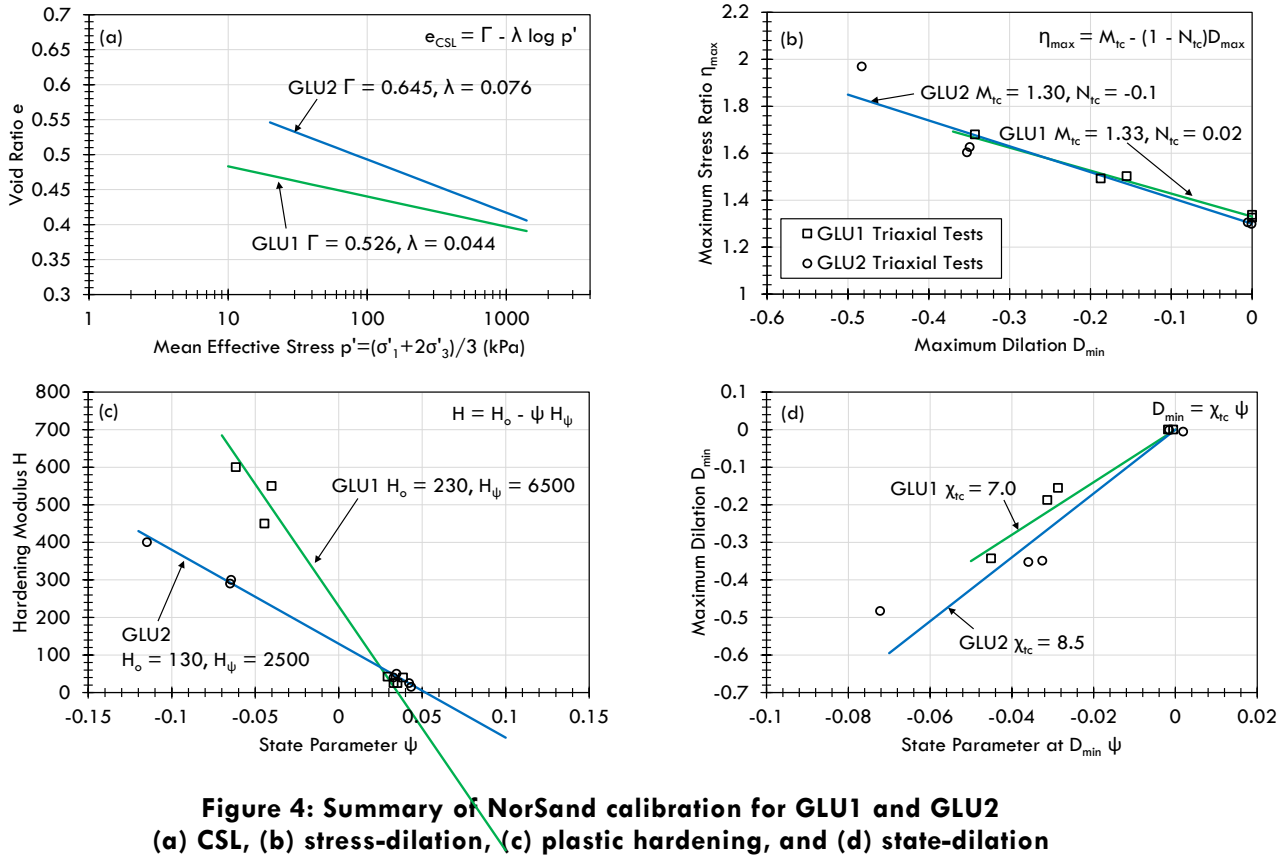

Figure 4: Summary of NorSand calibration for GLU1 and GLU2
(a) CSL, (b) stress-dilation, (c) plastic hardening, and (d) state-dilation

NorSand calibration

The triaxial tests results on GLU1 and GLU2 were used to calibrate the NorSand constitutive model (Jefferies and Shuttle, 2005; Jefferies and Been, 2016). Figure 4 shows the plots summarizing NorSand calibration for GLU1 and GLU2 as follows: Figure 4a shows CSLs in e – log p' plane; Figure 4b shows the stress-dilation relationship, which is the maximum dilation (D_{min}) versus the corresponding maximum stress ratio ($\eta_{max} = (q/p')_{max}$) fitted with $\eta_{max} = M_{tc} - (1 - N_{tc})\, D_{min}$, where M_{tc} and N_{tc} are the critical friction ratio and the volumetric coupling coefficient, respectively; Figure 4c shows plastic hardening parameter calibration, modulus (H) versus the corresponding values of state parameter (ψ) fitted with $H = H_o - H_\psi\, \psi$, where H_o and H_ψ are the intercept and slope of the plastic hardening modulus trendline; Figure 4d shows the stress-state relationship, D_{min} and its corresponding ψ values fitted with $D_{min} = \chi_{tc}\, \psi$, where χ_{tc} is the dilatancy parameter.

Typical CIU and CID test results alongside the corresponding NorSand simulations for GLU1 and GLU2 are shown on Figure 5. The model simulations fit test data reasonably well. The misfit of volumetric strains in CID105 (Figure 5g) and CID203 (Figure 5o) is attributed to the formation of a shear band, which onsets at an axial strain of approximately 1% to 2% in both tests.

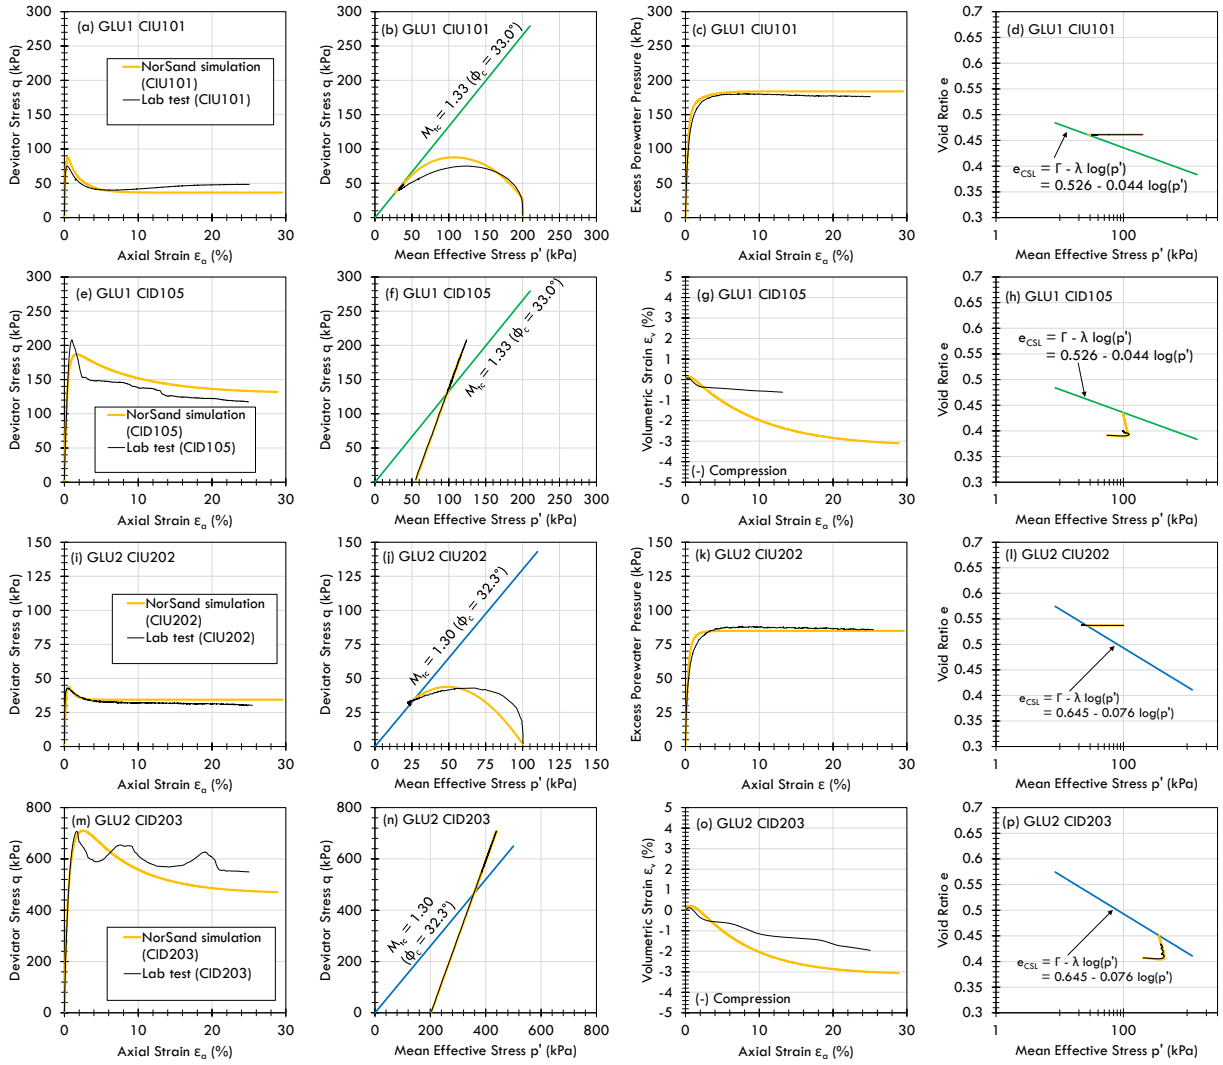

Figure 5: Comparison of NorSand simulations and typical CIU and CID test data for GLU1 (top two rows) and GLU2 (bottom two rows): (a), (e), (i), (m) stress-strain; (b), (f), (j), (n) p' – q; (c), (k) excess porewater pressure; (g), (o) volumetric strain; (d), (h), (l), (p) e – log p'

Influence of in-situ soil fabric on CSL interpretation

Several CIU triaxial tests were conducted on intact specimens recovered from Shelby tubes to assess the influence of in-situ laminated soil fabric on the CSL interpretations. These intact specimens were loose of GLU1 and GLU2 CSLs, and as such, it was expected that these samples would be contractive upon shearing, due to positive shear induced pore pressure development. However, test results on intact Shelby tube

samples generally showed dilative behavior. It was unclear whether the difference in behavior was the result of specimen variability or whether the destruction of laminated fabric during sample reconstitution was the cause.

To investigate this further, additional testing was completed on a third material referred to as GLU3. Following the same methodology used to prepare GLU1 and GLU2 samples, a Sonic core sample of GLU3 was thoroughly blended and mixed to create a batch of visually homogeneous soil. Figure 6 compares the gradation of GLU3 with those of GLU1 and GLU2. Similarly to GLU1, GLU3 was also categorized as non-plastic silt (ML) in the USCS.

One CID (CID301) and one CIU (CIU301) test were performed on loose reconstituted GLU3 specimens, each at a confining pressure of 200 kPa, as shown in Figure 7a. Both samples were contractive and converged on a CSL of similar slope to that of GLU1, albeit offset upwards by a void ratio of approximately 0.11. This "non-uniqueness" of the CSL is attributed to subtle variations in grain size distribution (and more specifically grain packing) and potentially initial void ratios of loose samples used to define CSLs for GLU1, GLU2, and GLU3. The "non-uniqueness" of CSL in e-logp' plane has been reported in the literature for several types of soils, e.g. Verdugo et. al (1995), Naesgaard and Byrne (2005), Martins et al. (2001), Nocilla et al. (2006), Shipton and Coop (2012), and Todisco and Coop (2019).

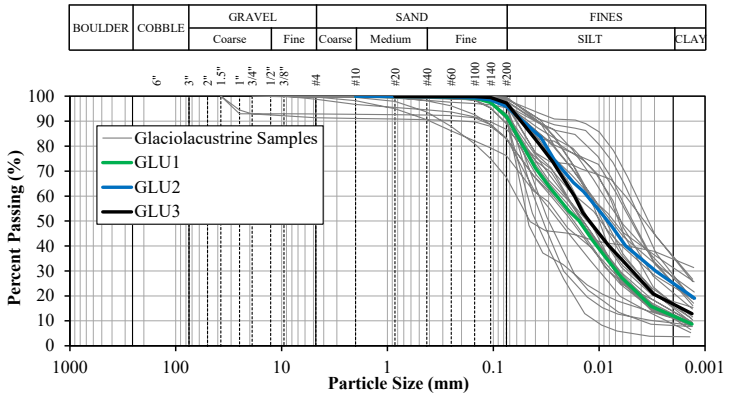

Figure 6: Comparison of GLU3 gradation with those of GLU1 and GLU2

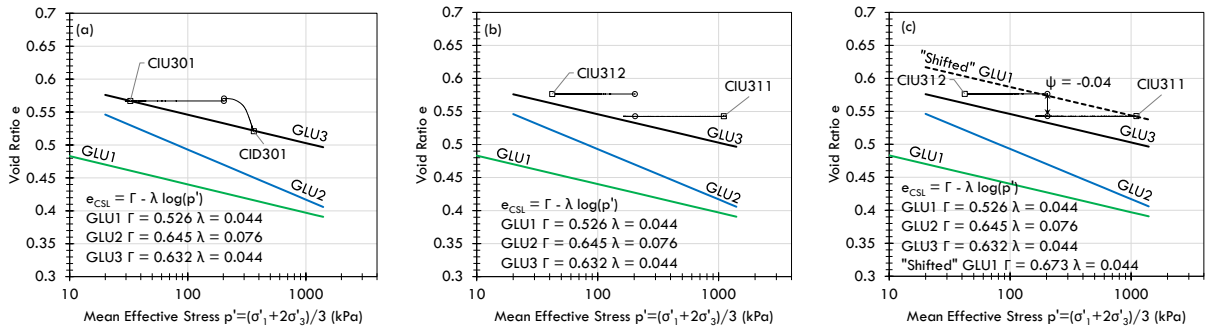

Figure 7: CIU triaxial tests on (a) reconstituted GLU3 samples, (b) intact Shelby and reused GLU3 samples, and (c) "Shifted" GLU1 CSL

Figure 7b shows the results of a CIU test (CIU311) on an intact Shelby tube sample of GLU3, recovered from directly below the Sonic core sample within the same borehole. CIU311 had an initial void ratio slightly above the CSL for GLU3, so it was expected that this specimen would be contractive or neutral in terms of pore pressure generation. Instead, the specimen was dilative with the state path moving away from the CSL, as shown in Figure 7b.

Following CIU311, the specimen was broken apart, thoroughly mixed, and reconstituted (moist tamped) to a similar, albeit slightly looser, initial void ratio. This allowed a direct comparison of behavior with the only difference being that the intact sample in CIU311 had the in-situ laminated fabric preserved, whereas the sample in CIU312 was completely homogeneous, with the acknowledgement that some minor gradational changes may have occurred as the material was retested. As shown in Figure 7b, the sample in CIU312 was now contractive and trended towards the reconstituted CSL of GLU3.

The comparison of CIU test results on intact Shelby tube and reconstituted samples of GLU3 clearly demonstrate the effects of soil fabric on the position of the CSL for this material. The difference in behavior is attributed to the fine laminated and heterogeneous structure of the in-situ material when compared to the uniform homogeneous reconstituted specimens. Similar observations of the effects of microlaminations on the position of the CSL for a tailings material were reported by Reid et al. (2021). Interestingly, the introduction of laminated structure appears to affect the vertical position of the CSL (specifically the term Γ) but does not appear to significantly change the slope (λ) of the CSL. This may be because λ is controlled by soil mineralogy as opposed to structure or minor gradational differences.

The NorSand constitutive model, which was previously developed for GLU1, was used to simulate the results from the intact GLU3 specimen in CIU311. In this case, the same NorSand parameters developed for GLU1 were used, with the exception being that the CSL was "shifted" upwards so that it coincided with the end point of CIU311 (refer to Figure 7c). The results of the NorSand simulation for CIU311 are shown in Figure 8. In general, the test data fit very well which demonstrates that the effects of in-situ laminated structure for this material are captured by changing the vertical position of the CSL (i.e. Γ), without change to λ, or to the other NorSand parameters.

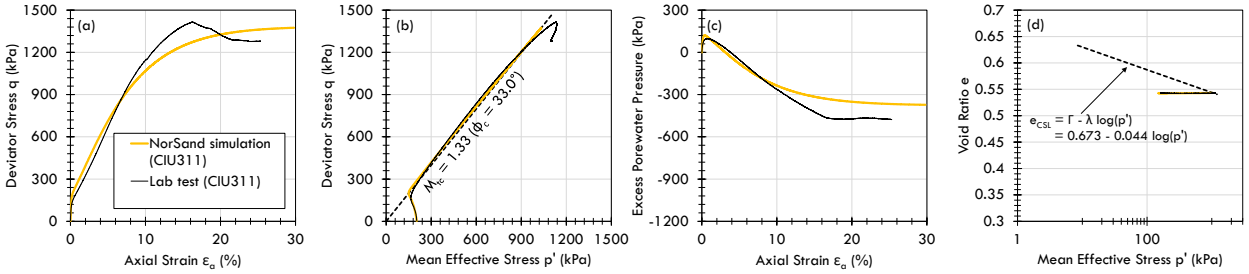

Figure 8: Comparison of NorSand simulation and test data for CIU311 (a) stress-strain, (b) p' – q, (c) excess porewater pressure, and (d) e – log p'

Influence of CSL variations on in-situ state parameter interpretation

The influence of CSL position on the ψ_o interpretations of GLU soils were investigated via cavity expansion numerical simulations. These simulations were completed under both drained and undrained conditions, using a Fortran based executable code referred to as "CPTwidget V3.1" (Shuttle 2018a; Shuttle, 2018b; Shuttle, 2018c). CPTwidget simulations were used to determine CPTu inversion coefficients, which were subsequently used to calculate ψ_o from measured CPTu data using equations recommended by Jefferies and Been (2016).

The work herein suggests that a laminated soil deposit is likely represented by a wide range of CSLs, all of similar slope (λ) but variable elevation (Γ), depending on subtle variations in laminated structure and gradation. It would also appear that the CSL of reconstituted "homogenous" materials are positioned at lower elevation on the e-log p′ plane, when compared to those of intact laminated specimens.

Figure 9 shows a comparison of interpreted ψ_o for a representative CPTu probe at the site. The analysis was first carried out by inversion using the CPTwidget and implementing the NorSand parameters established for GLU1. The process was then repeated with the only change being that Γ was increased to be consistent with the in-situ GLU3 CSL (refer to Figure 7c). From Figure 9, it is observed that changing Γ did not change the interpretation of ψ_o by inversion using the CPTwidget. This is because the cavity expansion methods used to interpret in-situ state from the dilative/contractive response of the CPTu are based on in-situ ψ_o as an offset from CSL as opposed to a direct measure of in-situ void ratio (e_0), and as such are not affected by variation of Γ.

This is an important finding because it suggests that provided the λ is unchanged during the reconstitution process (as appears to have been the case for the GLU material tested herein), the interpreted ψ_o from cavity expansion simulations in laminated soils can be considered as reliable even when the testing has been completed on reconstituted specimens where the laminated structure has been obliterated. This was confirmed by comparing the ψ_o of the CIU311 specimen from the laboratory testing data and using the interpreted intact CSL for GLU3 (refer to Figure 7c) with the in-situ ψ_o from the CPTWidget at the same depth (refer to Figure 10). In both cases the interpreted ψ_o was the same (-0.04) which appears to validate the approach.

When estimating the in-situ ψ_o of laminated soils, it is important to compare "absolute" void ratio measurements, such as those obtained from bulk density or natural water content of saturated samples, with critical state void ratios obtained from CSLs based on laboratory tests of intact laminated soil specimens. Using CSLs from reconstituted specimens to estimate in-situ void ratios may be inaccurate due to the vertical shift in the CSL for reconstituted versus intact samples.

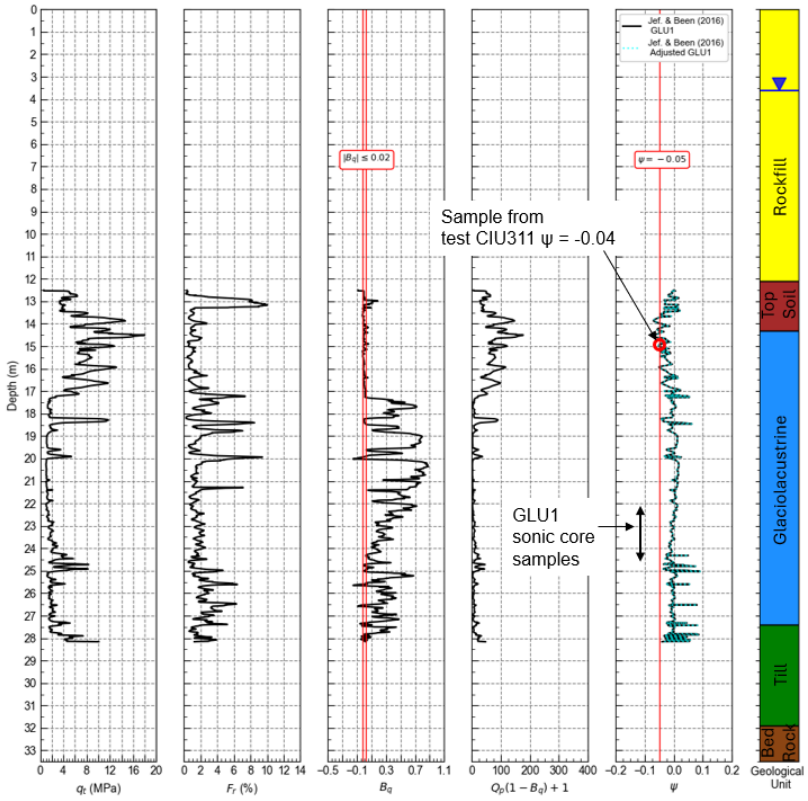

Figure 9: Interpreted in-situ state parameters for GLU1

Conclusion

A series of drained and undrained triaxial compression tests were conducted on reconstituted specimens of a fine-grained glaciolacustrine (GLU) soil to determine its CSL. Triaxial tests were also performed on intact Shelby tube samples and the results were compared to the CSL of reconstituted specimens. The following conclusions arose from this study:

1. A laminated glaciolacustrine deposit is characterized by a variety of similarly shaped (i.e., parallel) CSLs which vary in elevation (i.e., Γ) depending on differences in structure and gradation.
2. The CSL of reconstituted specimens were generally lower in elevation (i.e., Γ) when compared to those of the intact laminated specimens.
3. Provided the slope (λ) of the CSL does not change as a result of sample reconstitution (as was the case for the material tested herein), the loss of laminated structure induced by sample reconstitution does not adversely influence the reliability of ψ_o interpretated using CTP inversion (i.e., CPTWidget).
4. Caution must be used in laminated soils when comparing estimates of in-situ state based on "absolute" measurement of void ratio with interpreted critical state void ratios obtained from CSL's derived from laboratory testing of reconstituted specimens. In that case, the vertical shift in

reconstituted CSL arising from sample reconstitution may have a significant impact on the estimated in-situ ψ_o, which may lead to gross misunderstanding.

Mechanical Behavior of Gold Mine Tailings Dried by Natural Dewatering

Mayara Ferreira Rodrigues, Federal University of Rio de Janeiro – UFRJ, Brazil
Paula de Mello Martins, Ex-AngloGold Ashanti, Brazil
Jaime Pinheiro, AngloGold Ashanti, United States of America

Abstract

The various dam failures that have happened globally have resulted in changes in Brazilian legislation. As a result, the disposal of dry tailings in piles or stacks has become a widely used alternative, giving rise to a need to better understand the behavior of these tailings when dried and mechanically compacted in layers. Therefore, it is necessary to carry out experiments on a smaller scale with field and laboratory tests to evaluate the best construction methodology and geotechnical parameters to be adopted. This paper originated from the results of experimental landfills, and presents the field and laboratory results of the mechanical behavior of the naturally dewatered gold ore tailings, submitted to compaction with a road roller compactor and with a bulldozer. To this end, disturbed samples were used for characterization, compaction, and resistance tests and undisturbed samples were collected for resistance and permeability tests, in addition to the results of tests carried out in experimental landfills to verify the compaction conditions of the tailings.

The analyzed tailings come from the calcination process, part of the metallurgical process of gold ore beneficiation, classified as sandy silt with clay, with a specific gravity between 3.435 g/cm³ and 3.790 g/cm³, a maximum dry density between 1.384 g/cm³ and 1.516 g/cm³ and an average optimum moisture content of 33.5%. The resistance tests performed by undrained triaxial compression in the saturated condition showed null effective cohesion and a mean effective friction angle of 26°.

Although the experimental embankments did not aim to evaluate the dilating or contractile behavior of the tailings under the compaction conditions imposed by the experiment, or even its liquefaction potential, the analysis of the results allowed for this evaluation in an initial way, and it is now necessary to carry out specific tests to enable better data regarding such behaviors.

Introduction

The global history of accidents with dams, including notorious events in Brazil, has initiated the trend of disposal of tailings in piles or stacks, making it necessary to expand geotechnical studies related to tailings,

which can have considerable variations in geotechnical behavior.

Fourie et al. (2022), highlight that mining is growing, with production increasing every year. At the same time, ore bodies tend to have less and less ore content, which makes the increase in tailings generation into tailings disposal structures even larger. This reinforces the need to improve mining tailings disposal management processes, rethink design criteria, existing monitoring technologies, processes used, and several other issues.

For the construction of large geotechnical structures using materials whose behavior is not well known, it is necessary to carry out experiments on a smaller scale, using field and laboratory tests to evaluate the best construction systems and geotechnical parameters to be adopted in the project.

The main motivator of the experiment presented here was the need for a dam that receives the pulp tailings from the pyrometallurgy calcination process, one of the stages of gold ore processing. In this way, the tailings hydraulically deposited would go through a natural dewatering process and be deposited in piles.

It is noteworthy that this article is restricted to the results of the experimental landfill performed, considering tests carried out in situ and in the laboratory, and from these tests the characterization of the tailings, hydraulic conductivity and resistance parameters were determined. Evaluations of the contractile or dilating behavior of this tailings, as well as the potential for liquefaction, are initially based on the available results and were not the objective of the experimental landfills.

The study considered the execution of two experimental landfills, one with material compacted through a road roller compactor without vibration, called Experimental Landfill I, and the other compacted by a bulldozer, called Experimental Landfill II.

Materials and methods

Origin and processing of gold ore

The tailings analyzed come from the processing of gold ore mined from two underground mines located in the Iron Quadrangle of the state of Minas Gerais in Brazil.

Ore is extracted from underground mines and goes through the following processing stages: primary crushing, grinding, gravimetric separation, and flotation. In flotation, the separation takes place in two distinct processes, also separated into two parts, composed of 10% of the volume and 90% of the volume. The material that makes up 10% of the volume that comes out of the flotation is directed to metallurgy, where it goes through the processes of repulping, roasting, leaching, solid/liquid separation, CIP (Carbon in Pulp) processing, elution, precipitation with zinc and, finally, casting. In this metallurgical process, the tailings studied here are generated.

These tailings were directed to the reservoir of the dam, hydraulically disposed of by spiking along the reservoir, from where it was excavated and transported in weighbridge trucks to the site of the experimental landfills.

Characteristics of experimental landfills

In order to understand the behavior of the tailings when subjected to compaction, two different landfills were carried out, one with compaction of the tailings through a road compaction roller without vibration, called Experimental Landfill I, and the other with compaction of the tailings through the passage of a bulldozer, called Experimental Landfill II.

To prepare the foundation of the experimental landfills, a liner was laid in layers of waste material totaling a thickness of 80 cm. Then, above this liner, 3 layers were laid with the tailings itself with a thickness of 30 cm each and compacted to a degree of compaction equivalent to 95% Proctor and a moisture content in the range of ±2% in relation to the optimal moisture content. These layers served as the basis for the beginning of the experimental embankments and were defined to minimize the influence of the difference between materials and the stiffness of the soil in relation to the compacted landfill.

The tailings used in the experimental landfills were excavated with excavators and transported to the area close to the piles with dump trucks. At the time of excavation, the average moisture content of the tailings was approximately 52.4% and the optimum moisture content obtained through the standard Proctor compaction test was 33.5%. Treatment was needed to reduce the moisture. This treatment was carried out with a tractor with tires and rotating blades, and when the tailings reached the optimum moisture content, they were again transported to the area defined for the experimental landfills.

At the ends of both experimental area ramps, an acceleration and maneuvering area was maintained, approximately 20 m long and 20 m wide, so that the movement of machinery and equipment did not interfere with the control of the layers.

In Experimental Landfill I, tests were carried out to verify the degree of compaction after every two passes carried out by the compactor. This procedure was followed until 8 passes of the equipment were completed for the compaction of the layer. In the Experimental Landfill II, the degree of compaction was verified with 2, 4, and 6 passes of the compaction achieved by the bulldozer.

Table 1 presents the general characteristics of the experimental landfills.

Table 1: Characteristics of experimental landfills

Item	Landfill I	Landfill II
Compaction method	Road roller compactor without vibration	Bulldozer
Layer thickness (cm)	30	30
Width (m)	25	20
Height (m)	1.20	0.90
Volume (m³)	5.600	3.600
Moisture content for compaction	W_{opt} ±2%	W_{opt} ±2%

Sampling and laboratory and field tests

Samples were collected and assays were performed according to the standards shown in Table 2.

Table 2: Standards used as reference

Norm	Assay
ABNT NBR 6457:2016	Soil – Preparation of samples for compaction tests, characterization and determination of moisture content
ABNT NBR 6459:2017	Soil – determination of the liquidity limit
ABNT NBR 6508:2016	Cobblestone grains retained in the opening sieve 4.8 mm – Determination of specific mass, apparent specific mass and water absorption
ABNT NBR 7180:2016	Soil – determination of the plasticity limit

ASTM D4767-11:2020	Standard test method for consolidated undrained triaxial compression test for cohesive soils
ASTM D7181-11:2015	Standard test method for consolidated drained triaxial compression test for soils

Compaction control tests were performed in all layers using the Hilf methodology to verify the density and moisture content in situ. In addition to the in-situ tests, disturbed samples were collected from both experimental landfills for laboratory tests, for characterization and compaction. Undisturbed samples of the block type from the Experimental I embankment were collected for resistance and permeability tests. These results are presented in the following section.

The triaxial compression tests in the drained condition were performed in specimens prepared from the undisturbed samples, saturated by percolation and back pressure and at confining stresses of 100 kPa, 200 kPa, 400 kPa, and 800 kPa, both for the drained and undrained tests.

Results

The tailings are classified as sandy silt with little clay, have a specific gravity between 3.435 g/cm³ and 3.790 g/cm³, a maximum dry density between 1.384 g/cm³ and 1.516 g/cm³, and an optimum moisture content ranging from 31.9% to 38.2%. The results of the characterization and compaction tests performed on the samples collected in the experimental landfill are summarized in Table 3.

Table 3: Summary of characterization and compaction tests

Sample	Particle size distribution				Specific gravity (g/cm³)	Liquidity and plasticity limits			Standard Proctor compaction	
	Clay (%)	Silt (%)	Sand (%)	Gravel (%)		Liquid Limit (%)	Plastic Limit (%)	Plasticity Index (%)	Maximum dry density (g/cm³)	Optimal moisture content (%)
1	13	67	19	1	3.649	Non-liquid	Non-plastic	Non-plastic	1.384	34.0
2	10	76	14	0	3.664				1.451	31.9
3	11	63	21	5	3.790				1.470	37.9

10	12	78	10	0	3.821				1.347	42.8

Two undisturbed samples of the block type were collected at Experimental Landfill I, identified as AI-01 and AI02, and were submitted for isotropic triaxial compression tests of the drained and saturated type (CIDsat) and the saturated undrained type (CIUsat), at the confining stresses of 100 kPa, 200 kPa, 400 kPa, and 800 kPa. Permeability tests at constant load were also carried out on specimens molded in the blocks, vertically and horizontally to the compaction plane. On a disturbed sample, identified as AD-01, an isotropic triaxial compression test of the drained and saturated type (CIDsat) was performed at the confining stresses of 200 kPa and 400 kPa and of the saturated undrained type (CIUsat), at the confining stresses of 100 kPa, 200 kPa, 400 kPa and 800 kPa, all specimens molded under two conditions. One with a degree of compaction of 90% and optimum moisture content and the other with a degree of compaction of 98% and

optimum moisture content, in relation to the standard Proctor compaction test. The results are presented in Table 4 below.

Table 4: Summary of strength and permeability tests

Sample	CIUsat				CIDsat		Permeability at constant load	
	Cohesion (c)	Friction Angle (ϕ)	Cohesion (c')	Friction Angle (ϕ')	Cohesion (c')	Friction Angle (ϕ')	Vertical (cm/s)	Horizontal (cm/s)
AD-01 – GC=90 %	0	12	0	22	10	31	–	–
AD-01 – GC=98 %	0	16	0	28	–	–	–	–
AI-01	0	14	0	23	12	22	9.75E-05	2.04E-04
AI-02	0	17	0	33	12	22	9.75E-05	2.10E-04

In Experimental Landfills I and II, tests were carried out to verify the density and moisture content in situ as the number of passes of compactor equipment increased. The summaries of the results of each experimental landfill are presented in Table 5 and Table 6 below.

Table 5: Results of the verification of density and moisture content in situ carried out at Experimental Landfill I

Assay	In-situ density verification				Number of passes of the equipment over the layer

Discussion of the results

As previously shown in Table 3, the particle size analyses showed a sandy silt matrix material, with about 75% silt and 20% fine sand, with specific gravity ranging from 3.435 g/cm³ to 3.821 g/cm³, non-plastic. These values of the actual specific gravity fit within the variability of the specific gravity of mining tailings (from 1.5 g/cm³ to 3.8 g/cm³) proposed by Fourie et. al. (2022). Figure 1 shows the particle size range obtained from the particle size curves of the tests performed.

In this same figure, the ranges of materials susceptible to liquefaction and of materials with greater susceptibility to liquefaction are indicated, determined by the limits for analysis of liquefaction potential suggested by Terzaghi, et. al. (1996) (*apud* Tsuchida, 1970). The liquefaction process can be defined as the abrupt reduction of the effective tension as a function of an undrained loading in a saturated granular soil. It can be seen that part of the particle size range of the analyzed tailings is within the lower limit of the particle size distribution of the materials susceptible to liquefaction suggested by the authors for an initial evaluation of the liquefaction potential. Therefore, geotechnical studies aimed at the mechanics of soils in a critical state are necessary.

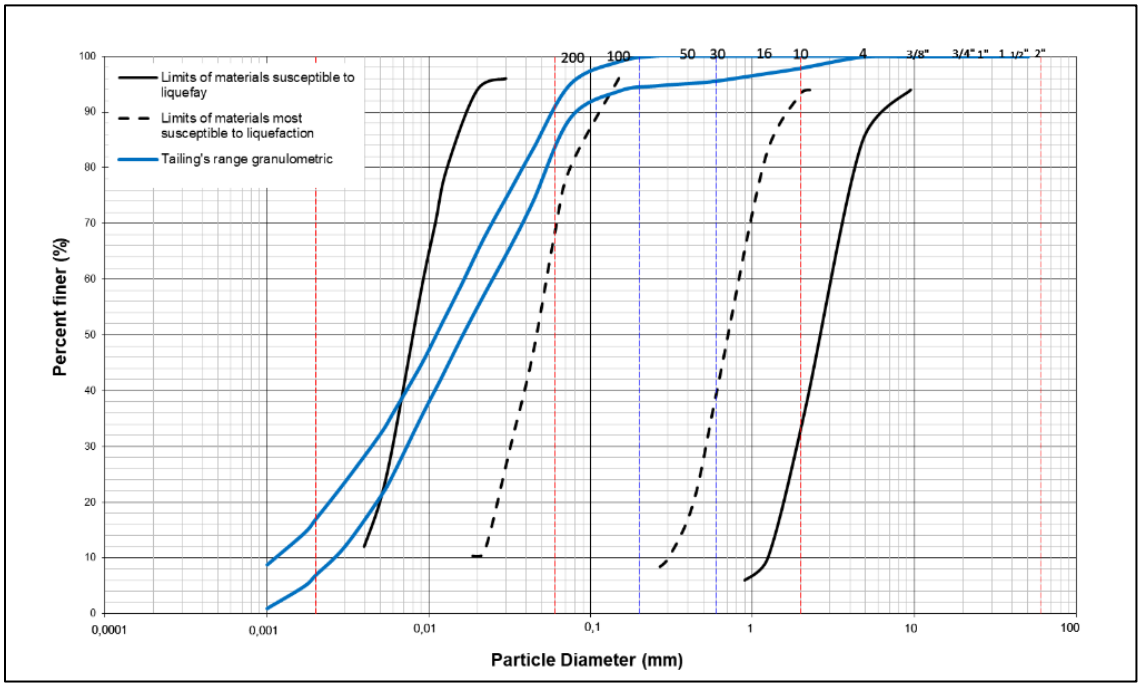

Figure 1: Particle size range of the tailings

The standard Proctor compaction tests showed an average maximum dry density of 1.469 g/cm³ and an average optimum moisture content of 33.5%. To determine the mean values, the result of sample 10 was disregarded because it was outside the sample standard deviation. The consolidation of the curves of the

standard Proctor compaction tests performed is shown in Figure 2, where it is also possible to highlight the mean curve obtained.

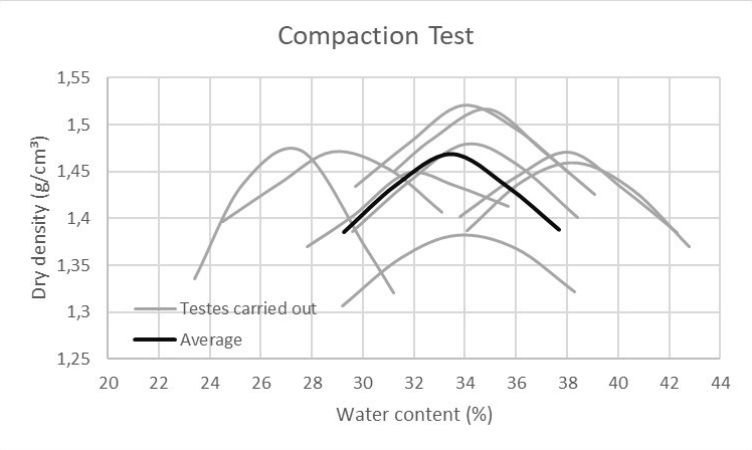

Figure 2: Consolidation of the standard Proctor compaction curves of the tests performed

When analyzing the degree of in-situ compaction from the two different conditions employed in the two experimental landfills, it can be seen that the tailings can be well compacted both using a road roller compactor or a bulldozer. Also, as expected for soil compaction, whether natural or not, there is a gain in the degree of compaction as the number of passes of compactor equipment increases. Another observation from the analysis of the tests is that, for this tailings, 4 passes of compaction equipment are sufficient to achieve a degree of compaction equal to or greater than 98%. These observations can be seen in the graph shown in Figure 3.

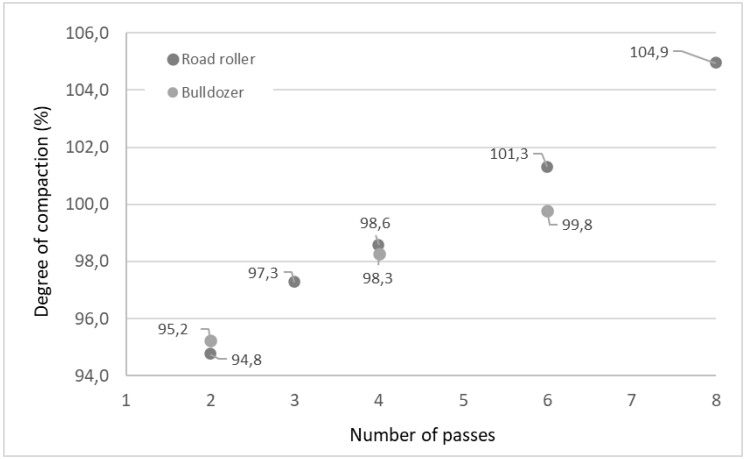

Figure 3: Graph of the degree of compaction as a function of the number of passes and type of equipment used for compaction

According to the results presented, the resistance tests performed on undisturbed samples indicate that the material has zero cohesion and an average effective friction angle of 28º for a degree of compaction of

approximately 98%. While the test performed on specimens molded at a degree of compaction of approximately 90% also indicates zero cohesion and an effective friction angle of 22º, in this test condition the tailings showed contractile behavior, as shown in Figure 4. It is noteworthy that for the tests performed on undisturbed samples whose degree of compaction was approximately 98%, this behavior was not observed.

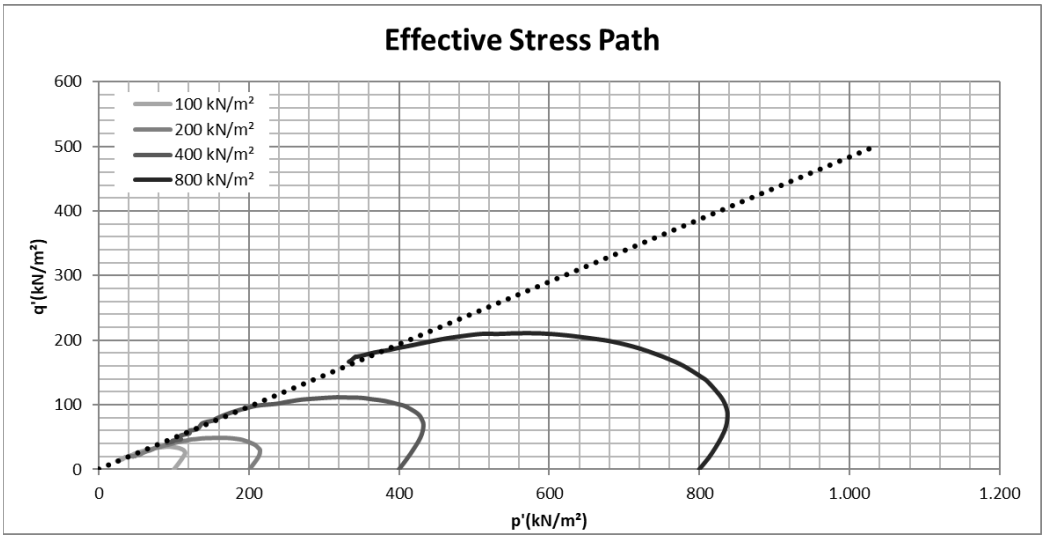

Figure 4: Effective stress trajectory of the CIUsat test performed on molded specimens at GC=90%

Based on the behavior of the tailings previously observed in Figure 4, it is necessary to develop more in-depth studies to establish the critical state line of this tailings and the trend of behavior as the degree of compaction increases.

To study the critical state line, Viana da Fonseca et al. (2021) highlighted that the most appropriate procedures for triaxial compression tests include the use of enlarged and lubricated extremities and recommend that the specimens be frozen at the end of the test to verify the total saturation condition and obtain the final moisture content. The authors explain that these procedures reduce the friction effect at the top and bottom of the specimens, allowing the deformations during the shear step to be more uniform. These procedures were not performed for the triaxial compression tests presented here. In addition, a test campaign was not carried out with laboratory-molded specimens in different degrees of compaction.

Conclusion

The results show that it is possible to carry out the compaction of these tailings in layers of 30 cm thickness both with a smooth roller and with bulldozer equipment. It is noteworthy that bulldozer equipment for the compaction of soils or tailings must be used with caution and supervision, to ensure that there is no

heterogeneity in the compaction of the layers, in strips or zones that the tracks of the bulldozer have not covered, creating fluffy or more fragile zones.

Regarding the evaluation of the liquefaction potential of the tailings, the tests carried out were insufficient to define the line of the critical state of the tailings. A complementary study is necessary for a better understanding of the behavior of the material.

There is a fundamental need to further the studies, and to widely share the results and experiences with the various types of tailings. There is also a fundamental need to review previously existing concepts in order to improve the disposal of dry tailings in piles or stacks, thus contributing to the quality of the processes and the structures, and developing a better technical basis for projects.

Finally, it cannot be said that the same parameters obtained in these tailings will be achieved in other materials, since the mechanical behavior of the tailings depends on several factors, especially the industrial processes used from mining to processing, the regional geology, and the mineralogical composition.

Analysis of Video Images Obtained during Cone Penetration Testing

Gerald Verbeek, Eijkelkamp North America, USA
Gustavo Hamu, Royal Eijkelkamp, The Netherlands
Oksana Khomiak, TU Bergakademie Freiberg, Germany

Abstract

One of the ways to enhance the efficiency of the cone penetration testing process is to mount modules behind the cone. In this way the test will not only generate the standard CPT data (i.e., cone tip resistance, sleeve friction, and dynamic pore water pressure) but also the data obtained by the module pushed into the soil together with the cone. While for certain modules it is common practice to analyze the acquired data extensively (e.g., the seismic module) for other modules this is not necessarily the case. A good example of the latter is the video module when it is deployed with visible light, in which case the analysis is typically limited to viewing the recording and adding observation notes. During the recent TRIM4 research project the video module was deployed and initial attempts were made to identify the soil type and to determine the grain size distribution using the video images. This approach mitigates the effect of the CPT data, reflecting changes in soil strength behavior before a layer is actually penetrated by the cone. In this paper the authors will describe the analysis options they have identified for the video recordings.

Introduction

Cone Penetration Testing (CPT) is a widely accepted and applied soil investigation technique and the data generated during the testing (the cone tip resistance, the sleeve friction and the dynamic pore pressure) are used as inputs in numerous geotechnical and geohydrological engineering processes (e.g., the design of deep foundations, the assessment of the hydraulic conductivity of the soil, and the assessment of the condition of tailings storage facilities). To supplement the data acquisition one or more modules can be installed behind the cone and depending on the type of sensors mounted in the module, information can be obtained; for example, on seismic wave speed through the soil (when using a seismic module) or on the electric conductivity of the soil (when using a dieelectric module).

A module type that is not frequently used is the video module, which contains a camera that records data as the cone is pushed into the ground. This module is often used in combination with UV light sources

to record the visible light emitted by certain contaminants as they absorb UV light. Analysis of that visible light (intensity and frequency) can provide useful information on the type and extent of the contamination, which is very useful in geoenvironmental investigations.

However, the video module can also be used in combination with visible light to simply record imagery of the soil passing by the lens as the cone penetrates the soil. The analysis of that data is typically limited to viewing the recording and adding observation notes, but during the recent TRIM4 research project the video module was deployed and initial attempts were made to identify the soil type and to determine the grain size distribution using the video images.

TRIM4 Research Project

The TRIM4Post-Mining Research Project was a project funded by the European Union that brought together a consortium of European experts from industry and academia to develop an integrated information modelling system, designed to support decision making and planning during the transition from coal exploitation to a revitalized post-mining landscape, enabling infrastructure development for agricultural and industrial utilization, and contributing to the recovery of energy and materials from coal mining dumps. The basis of this system is a high-resolution spatiotemporal database, utilizing state-of-the-art multi-scale and multi-sensor monitoring technologies, which allow characterization of dynamic processes in mining waste dumps related to timely, dependent deformation and geochemical processes. As such it integrates efficient methods for operational and post-mining monitoring, comprehensive spatiotemporal data analytics, feature extraction, and predictive modelling; this then allows for the identification of potential contamination areas and the forecasting of geotechnical risks and ground conditions.

For the interactive exploration of alternative land-use planning scenarios – in terms of residual risks, technical feasibility, environmental and social impact, and affordability – up-to-date data and models are embedded in an interactive planning system, forming a TRIM – a Transition Information Modelling System. This system is designed to support decision making and planning during the transition from mine exploitation to a re-vitalized post-mining landscape enabling infrastructure development for agricultural and industrial utilization, and also to contribute to recover energy and materials from coal mining dumps.

Cone penetration testing (CPT)

For the TRIM4 Post Mining Project cone penetration testing was performed at two locations using a 10 cm^2 subtraction cone. The main objective of the CPT was to determine whether this soil investigation technique is useful to support decision making and planning during the transition from mine exploitation to a re-vitalized post-mining landscape enabling infrastructure development for agricultural and industrial utilization.

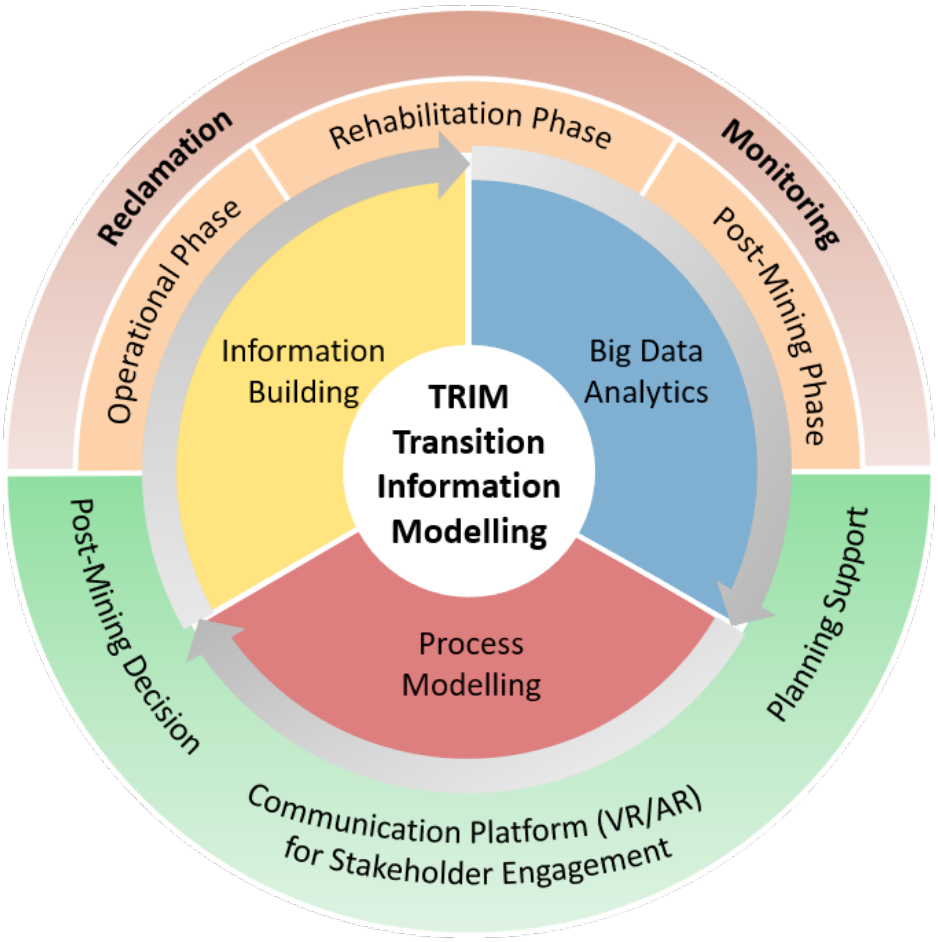

Figure 1: The structure of the TRIM

CPT – Location 1

At the first location CPT was performed to a depth of approximately 31 m when the tip resistance implied refusal. As shown in Figure 2 below, the data indicated that between a depth of 2 m and 18 m the cone tip resistance was generally low, with a sleeve friction that equated to a friction ratio of 2 % or higher, implying soil with a cohesive soil type behavior. Below 18 m the tip resistance increased, resulting in a lower friction ratio, implying the presence of soil with a granular soil type behavior. This was also clearly seen in the pore pressure readings. Due to the dynamic action associated with the testing, the recorded pore pressure increased, but then dropped to 0 kPa as soon as the cone entered the soil with a granular behavior, which allowed the excess pore pressure to dissipate immediately.

At the same location a soil boring was performed, and samples were obtained at various depths. The soil types for those samples were reported as shown in Figure 3 below, and they show a reasonable correlation with the soil type behavior derived from the CPT. While the two results don't match entirely, the results confirm the common understanding that CPT data can be used to obtain a realistic soil profile.

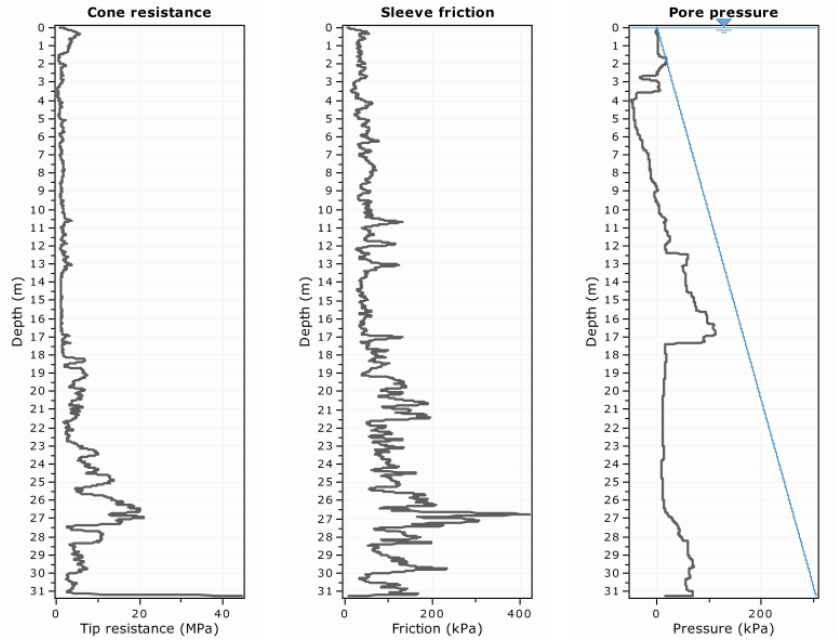

Figure 2: CPT data Location 1

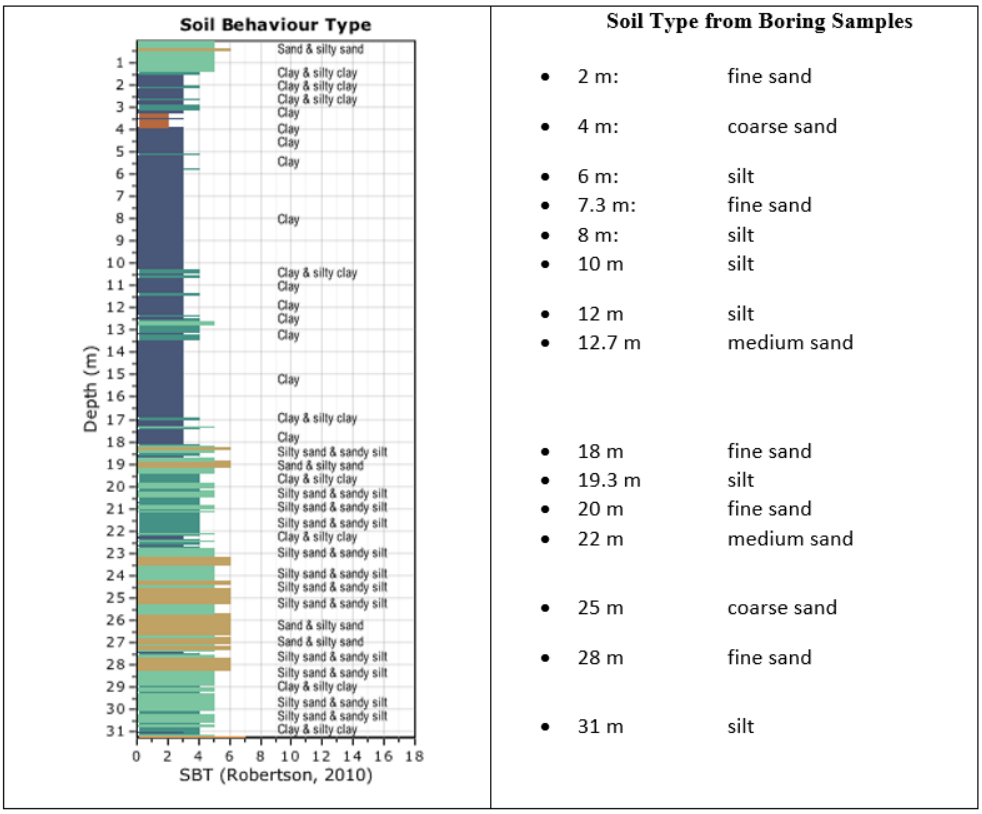

Figure 3: Soil profile characterization Location 1

CPT – Location 2

The CPT data for location 2 (see Figure 4) showed a different soil profile with mainly cohesive type soils down to approximately 44 m, albeit broken up by an intermediate granular soil type layer between 13 m and 21 m, with granular soil type underneath. Once again the dynamic pore pressure curve clearly showed the transition to the granular soil type at approximately 13 m. And while in a tailings facility there may be multiple hydrostatic regimes, it seems that the groundwater table was at a depth of approximately 40 m. This can be derived by simply extending the pressure reading once they follow the hydraulic gradient (as indicated in the light blue line) at say 45 m upwards until they cross the 0 kPa line.

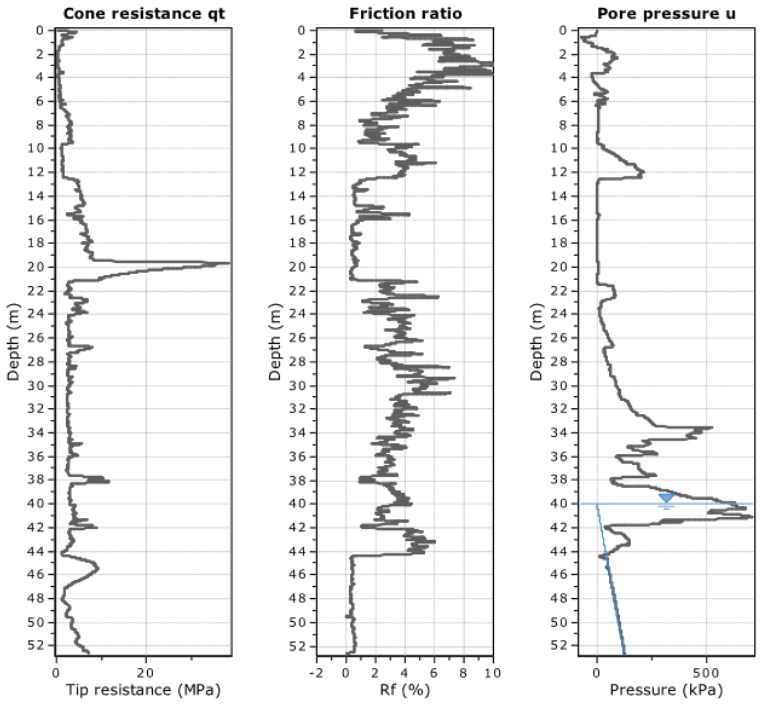

Figure 4: CPT Data Location 2

At this location a soil boring was performed as well with samples obtained at various depths. The soil types for those samples were reported as shown in Figure 5 below, and they show very good correlation with the soil type behavior derived from the CPT. Once again, while the two results don't match entirely, the results confirm the common understanding that CPT data can be used to obtain a reliable soil profile.

Video module

The video module used for the TRIM4 research project consists of a Standard Definition camera and 8 visible light LEDs housed inside a dedicated module and protected by a double layered sapphire window with a 10 mm x 10 mm view (see Figure 6). The module recorded images that showed the soil texture, color, and grain size as the soil passed the camera.

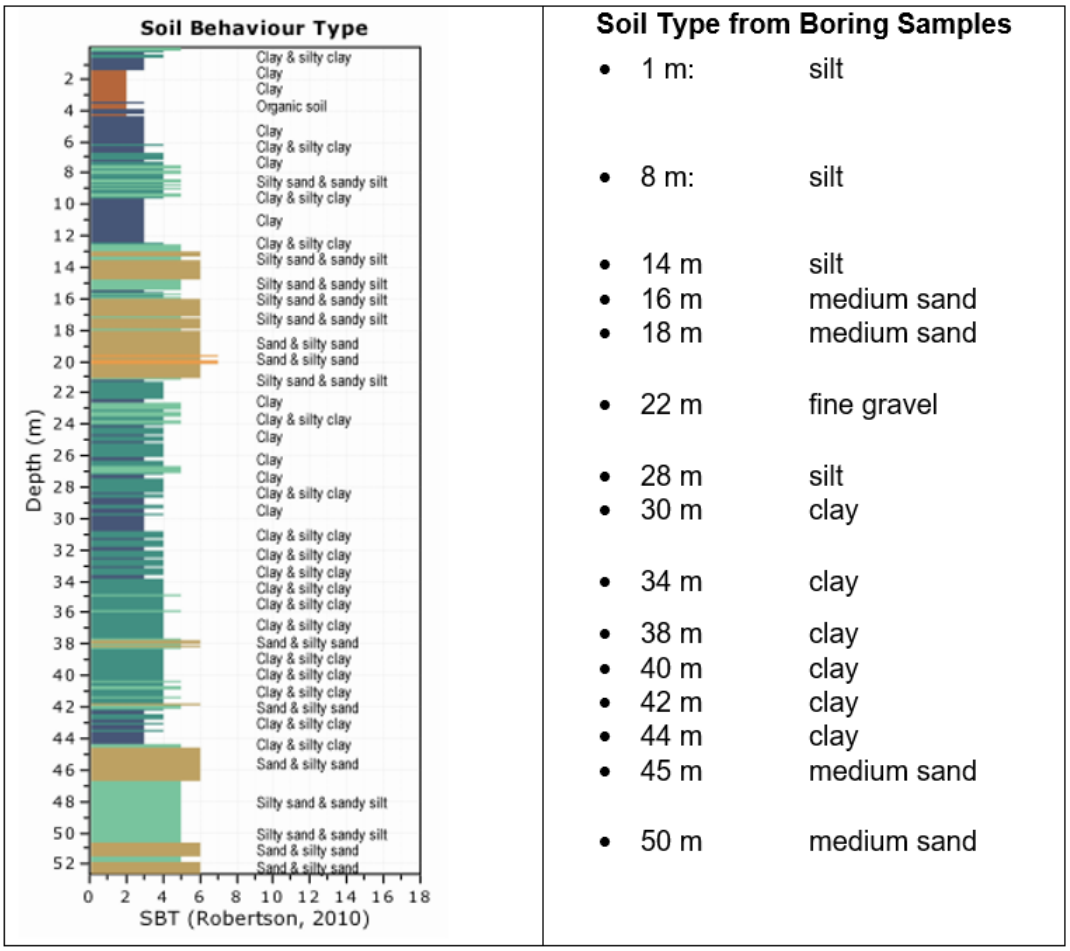

Figure 5: Soil profile characterization Location 2

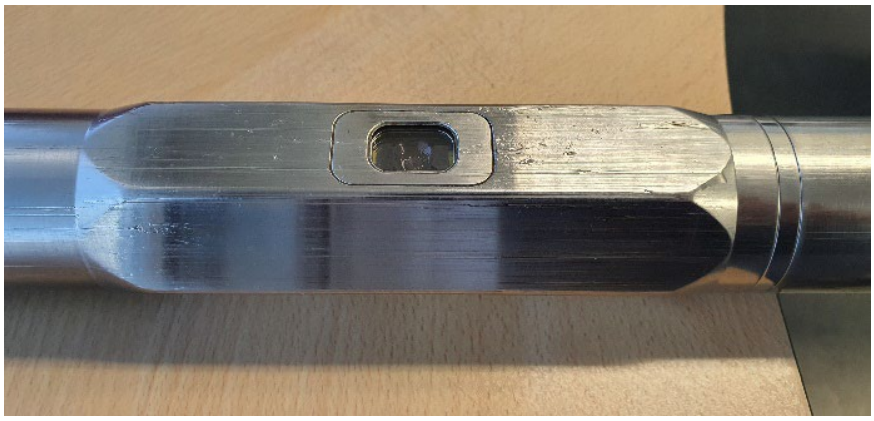

Figure 6: Video module

The initial intention was to try to derive a particle distribution from the recorded images by applying an automatic RBG interpretation to outline the particle in a particular image.as shown in Figure 7. During the project it became obvious that the resolution of the video images was not high enough to generate reliable results and it also raised the question whether fine particles were pushed into the soil away from

the cone, which would distort any particle distribution based on the soil immediately in front of the window. Based on this it was concluded that the test would have to be repeated with a high-definition camera.

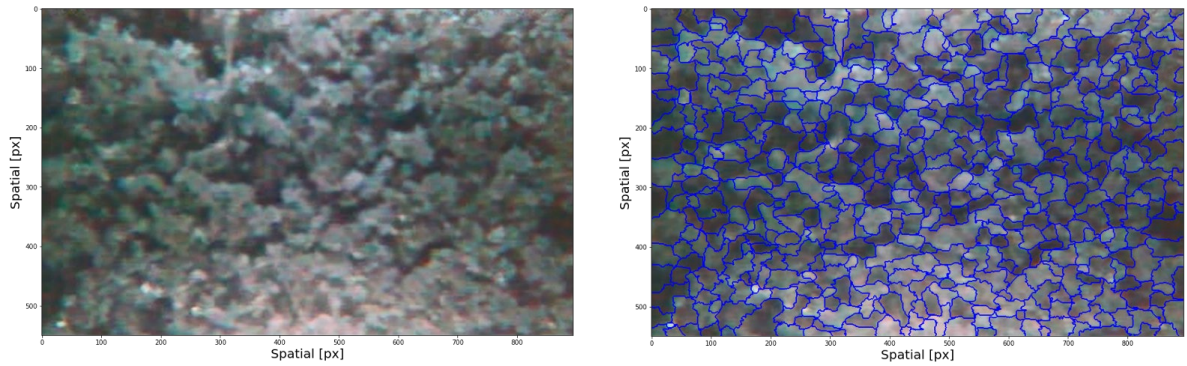

Figure 7: RGB interpretation of the video image shown at the left to delineate the soil particles (shown at the right) to derive a particle size distribution

Soil type transition identification based on video images

While the efforts to derive a particle distribution did not generate the desired results, the images did demonstrate that they can clearly identify transitions in the soil profile. To illustrate this, Figure 8 shows the image at 13.75 m, 13.99 m and 14.01 m, which clearly shows such a transition from granular to cohesive soils. And since they show the situation at a very specific depth, the images can define the transitions much better than the CPT data as both the tip resistance and the sleeve resistance are an average value for a certain (and different) depth interval.

Figure 8: Soil type transition based on video images at 13.75 m, 13.99 m and 14.01 m depth

The images were then analyzed as described in detail by Oksana et al. (2024). In summary the analysis involved a so-called *Grey level co-occurrence matrix (GLCM),* a statistical method to derive texture features considering the relationship between groups of two pixels in the image at certain distance and at certain angle. The distance parameter can range from 1 pixel to the entire image size, while for the angles 4 directions are used: horizontal (0°), diagonally upwards (45°), vertical (90°) and diagonally downwards (135°).

To describe the outcome there are two parameters:

- The GLCM Correlation, a measure of grey levels linear dependencies of neighboring pixels on an image.

$$\sum_{i,j=0}^{N-1} P_{i,j} \left[\frac{(i-\mu_i)(i-\mu_j)}{\sqrt{(\sigma_i^2)(\sigma_j^2)}} \right] \quad \text{(Equation 1)}$$

where μ_i and μ_j are mean values of GLCM and σ_i^2, σ_j^2 its variance. This correlation between neighboring pixels indicates their predictable and linear relationship and ranges -1 to 1.

- The GLCM Dissimilarity, which reflects the contrast of texture features using weights related to the distance from the GLCM diagonal.

$$\sum_{i,j=0}^{N-1} P_{i,j} |i-j| \quad \text{(Equation 2)}$$

To assess the use of this method 8 images were initially selected: 4 of soil that was cohesive and 4 others that depicted granular soil (see Figure 9). Each of these images was then analyzed in 3 directions: horizontally, diagonally and vertically and the results are shown in Figure 10.

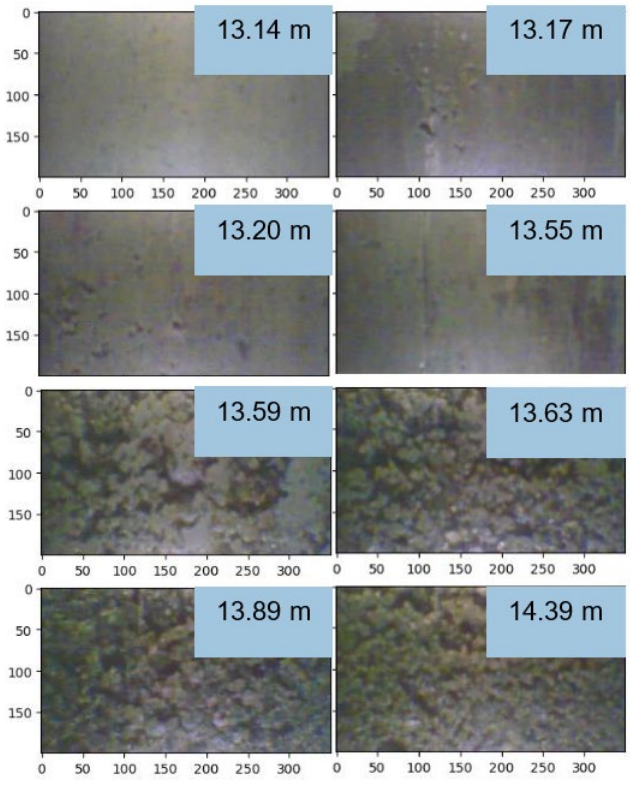

Figure 9: Video images to characterize soil type

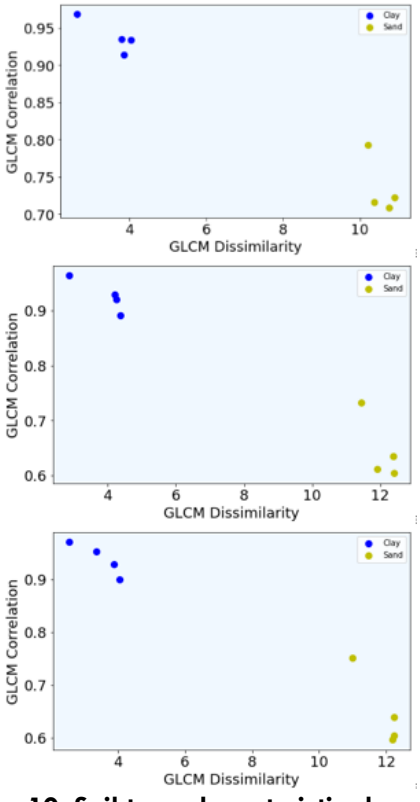

Figure 10: Soil type characteristics based on interpretation of video images (horizontally, diagonally and vertically from top to bottom)

The results showed clearly different values for both the correlation and dissimilarity for clay and sand, and very similar results for the 3 analysis directions. Given that outcome 13 minutes of video data was analyzed, again in 3 directions, with several distinct transitions between granular and cohesive soil. This time period covered the recordings of the depth interval between 11.52 m and 14.58 m related to the camera position (which equates to 11.95 m and 15.01 m based on the cone tip position). Once again for both parameters the results for the three different analysis directions (horizontal, diagonal and vertical) were very similar as is seen in Figure 11.

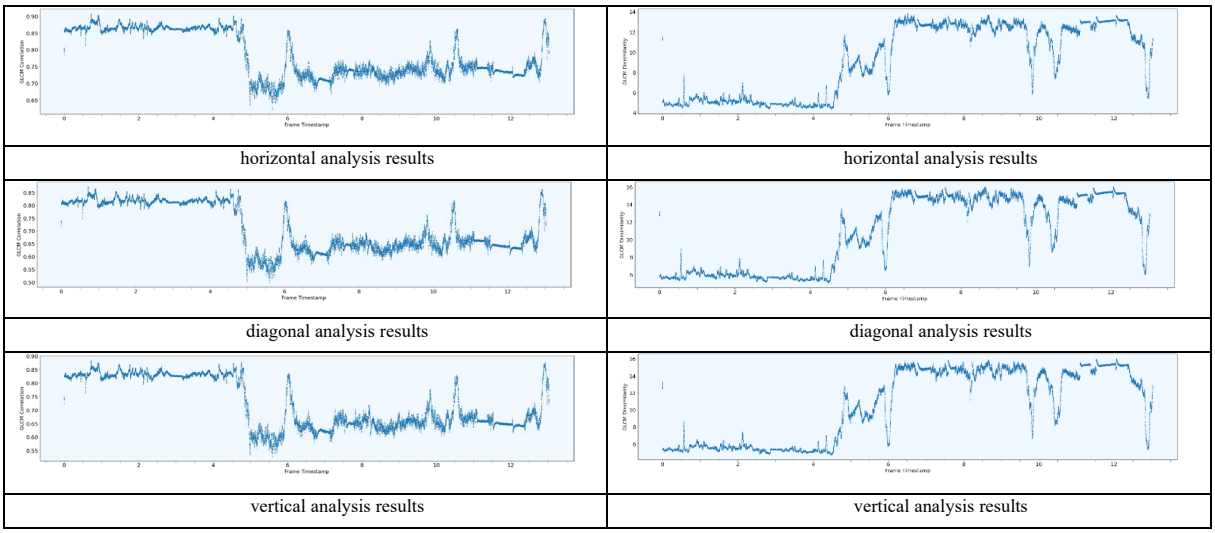

Figure 11: Soil type characteristics based on interpretation of video images (horizontally, diagonally and vertically from top to bottom); correlation values for 13 minutes of video images shown on the left and dissimilarity values for these images on the right

As the range of the dissimilarity values is larger (5 – 16 vs. 0.55 – 0.87 for dissimilarity and correlation values respectively), the dissimilarity results were then compared to the Soil Behavior Type (SBT) generated by the CPT data to try to correlate the results. It should be noted that these soil behavior types were confirmed as the actual soil types by soil borings that were performed in the direct vicinity of the CPT soundings. The outcome of the comparison of the SBTs and the dissimilarity values is shown in Figure 12, whereby in the graph for the dissimilarity results an initial attempt was made to classify the soils using the colors shown in Table 1.

Table 1: Color coding dissimilarity results

Soil type	SBT color	Video analysis color
Clay		
Clay & silty clay		
Silty sand & sandy silt		

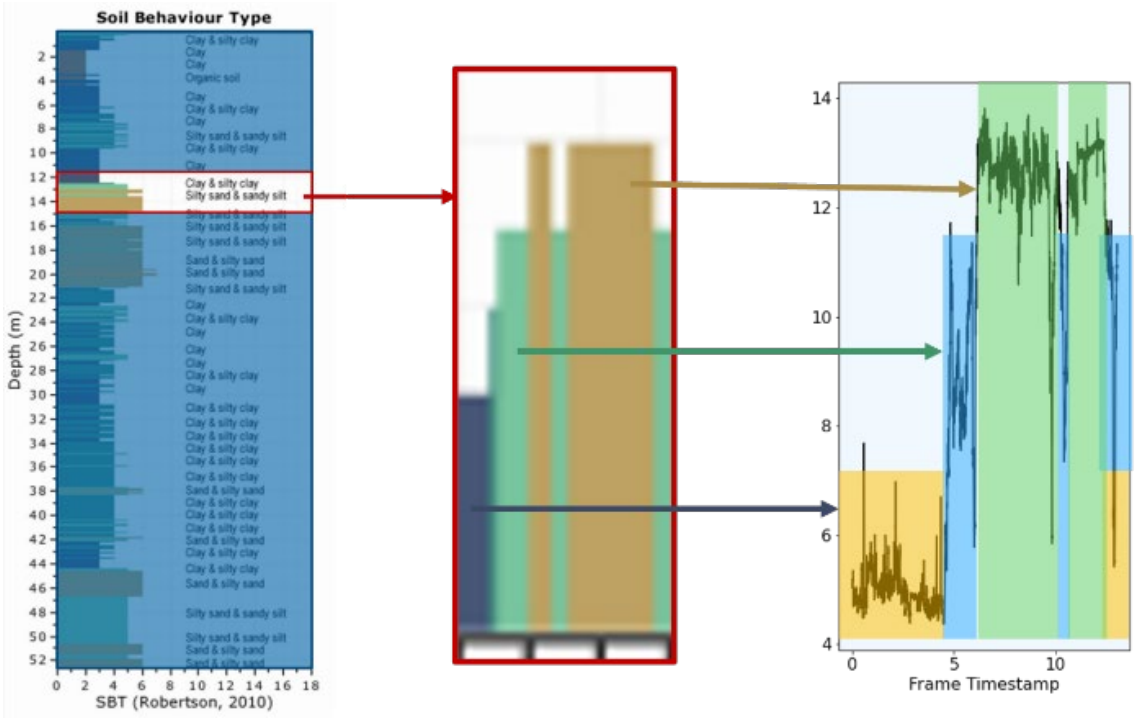

Figure 12: Dissimilarity values correlated with Soil Behavior Type with the graph in the center showing the Soil Behavior Types in the depth interval for which the comparison was made, and the graph on the right the dissimilarity results and interpretation

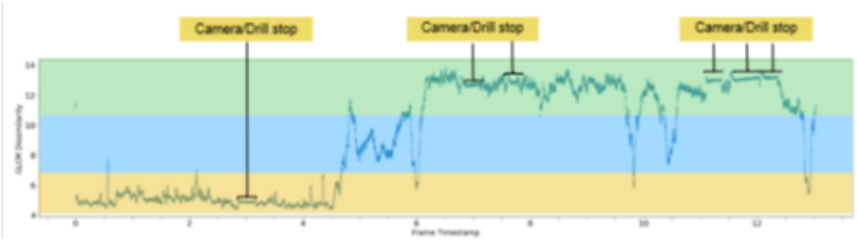
Since these seemed to be a good correlation the dissimilarity values for the same depth interval were also correlated with the actual SBT index values as shown in Figure 13. It should be noted that the sections in the graph where the cone was note moving (to add a CPT rod at the surface) are designated by the comment "camera/drill stop". Therefore, the camera depth values are listed with the associated cone tip depth. This cone tip depth values are then shown on the horizontal axis of the bottom graph that displays the SBC index values (I_c values). It is interesting to note that both characterizations show a distinct change from clay to more granular soils, but the I_c values (i.e., the CPT data) show this much sooner than the video data, reflecting once again the impact that the soil below the cone tip has on the readings.



Conclusion

The video images obtained with visible light during a standard CPT seem to show great potential for in-depth analysis instead of a perfunctory visible review of the recorded images. However, before this can become a standard practice more testing is required:

1. Future testing should be done using a High-Definition camera to obtain images that will provide more suitably imagery to delineate soil particles, from which a soil particle distribution can be derived.

2. The soil particle distributions generated during future testing should be validated with actual sieve analysis results.
3. Analysis of additional video data should be performed to determine the dissimilarity values and comparison with the Ic values to confirm the correlation.

The authors will continue to explore the analysis of visible data and hope to present more results at the Tailings and Mine Waste conference in 2025.

Predicting Tailings Properties Using Hyperspectral Sensing and Machine Learning

Joseph Bindner, ConeTec Group, Canada
Joseph Scalia IV, Colorado State University, USA
Christopher Bareither, Colorado State University, USA
Iman Entezari, ConeTec Group, Canada
Dallas McGowan, ConeTec Group, Canada

Abstract

Understanding tailings properties at high spatial resolutions is critical for geotechnical and geochemical analyses. While tailings properties can be characterized using undisturbed samples and in-situ tests, the current methods have limitations. Tailings properties determined from undisturbed samples represent a point measurement and obtaining enough samples to characterize tailings at high spatial resolutions may not be feasible. The characterization of tailings in situ, using methods such as the cone penetration test (CPT), can provide high resolution data, but does not provide information related to all relevant tailings properties. This study explores the use of hyperspectral sensing and convolutional neural networks (CNN) for the prediction of tailings properties, including percent sand, silt, clay, solids content, moisture content, and degree of saturation. Tailings from a gold, silver, lead, and zinc producing mine were used to create samples with diverse properties and hyperspectral scans of each sample were captured. The tailings-hyperspectral dataset was then split into training and testing subsets and a CNN was optimized and trained. Model performance was assessed using the testing data and the results demonstrate strong promise for the use of hyperspectral data and CNNs for the prediction of tailings properties.

Introduction

Tailings properties can inform geotechnical and geochemical analyses and include particle size distribution (PSD), solids content, moisture content, and degree of saturation. The PSD of tailings influences shear strength, hydraulic conductivity, consolidation, dry density, and beach angle, and can inform geochemical and rheological characterization of the material. The moisture content of tailings influences hydraulic conductivity, bearing capacity, compaction behavior, and acid-generation potential. At saturations below approximately 80%, geotechnical stability is improved (Rodriguez et al., 2021) and at saturations above

approximately 85%, oxygen diffusion exponentially decreases, indicating reduced acid generation in sulfide tailings (Aachib et al., 2004).

Tailings can be characterized by sampling and laboratory testing. However, the results only represent a point measurement and obtaining enough samples for high resolution characterization of tailings throughout a tailings facility is impractical. In-situ methods can be a cost-effective alternative for high resolution characterization and include the cone penetration test (CPT). Data from the CPT can be used to better understand tailings behavior; however, current methods for CPT interpretation may not apply universally and the CPT does not provide information on all geotechnically relevant tailings properties. Alternatively, hyperspectral sensing has shown promise for the characterization of soil and tailings properties.

Figure 1 illustrates a simplified conception of hyperspectral sensing, which involves illuminating a sample and measuring the intensity of reflected radiation from the material surface. Hyperspectral reflectance can be measured with a spectrometer and varies with tailings properties including water content, PSD, and mineralogy. Hyperspectral sensing is typically used to measure reflectance in the visible, near infrared, and short-wave infrared portions of the electromagnetic spectrum and can be conducted on disturbed or undisturbed samples in either laboratory or field settings.

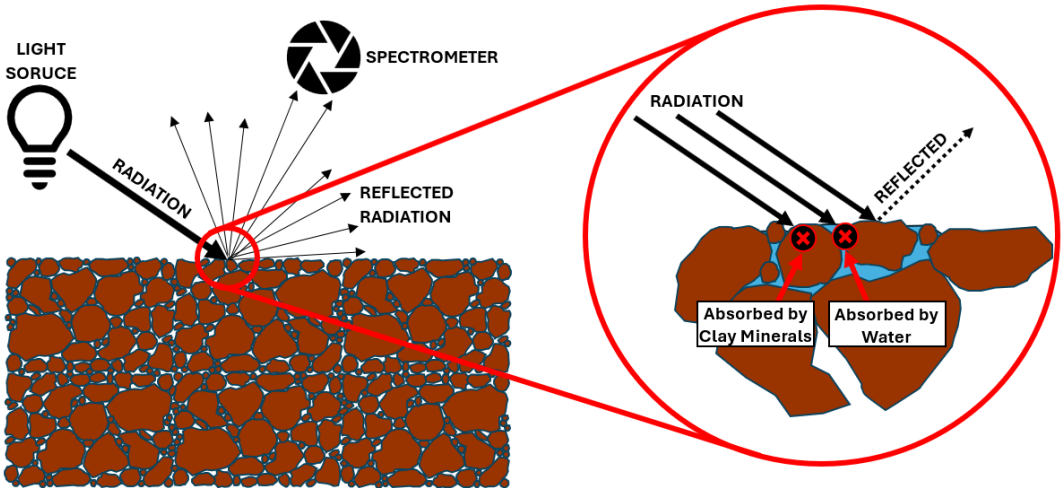

Figure 1: Simplified illustration of hyperspectral sensing for tailings

Machine learning models have been successfully used to predict soil texture from laboratory measured hyperspectral reflectance (Riese and Keller, 2019; Tsakiridis et al., 2020). In agriculture, studies have demonstrated the use of probe-based hyperspectral sensing for the estimation of in-situ soil texture and moisture content for near surface soils (Cho et al., 2017; Pei et al., 2018). Additionally, ex-situ hyperspectral sensing has been used for the prediction of tailings solids content, fines content, and water content for oil-sands tailings (Entezari et al., 2022). While machine learning models, such as convolutional neural networks (CNNs), and hyperspectral reflectance can be used to predict some tailings properties, less is

understood regarding the use of hyperspectral sensing for the prediction of tailings percent sand, silt, clay, and degree of saturation.

The objective of this study is to measure hyperspectral reflectance for tailings with diverse properties and assess how hyperspectral reflectance and CNNs can be used to predict geotechnically relevant tailings properties. Tailings from a gold, silver, lead, and zinc producing mine were processed to obtain 300 test specimens with unique PSDs, moisture contents, and densities. Hyperspectral reflectance was captured using a spectrometer and test specimen properties were measured using standard laboratory procedures. The tailings-hyperspectral dataset was separated into training and testing subsets and a CNN was constructed to assess the use of hyperspectral reflectance for the prediction of tailings properties including percent sand, percent silt, percent clay, solids content, gravimetric moisture content, and degree of saturation. The CNN was trained and tested using (1) the full range of measured wavelengths and (2) a limited range of wavelengths, to better understand how short-wave infrared data impacts the model's performance, as a potential cost-reducing measure.

Methodology

Test specimens

Table 1 outlines the engineering characteristics for a bulk tailings sample from a gold, silver, lead, and zinc producing mine (whole tailings). The tailings were processed to artificially prepare tailings specimens with diverse properties including PSD, moisture content, and density (test specimens). The whole tailings properties were determined according to ASTM standards and sensor testing manuals (see Table 1).

The whole tailings underwent a series of sieving and sedimentation procedures to separate out fractions of the whole tailings that were dominated by (1) sand, (2) silt, and (3) clay. Unique mass ratios of each tailings fraction were combined to prepare 100 test specimens with different PSDs (PSD specimens). Figure 2 displays the percentile ranges for the 100 PSD specimens and the typical range for tailings PSD from the literature.

Table 1: Whole tailings properties

Method	Property	Sample Value
ASTM D4318	Liquid Limit, LL (%)	21
	Plasticity Index, PI (%)	1
ASTM D6913	Percent Gravel (4.75 mm – 76.2 mm)	0
	Percent Sand (75 µm – 4.75 mm)	46
	Percent Fines (< 75 µm)	54
ASTM D2487	USCS Classification	ML
METER PARIO Plus	Percent Silt (75 µm – 2 µm)	47
	Percent Clay (< 2 µm)	8
ASTM D698	Optimum Water Content, w_{opt} (%)	12
	Maximum Dry Density, ρ_d (Mg/m^3)	1.85

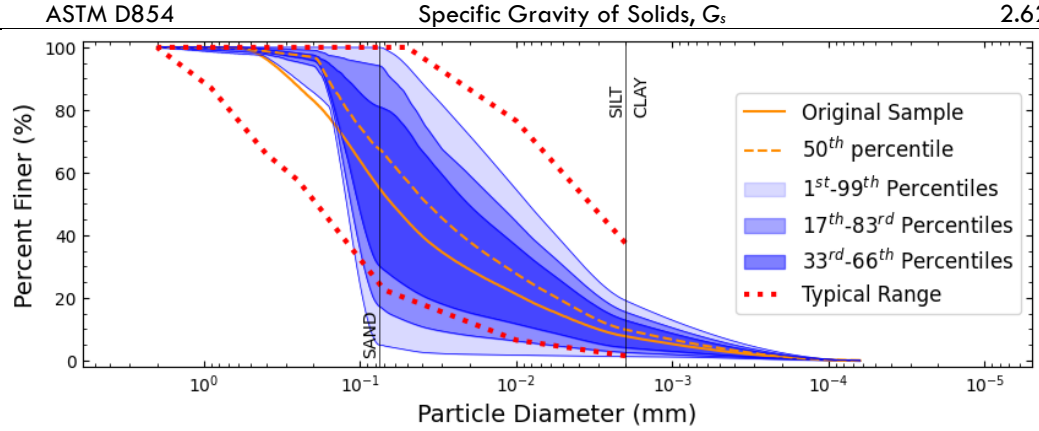

Figure 2: Particle size distribution of the whole tailings and the percentile ranges for all PSD specimens. Solid vertical lines differentiate sand, silt, and clay sized particles. Red dashed lines represent the average lower and upper bounds of PSD for typical mine tailings from the literature (after Gorakhki et al., 2019, adapted from Hamade, 2017)

Each PSD specimen was prepared to three moisture and density conditions, totaling 300 test specimens. Each test specimen was moisture conditioned using de-ionized water, sealed, and allowed to moisture equilibrate for 12 hours. Test specimens were then compacted in a 50 mm inner diameter, 15 mm height, petri dish to target a density, which was randomly determined and between 0.9 and 1.7 Mg/m³. Each specimen's total mass, volume, and gravimetric moisture content was measured and used to calculate solids content and saturation based on phase relationships.

Figure 3 illustrates the frequency distributions for the test specimens' properties. The sand, silt, and clay content ranged between 0–99%, 2–84%, and 1–20%, respectively (Figure 3a-c). Solids content spanned 65–100%, capturing a portion of the tailings continuum including thickened, paste, and filtered tailings (Figure 3d). Gravimetric moisture content ranged from 0–55% and saturation varied from 0–100% (Figure 3e-f).

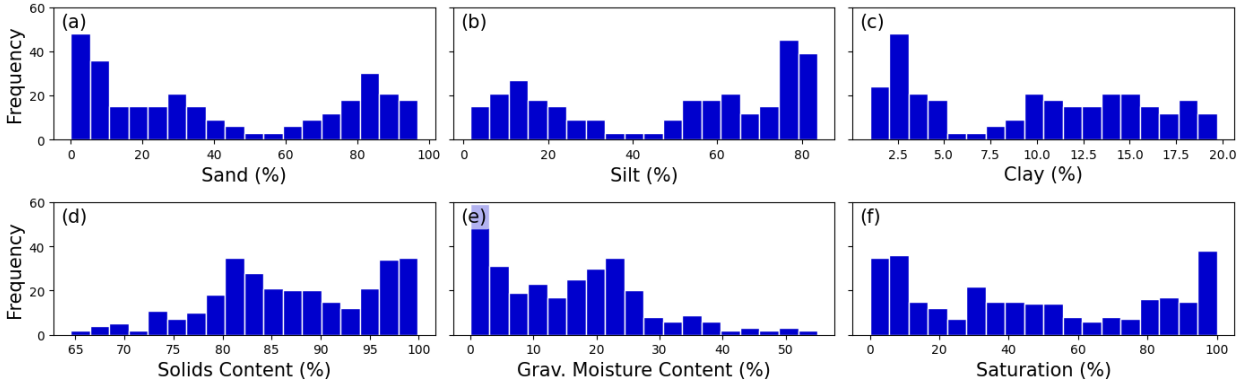

Figure 3: Distribution of test specimen properties including (a) percent sand, (b) percent silt, (c) percent clay, (d) solids content, (e) gravimetric moisture content, and (f) degree of saturation

Hyperspectral sensing

Figure 4 illustrates the preparation of test specimens and the spectrometer used to capture hyperspectral reflectance. Immediately following test specimen preparation, the specimen's reflectance intensity was measured at wavelengths ranging from 350 – 2500 nm. The spectrometer contains: (1) a visible-near-infrared sensor (VNIR) (350–1,000 nm); (2) two short-wave infrared sensors, referred to as SWIR-1 (1001–1,800 nm) and SWIR-2 (1,801–25,00 nm); and (3) an internal halogen light for sample illumination. The spectrometer's viewing window was placed in direct contact with the test specimen and hyperspectral reflectance was measured at two locations for each test specimen. The data from these two locations were averaged to generate a single hyperspectral signal for each test specimen.

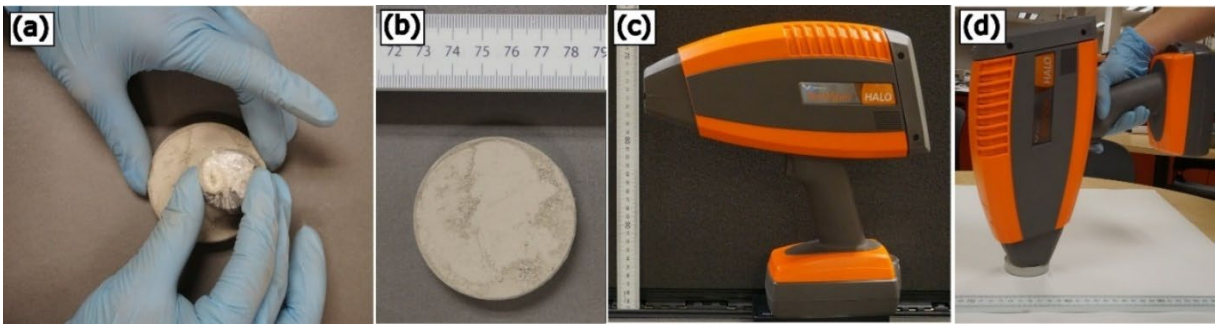

Figure 4: Photographs illustrating (a) test specimen compaction, (b) prepared test specimen, (c) spectrometer, and (d) spectrometer measuring hyperspectral reflectance of a test specimen

Data processing

Various preprocessing procedures were applied to the hyperspectral data including the discrete wavelet transform (Anand et al., 2021; Bruce et al., 2022) and the standard scaler transform (Pedregosa et al., 2011) to reduce data dimensionality and standardize data, which has been associated with improved model performance (Pedregosa et al., 2011; Anand et al., 2021; Bruce et al., 2022). The tailings-hyperspectral dataset was then split into training and testing sub-datasets using conditioned Latin Hypercube Sampling (cLHS) (Minasny and McBratney, 2006). The cLHS algorithm was used to create training and testing datasets that have similar distributions of hyperspectral data, which has been linked to improved model performance (Althnian et al., 2021). The testing data contains 20% of all samples (n=60) and the training data contains 80% (n=240).

Figure 5 illustrates the distribution of properties among test specimens in the training and testing datasets derived from cLHS. Results from cLHS demonstrate that the testing data has a similar distribution and range of properties as that seen in the training data.

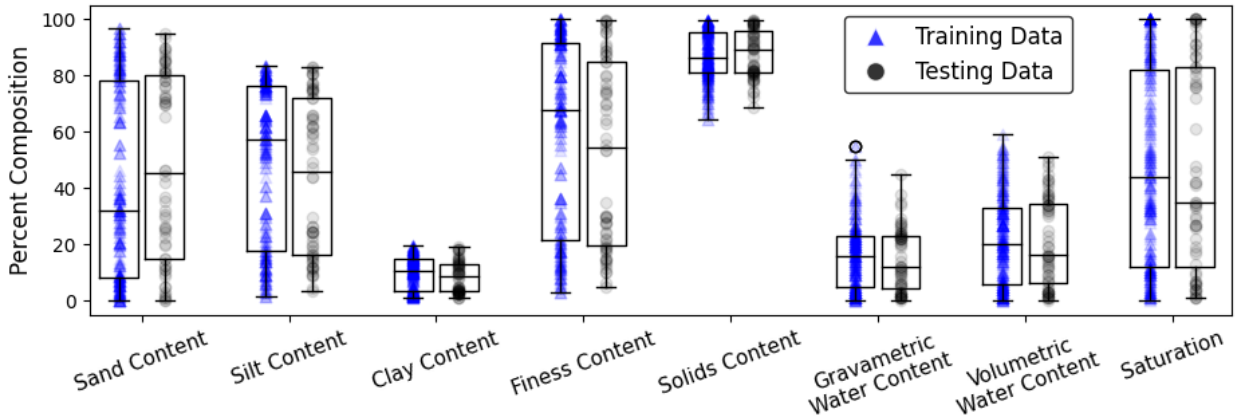

Figure 5: Distribution of tailings properties in the training and testing datasets

Machine learning

Convolutional neural networks have been shown to outperform other common algorithms in soil spectroscopy (Tsakiridis et al., 2020) and were used to predict tailings properties from hyperspectral data in this study. K-fold cross validation helps to generalize models for predictions on unseen data (i.e., the testing data) and was used to select the CNN architecture. The Keras deep learning application program interface was used for machine learning procedures (Chollet, 2015). The model was first trained and tested using the entire hyperspectral dataset, including VNIR, SWIR-1, and SWIR-2 data (V-S2 model). Then, to assess how the SWIR-2 data influences model performance, the model was trained and tested using only VNIR and SWIR-1 data (V-S1 model).

Results

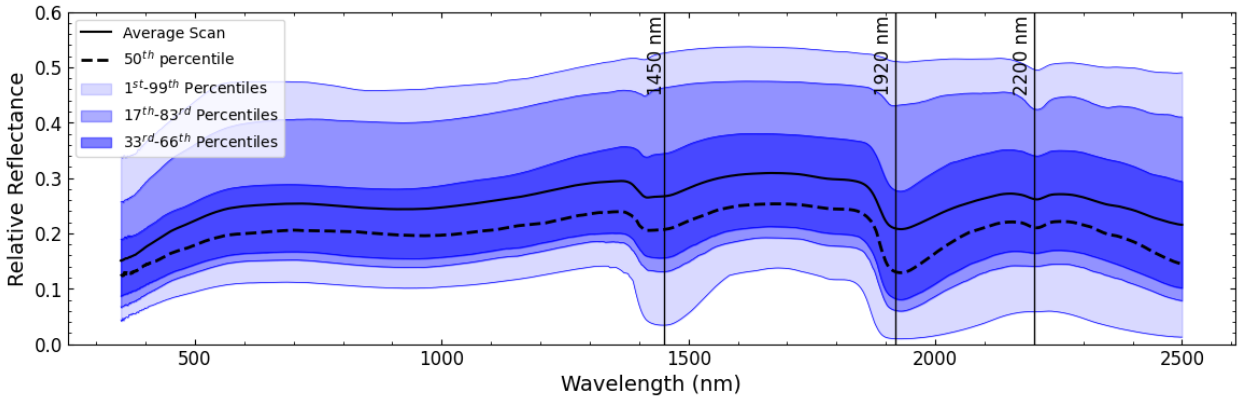

Figure 6: Hyperspectral signal percentile ranges including percentiles 1–99, 17–83, and 33–66. Vertical lines are shown at major absorptive features

Figure 6 illustrates the range of hyperspectral signals for test specimens. Relative reflectance denotes the spectrometer's measurement of radiation reflected from the surface of the test specimen and ranges from 0 to 1. A value of 0 indicates complete absorption, while 1 signifies total reflectance. Distinct absorptive

features are observed in the hyperspectral signals at wavelengths near 1,450 nm and 1,920 nm, indicating the presence of water (van der Meer, 2004). Additionally, the absorptive feature at 2,200 nm is attributed to clay minerals containing hydroxyl groups such as illite, chlorite, and kaolinite (Laukamp et al., 2021), which were present in the whole tailings based on X-ray diffraction analysis.

Figure 7 displays the results from the V-S1 and V-S2 models along with the root mean squared error (RMSE), mean bias error (MBE), and coefficient of determination (R^2) of predictions. For predictions of percent sand and silt, the V-S2 model has RMSEs of 5.9% and 5.1% respectively, which are approximately 2.5% lower than the V-S1 model (8.5% and 7.5% respectively). Additionally, the R^2 values are approximately 0.04 higher for the V-S2 model compared to the V-S1 model. Both models have MBEs near 0% for sand and silt predictions. Performance metrics for percent clay and solids content are comparable between both models with RMSEs less than 2%, MBE near 0%, and R^2 greater than 0.94. The V-S2 model performed slightly better than the V-S1 model for prediction of gravimetric moisture content (RMSE of 2.2% and 2.7% respectively). Conversely, for the prediction of degree of saturation, the V-S1 model outperforms the V-S2 model with RMSEs of 7.5% and 8.3% respectively and MBEs of 0.6% and 2.1% respectively.

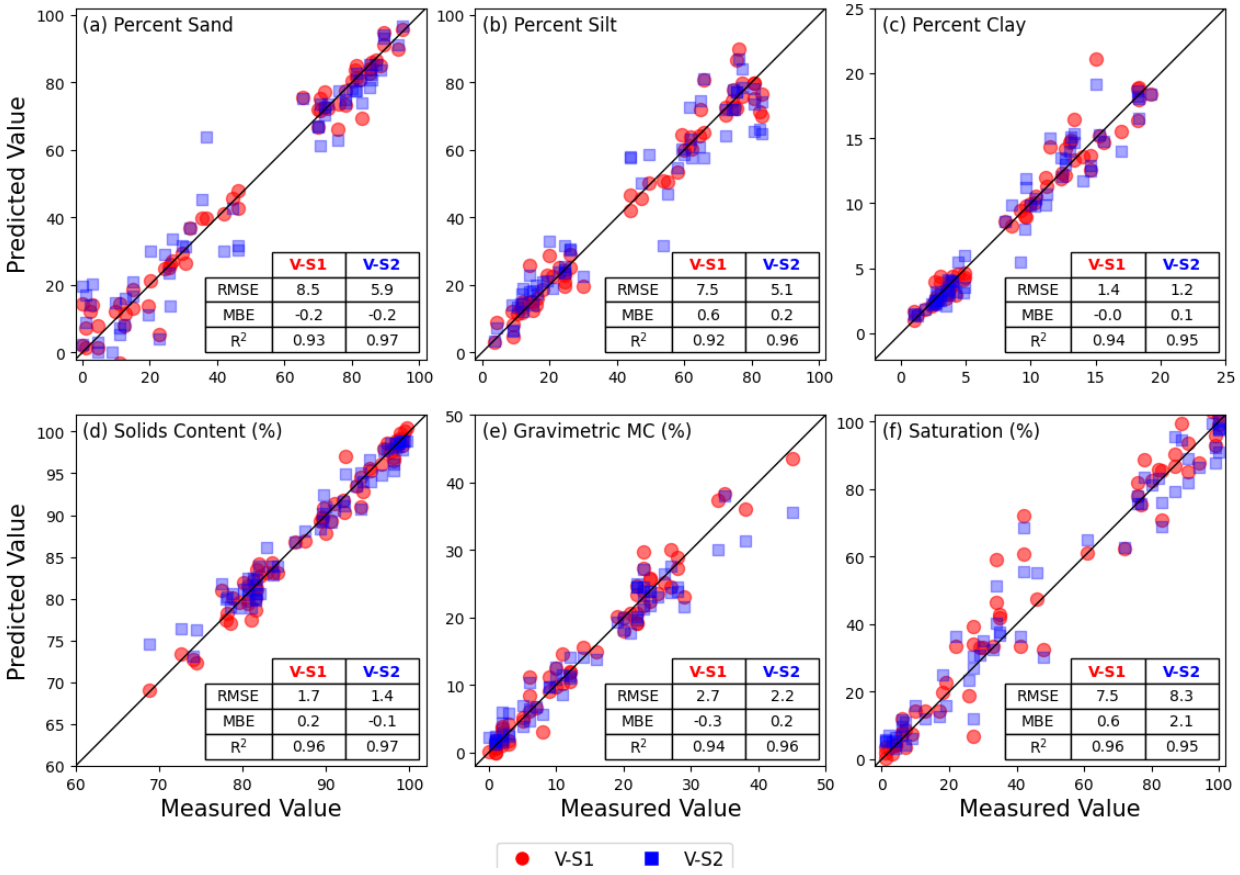

Figure 7: Results from V-S1 and V-S2 models for (a) percent sand, (b) percent silt, (c) percent clay, (d) solids content, (e) gravimetric moisture content, and (f) degree of saturation

Figure 8 shows results from the Shapley Additive Explanations (SHAP) analysis, which uses game theory to explain the importance of various input features in machine learning models (Lundberg and Lee, 2017). The SHAP analysis was used to understand wavelength importance for the V-S2 model, where greater SHAP values correspond to greater influence on the model output for a given wavelength. Results show the predictions of percent sand and silt are strongly influenced by wavelengths from 2,100 – 2,400 nm. For the prediction of percent clay, solids content, gravimetric moisture content, and degree of saturation, most wavelengths appear to have moderate influence on the prediction of these properties.

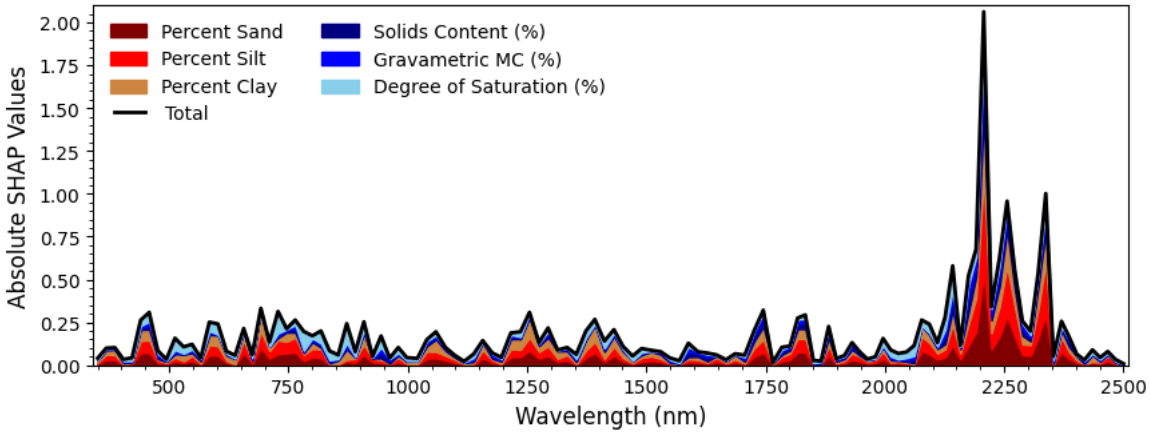

Figure 8: Absolute SHAP values for the V-S2 model where greater values correspond to greater influence of a wavelength on the model outputs. Cumulative absolute SHAP values are shown by the solid back line

Discussion

The model performance demonstrates that hyperspectral sensing can be used to estimate tailings properties including percent sand, silt, clay, solids content, moisture content, and saturation. Tsakiridis et al. (2020) used machine learning and laboratory hyperspectral reflectance to predict percent sand, silt and clay from hyperspectral data on 18,000 natural soil samples and achieved RMSEs of 12.0%, 9.3%, and 4.8% respectively. In comparison, the V-S1 and V-S2 models predictions of tailings sand, silt, and clay have lower RMSEs than Tsakiridis et al. (2020), possibly due to the simplified mineralogical composition of the tailings test specimens, which were derived from a single bulk sample. The coefficients of determination for predicted sand, silt, and clay percentages for the V-S1 and V-S2 models exceed 0.92, highlighting the capacity of hyperspectral reflectance to capture variability in particle size distribution.

For the prediction of tailings moisture content, the model demonstrates high accuracy, which is supported by the strong correlation between soil moisture and hyperspectral reflectance (van der Meer, 2004). Entezari et al. (2022) used hyperspectral sensing and machine learning to predict solids content and gravimetric moisture content of oil-sands tailings, yielding results comparable to those from the V-S1 and V-S2 models. While prior research has not explored the use of hyperspectral sensing for predicting tailings

saturation, the model results highlight the potential of hyperspectral sensing for the rapid characterization of tailings saturation.

The strong influence of wavelengths in the SWIR-2 sensor range on the predictions of percent sand and silt support the improved performance of the V-S2 model compared to the V-S1 model for these properties. However, for predictions of percent clay, solids content, moisture content, and degree of saturation, predictive accuracy between the two models did not vary substantially. Omission of the SWIR-2 sensor may result in cost savings for some applications. However, the potential implications of this on predictive accuracy should be considered.

Hyperspectral sensing shows promise for the rapid assessment of tailings properties in field settings. Recent research has used visible light cameras on CPT probes for enhanced soil profile characterization (Ventola et al., 2020). Additionally, hyperspectral sensing has been used in subsurface probes to analyze agricultural soil properties (Cho et al., 2017; Pei et al., 2018). Combining data from multiple sensors, such as hyperspectral sensing, current generation sensors, and the CPT, is anticipated to enhance the accuracy of predictive models for tailings properties (Pei et al., 2018; Riese and Keller, 2019). Future research should investigate the application of probe-based hyperspectral sensing for real-time characterization of in-situ tailings properties.

Conclusion

The objective of this study was to assess the use of hyperspectral sensing for the prediction of various tailings properties. Tailings from a bulk sample were processed to create a diverse tailings-hyperspectral dataset with 300 unique test specimens. Hyperspectral reflectance was captured for each test specimen and geotechnical properties were measured. The dataset was used to construct, train, and test a convolutional neural network for the prediction of percent sand, silt, clay, solids content, gravimetric moisture content, and degree of saturation. The model was evaluated using two scenarios: (1) using only VNIR and SWIR-1 sensor data (V-S1 model), and (2) using VNIR, SWIR-1, and SWIR-2 sensor data (V-S2 model). Based on the findings, the following conclusions were reached:

1. Hyperspectral sensing and machine learning show promise for the prediction of tailings percent sand, silt, and clay. Based on SHAP analysis, the V-S2 model is strongly influenced by SWIR-2 data for the prediction of percent sand and silt, which aligns with the reduced error in the V-S2 model results, compared to the V-S1 model for the properties. Both models have RMSEs less than 9% and R^2 values greater than 0.92 for the prediction of sand, silt, and clay.
2. Predictions of solids content, gravimetric moisture content, and degree of saturation using hyperspectral reflectance shows promise. The V-S1 and V-S2 models performed similarly for the predictions of these properties and have RMSEs less than 9% and R^2 values greater than 0.94.

Hyperspectral sensing can rapidly produce data related to tailings properties and demonstrates the potential for the high-speed characterization of tailings properties for various applications. Including data from hyperspectral sensing and other sensors in machine learning procedures is expected to improve tailings property predictions. Future studies should consider applying similar methodologies in situ for the characterization of tailings and explore how this methodology applies to tailings from other sites.

Fundamental Properties of Filtered Tailings on Density-Moisture Curves

Uddav Ghimire, University of Arizona, USA
Jackson S. Norbutas, University of Arizona, USA
Tejo V. Bheemasetti, University of Arizona, USA

Abstract

Mine tailings' disposal, maintenance, and rehabilitation measures present substantial challenges within the mining sector, encompassing environmental and geotechnical stability. Dry stacking of filtered tailings has emerged as a promising alternative to conventional slurry disposal methods. Ensuring the overall stability of dry stacks necessitates a thorough understanding of the physical and mechanical properties of unsaturated filtered tailings at different moisture levels over the compaction curve. Classical soil mechanics principles have established various properties of soils over the compaction curve. However, due to their distinct formation processes, these principles may not necessarily apply to tailings materials. This study investigates the properties of copper mine tailings across various moisture contents relative to the Optimum Moisture Content (OMC). Tests include Unconfined Compressive Strength (UCS), stress-strain behavior, failure patterns, permeability, and scanning electron microscopy (SEM) analysis. The samples were prepared at five different moisture contents at OMC, ± 10 % of OMC, and ± 20 % of OMC, which represents the moisture content variation of filtered tailings in the field. All the tests were performed in triplicate to establish the reliability of the properties. The results highlighted the performance of dry stack tailings at different moisture levels, with tailings fabric changing from flocculated to dispersed, leading to changes in their physical and mechanical properties.

Introduction

The management and disposal of mine tailings present significant environmental and geotechnical challenges within the mining industry. Traditional slurry disposal methods, which often involve the construction of large tailings dams, have been widely adopted. However, these dams can be prone to catastrophic failures and environmental contamination. Since 1915, there have been 257 major tailings dam failures, including the notable incidents of the Bento Rodrigues Dam (Samarco) in Brazil in 2015 and the Brumadinho Dam in 2019 (Piciullo et al., 2022). As an alternative, dry stacking of filtered tailings has

emerged, providing a more stable and sustainable solution (Gomes et al., 2016; Cacciuttolo and Atencio, 2023).

Dry stacking of tailings involves mechanically dewatering tailings to form a filter cake, allowing for stackable storage without the need for a dam, thereby enhancing safety and reducing environmental impacts. It offers multiple advantages over slurry disposal: reducing failure risks, conserving water by recycling dewatering process water, using less space, thus minimizing environmental disturbance, and supporting progressive reclamation and dust control for improved environmental management during and after mining operations (Davies and Rice, 2022). However, the conditions of filtered tailings at deposition can vary significantly due to differences in the parent ore, mineral gradation, and the processes they undergo. Additionally, the post-filtration moisture content varies because of different filtration plant processes. Consequently, understanding the properties of filtered tailings is crucial for the safe design and construction of dry stacks.

Tailings generated from ore extraction and beneficiation processes, ranging from crushing and screening are clastic in nature (Carvalho, 2024). Unlike natural soils, tailings exhibit distinct characteristics such as pronounced angularity, high surface roughness, and the presence of plastic or non-plastic fines (Yang et al., 2019; Carvalho, 2024). The primary difference between soils and tailings lies in their formation. The soils are derivative of rocks that undergo several physical and chemical weathering processes with seasonal cycles, whereas the mine tailings are derivative of industrial processes. This implies that the clay-size particles in tailings do not necessarily have similar physio-chemical characteristics as the weathered clay minerals (Schnaid, 2021). Classical soil mechanics demonstrates that clay structures are flocculated and dispersed when compacted on the dry and wet sides of the OMC, respectively. However, these principles may not necessarily apply to tailings materials due to their distinct formation processes. Thus, understanding their fundamental behavior over a range of moisture contents across the compaction curve is crucial. This knowledge is essential for designing and constructing safe and stable filtered tailings dry stacks.

Recently, numerous studies have expanded an understanding of the behavior of filtered tailings, shedding light on fundamental geotechnical characteristics such as Atterberg limits, density-moisture relationships, and specific gravity (Lara et al., 2013; Amoah et al., 2018). The compaction characteristics of filtered tailings are influenced by their particle size distribution and mineralogy. Fine-grained tailings with high clay content tend to exhibit higher water retention and lower permeability, making compaction more challenging (Qiu and Sego, 2001). Research indicates that the mechanical properties of filtered tailings are highly variable, depending on their source and processing methods (Blight, 2009). Filtered tailings typically show lower compressibility compared to slurry tailings, leading to reduced settlement over time, which is beneficial for maintaining the structural integrity of tailings stacks (Vick, 1990).

Additionally, the mechanical properties of tailings can be improved through soil enhancement techniques, such as using cement to increase strength and stiffness, or fibers to enhance strength and ductility and prevent liquefaction (Consoli et al., 2022, 2023).

This research study examined the fundamental physical properties of copper mine tailings including Unconfined Compressive Strength (UCS), stress-strain relationship, failure patterns, permeability, and fabrics at different moisture contents across the compaction curves. The samples were prepared at five different moisture contents at OMC, ± 10 % of OMC, and ± 20 % of OMC, which represents the moisture content variation that may exist in filtered tailings. The permeability of the samples was determined using a constant head permeameter and the fabric of the tailings using a Scanning Electron Microscope (SEM). All the tests were performed in triplicate to establish the reliability of the properties.

Materials and methods

Materials

In this study, copper mine tailings were collected from a mine in Arizona, USA, and subjected to basic geotechnical characterization studies. Basic characterization studies including sieve analysis, specific gravity, Atterberg limits, and compaction properties were determined in accordance with relevant ASTM standards (D422-63; D854-14; D4318; D698). Table 1 presents the physical indexes of copper tailings used. X-Ray Diffraction (XRD) analysis was performed to understand the mineralogical composition of tailings used for study. The results showed that copper mine tailings consisted of Muscovite (40.5 %), Quartz (18 %), Microcline (24 %), and others (Figure 1).

Table 1: Physical indexes of copper tailings used for the study

Index properties	Value
Specific gravity, Gs	2.6
Plasticity index, %	Non-plastic
Coarse Fraction (0.075 mm<diameter<4.75 mm), %	91
Fine Fraction (diameter<0.075 mm), %	9
Optimum moisture content (OMC), %	15
Maximum dry density (kN/m^3)	16.9

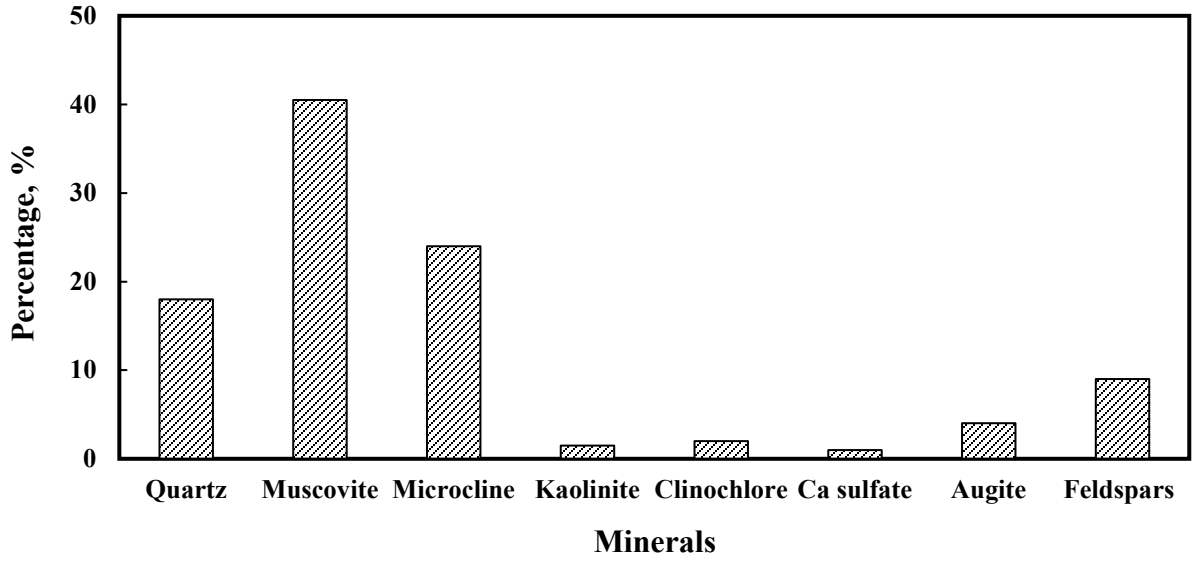

Figure 1: XRD test results of copper tailings used for this study

Experimental plan

The experimental plan for this study involves examining the fundamental physical properties of copper tailings at various moisture contents relative to the OMC. These moisture levels are set at OMC, ±10% of OMC, and ±20% of OMC, as illustrated in Figure 2. Specifically, point 1 represents -20% of OMC, point 2 represents -10% of OMC, point 3 represents OMC, point 4 represents +10% of OMC, and point 5 represents +20% of OMC. The molding points properties are tabulated in Table 2. Points 1 and 2 represent the dry side of the OMC, while Points 4 and 5 represent the wet side of the OMC. Samples were prepared at each of these points (1-5) and subjected to respective tests for analysis.

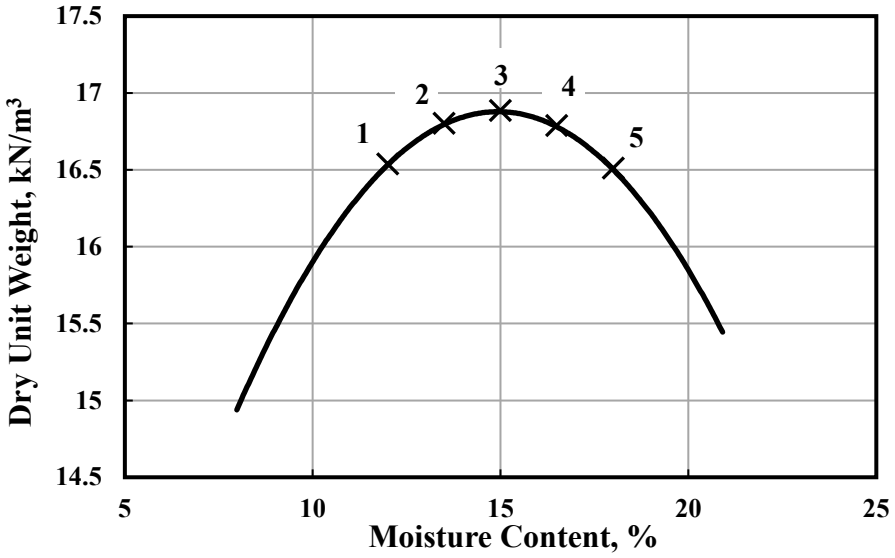

Figure 2: Standard energy compaction curve: density-moisture curve

Table 2: Molding points properties

Molding Points	Properties	
	Moisture content, %	Dry unit weight, kN/m³
1	12	16.55
2	13.5	16.8
3	15	16.9
4	16.5	16.75
5	18	16.5

Unconfined Compressive Strength (UCS) Tests

The static method of compaction was used to prepare cylindrical specimens, which were compacted in three layers. The top of each layer was slightly scarified before adding the next. Each specimen measured 72 mm in height and 33 mm in diameter. To prevent moisture loss, the prepared samples were wrapped in plastic and cured in a room at a temperature of 25°C ± 1°C for 48 hours, allowing moisture to move within the specimens. The strength of the specimens was measured using the unconfined compressive test apparatus, following the ASTM D2166 standard (ASTM, 2016). The load was applied to produce an axial strain at a rate of 1% per minute, continuing until failure bands formed and the stress dropped to 30% of the peak stress. After testing, the failure bands were photographed for further analysis. Tests were conducted in triplicate.

Permeability tests

The permeability of copper tailings was measured using the constant head permeability method following ASTM D2434-19. The specimens were prepared in the standard Proctor mold using standard energy efforts at respective molding points. Tests were conducted in triplicate and the average value was adopted for analysis.

SEM tests

SEM imaging was conducted to examine how the microstructure evolved within copper tailings compacted at different molding points. This analysis focused on observing the fabrics of copper tailings particles. The imaging was carried out using the SEM equipped with a tungsten filament, a secondary electron detector for standard imaging, a backscattered electron detector, Thermo Noran System Six X-ray microanalysis system (EDS), and a J.C. Nabity Nanometer Pattern Generation System (NPGS) for electron beam patterning and lithography and was operated in an environmental mode.

Results and discussion

Unconfined compressive strength

Figure 3 shows the UCS values of copper tailings at different molding points. The UCS value at OMC (point 3) is 178 kPa, which is the highest among all the points tested. This indicates that the copper tailings achieve their maximum strength when compacted at the optimum moisture content. It is clear from the plot that the copper tailings have higher strengths on the dry side as compared to the wet side of the compaction curve. Since the strength decreases significantly on the wet side of the OMC, care must be taken to avoid over-wetting the tailings during compaction.

On the other hand, compaction on the dry side can still yield relatively high strength, as observed at points 1 and 2. This understanding is critical when compacting filtered tailings for construction. Ensuring that the moisture content is close to the OMC will lead to more durable and stable structures.

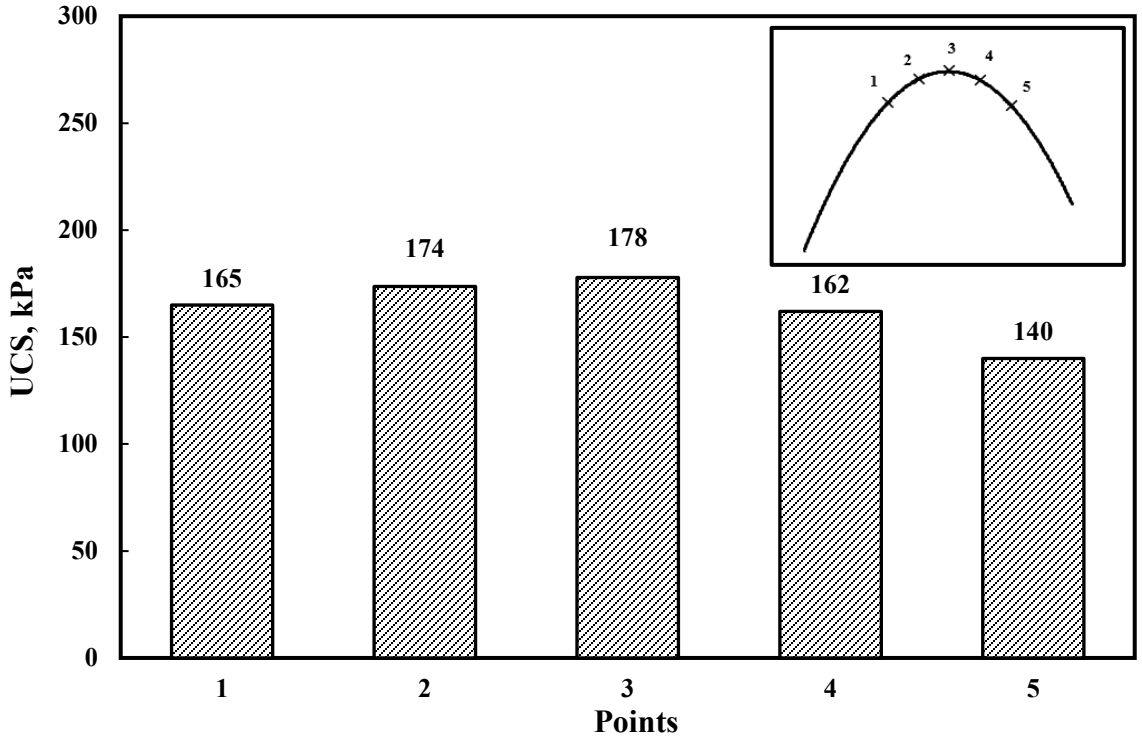

Figure 3: UCS values of copper tailings used for this study at different molding points

Stress-Strain Response

Figure 4 illustrates the typical stress-strain behavior of compacted copper tailings at various molding points. The stress-strain curves reveal that specimens compacted on the dry side (points 1 and 2) exhibit a steep initial slope, indicating higher initial stiffness, and fail at lower strains (0.7% and 1%, respectively). These specimens achieve higher peak stresses but demonstrate a rapid post-peak stress decline, signifying brittle

failure. In contrast, specimens compacted on the wet side (points 4 and 5) show a more gradual increase in stress with strain, reflecting lower initial stiffness, and fail at higher strains (1.39% and 1.41%, respectively). These specimens reach lower peak stresses and display a more gradual post-peak stress reduction, indicating ductile behavior. Point 3, located near the OMC, exhibits intermediate characteristics with a balanced combination of stiffness and ductility, failing at around 1.2% strain and reaching a maximum peak stress. This variability in mechanical response based on moisture content underscores the importance of precise moisture control in the compaction process to achieve desired stability and strength characteristics in tailings storage facilities.

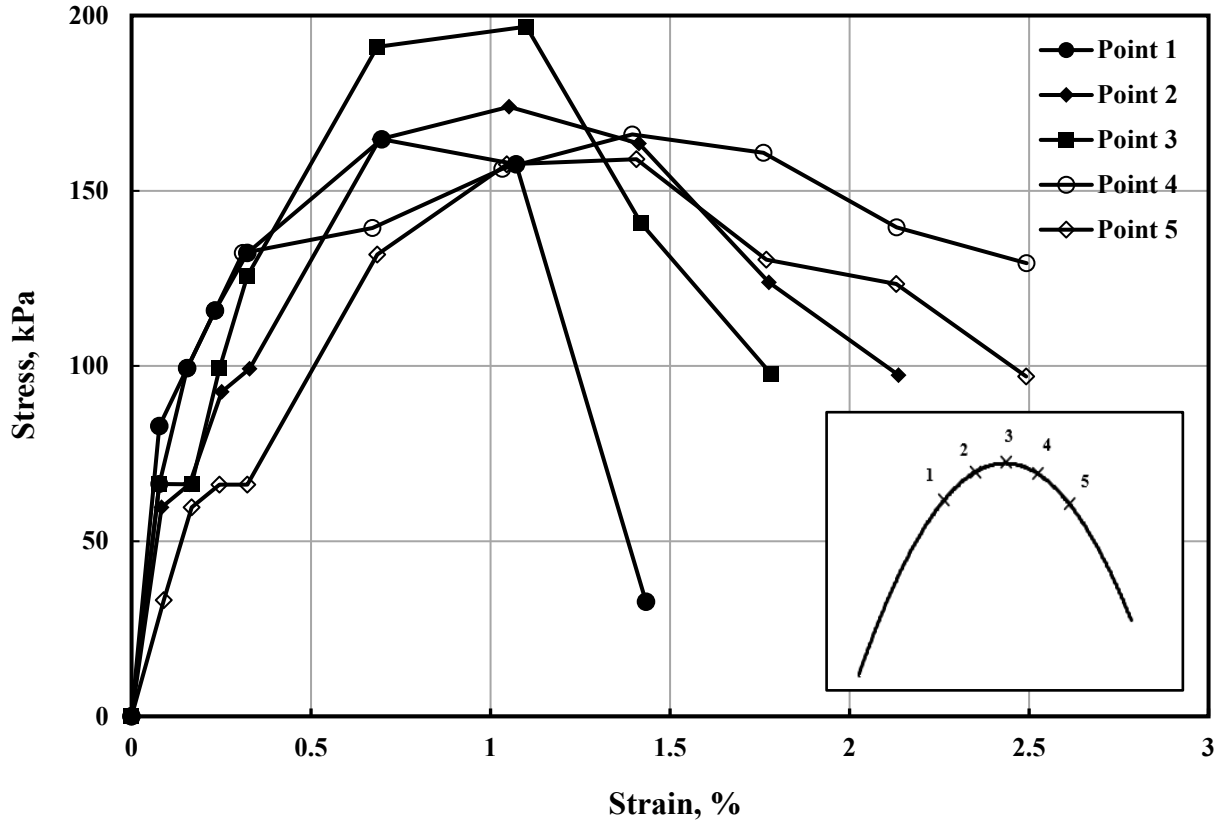

Figure 4: Stress-strain curves for compacted copper tailings at different molding points

Failure patterns

Figures 5(a-e) illustrate the failure patterns of compacted copper tailings at five different molding points, corresponding to the stress-strain behavior shown in Figure 4. Figures 5(a and b) display the failure patterns of specimens compacted on the dry side of the OMC (points 1 and 2, respectively). These specimens exhibit distinct shear bands with minimal bulging or microcracks, indicating brittle behavior characterized by abrupt failure along a shear plane. Figure 5(c) shows the failure pattern of the specimen compacted near the OMC (Point 3), which reveals a combination of a shear band, microcrack formation, and the initiation of

bulging, suggesting a more ductile failure mode compared to the dry side. Figures 5(d) and 5(e) depict the failure patterns of specimens compacted on the wet side of the OMC (points 4 and 5, respectively). These specimens show a combination of random microcracks and significant bulging, indicative of ductile failure.

These visual observations correlate with the stress-strain curves (Figure 4), where specimens on the dry side fail at lower strains with sharp stress drops, reflecting brittleness, while those on the wet side endure larger strains before failure, with gradual stress declines and extensive cracking and bulging, demonstrating ductile behavior. The specimen near the OMC exhibits mixed characteristics, indicating a transition from brittle to ductile failure. These findings underscore the critical influence of moisture content on the mechanical behavior and failure modes of compacted tailings.

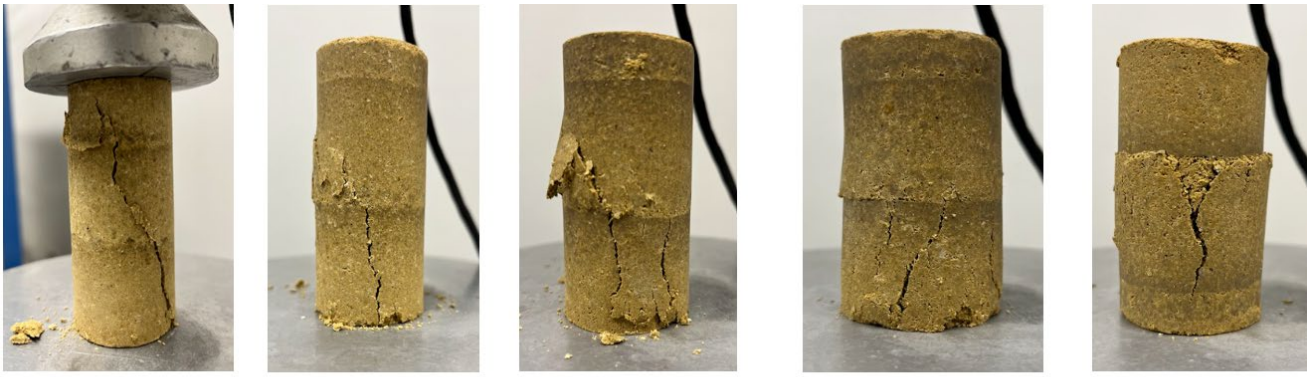

Figure 5: Failure patterns of specimens compacted at points: (a) 1; (b) 2; (c) 3; (d) 4; (e) 5

Permeability test results

Figure 6 illustrates the permeability values of copper tailings specimens compacted at various molding points. The highest permeability is observed at point 1, which gradually decreases until reaching its lowest value at point 3, before slightly increasing up to point 5. On the wet side, the permeability values are consistently lower compared to the dry side. This can be attributed to the larger pore spaces on the dry side due to less moisture and looser packing. In contrast, the wet side has more moisture, resulting in initially tighter packing, followed by slight separation due to excess water. At point 3, the particles are most densely packed, leading to fewer voids and the lowest permeability.

The collaborative evidence of these findings is presented in section 3.5 through SEM images. Permeability observations of copper tailings specimens offer crucial information for optimizing the compaction process of filtered tailings. By carefully adjusting the compaction level and moisture content, engineers can effectively control the permeability of the tailings.

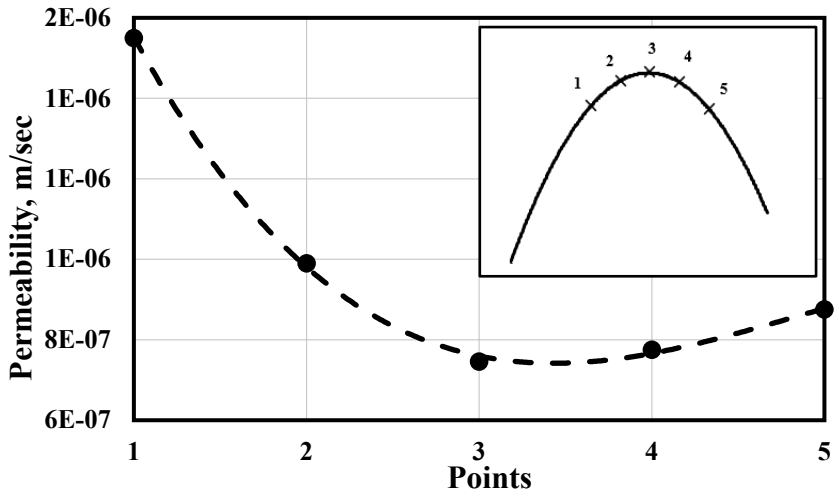

Figure 6: Permeability of compacted copper tailings at different molding points

SEM results

This section presents the results of SEM tests conducted on compacted copper tailings, as shown in Figures 7(a-c). Figure 7(a) depicts the particle distribution and fabric of copper tailings compacted at -20% OMC (point 1). In this condition, particles appear flocculated or randomly oriented within clusters, creating larger pore spaces. Figure 7(c) shows the SEM result of the specimen compacted at +20% OMC (point 5). It can be observed that the particles are dispersed and exhibit a more oriented and laminated structure, leading to smaller pore sizes. This arrangement is characterized by particles aligning more uniformly, which reduces the interconnected pore spaces. Figure 7(b) illustrates the densely packed particles at OMC (point 3), where minimal interconnected pore spaces are present, leading to the lowest permeability, consistent with earlier findings. The higher strength observed on the dry side can be attributed to the closely packed angular particles (Figure 7(a)) and increased interparticle friction. Conversely, the increased moisture on the wet side reduces interparticle friction, generally leading to lower strength.

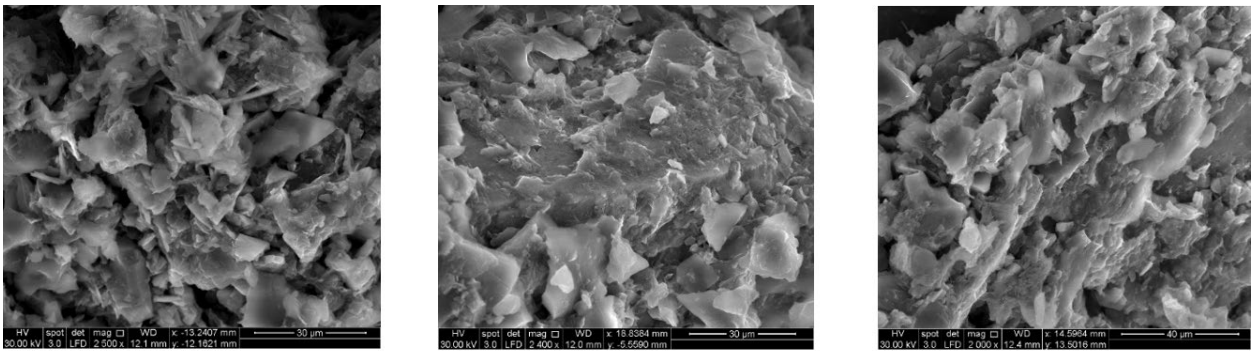

Figure 7: SEM images of copper tailings compacted at points: 1; 3; 5

Conclusion

This study highlights the critical importance of understanding filtered copper tailings' physical and mechanical properties across various moisture contents relative to the OMC. The findings emphasize that properly preparing filtered tailings at appropriate moisture levels is vital for ensuring the stability and performance of dry stack tailings facilities. With moisture contents less than optimum, the tailings can exhibit higher unconfined compressive strength and initial stiffness, but are prone to brittle failure with abrupt shear bands and minimal bulging. These tailings are vulnerable to sudden failure and increased permeability, potentially compromising the stability of the tailings stack. Whereas the tailings compacted on the wet side demonstrate lower strength and ductile failure patterns, with significant bulging and microcracking. The permeability is generally lower due to tighter initial packing, although excess moisture can cause a slight separation of particles. If filtered tailings are over-wetted, the resulting structure may lack strength and be prone to excessive deformation, undermining the structural integrity and stability of the tailings stack. Achieving the OMC during compaction is crucial for maximizing strength and minimizing permeability. Tailings compacted at OMC display balanced properties with the highest strength and lowest permeability, ensuring a stable and durable structure.

Overall, the study highlights the importance of precise moisture control during tailings compaction for optimal performance in dry stack applications. If there is successful extraction of water to the desired moisture contents, dry stack tailings can potentially advance sustainable tailings management practices and mitigate the environmental risks associated with conventional disposal methods.

Acknowledgments

All SEM images and data were collected in the W.M. Keck Center for Nano-Scale Imaging in the Department of Chemistry and Biochemistry at the University of Arizona, RRID: SCR_022884, with funding from the W.M. Keck Foundation Grant. The authors wish to convey their gratitude to the W.M. Keck Center for granting them access to the SEM.

Paul Simms, Carleton University, Canada

Abstract

The consolidation characteristics of young soft geomaterials, such as dredged soils or clayey tailings, is important to their management, particularly to estimating the magnitude of settlement as well as the density and strength profiles with depth. Consolidation properties, however, are challenging to measure in these materials, specifically, determination of the hydraulic conductivity (or *k-e*) function can be time consuming (months for some clayey soils using standard methods), and the compressibility curve shifts with time due to ageing effects. This paper outlines a multi-test approach that can assess different parts of the *k-e* function relatively rapidly, as well as quantifying the magnitude of shifting of the compressibility curve. Tests to rapidly estimate the *k-e* curve in this paper use the settlement curve in settling columns as well as the final density profile with elevation.

Introduction

The oil sands industry has been producing for over five decades in Canada. The majority of Canada's oil sands are located in northeastern Alberta, specifically in the Athabasca region. There are also significant heavy oil deposits in northwestern Alberta (Peace River) and the Cold Lake/Lloydminster region, which spans Alberta and Saskatchewan. The oil sands deposits are a mixture of sand, water, clays, and bitumen (Fine Tailings Fundamentals Consortium, 1995). The primary production process includes open-pit mining, subsequent separation of bitumen from the ore using hot water and chemicals such as caustic soda (Masliyah et al., 2004), and subsequent refinement of the bitumen.

The residuals from the extraction process, including the sands and clays of the natural ore body, are deposited as tailings. Oil sands tailings naturally segregate into sand dominated and fines (silt and clay)

dominated fractions. The fines dominated tailings, called fluid fine tailings (FFT), typically form deposits that stabilize at ~ 200% gravimetric water content (30 to 40% solids content), much higher than their liquid limit (which is typically between 50% to 80%). FFT high natural water content is due to the high dispersion of the clays induced by the chemistry of the extraction process. In this state, FFT possess low strength and low permeability, rendering reclamation challenging (Abdulnabi et al., 2022).

Oil sands operations currently treat FFT with the goal of improving the dewatering properties. Treatments employ different combinations of flocculants and coagulants, the general objective being to reverse the dispersion of clays and generate larger flocs of an optimal size to improve dewatering. Generally, the success of a particular treatment is first evaluated in the laboratory, using specific key performance indicators (KPIs) such as settlement in a graduated cylinder over a set period, or CST (capillary suction time) tests. Selected treatments may be evaluated for consolidation properties using large-strain consolidation or seepage-induced consolidation tests; however, these usually take months for a single sample, even for treated FFT. The goal of this paper is to demonstrate the application of new methods to quickly estimate the consolidation properties of different treatments of FFT, and to show how such methods can be used as a screen for comparing the performance of different treatments. These methods are demonstrated by application to particular coagulant-polymer combinations, investigating substitution of alum with polymer-based coagulants.

Methodology

In the field the coagulation and flocculation processes occur in succession during the transportation of tailings to the tailings pond. Each amendment is introduced to the pipeline, where mixing may occur due to turbulent conditions, and/or may be enhanced by static mixers. After flocculation, the tailings will travel some distance in the pipeline (meters to hundreds of meters, depending on the operation). The influence of shear during transport on floc characteristics and subsequent performance is a critical consideration.

Various operators have come up with laboratory protocols that will create “field equivalent” samples, as verified by field campaigns to determine KPI (Key Performance Indicators) of field samples. These protocols allow for evaluating changes to tailings treatment before any changes are attempted at pilot or full scale. This study employs one of these protocols conforming to a particular mine in the oil sands, which is described in the following section. This protocol is developed to simulate treatment of legacy FFT.

The physical characteristics of the FFT utilized in this study were determined in accordance with ASTM standards, as detailed in Table 1 :

Table 1: Physical characteristics of the tailings

Properties	Unit	ASTM standard	Value
Solids content	%	D2216	34
Water content	%	D221	195
Liquid limit	%	D4318	65
Plastic limit	%	D4318	39
Bitumen content	%	D95	3.34
Specific gravity	Unitless	D854	2.13

Oil sands tailings are known to exhibit low specific gravity, due to the residual bitumen and other hydrocarbons tightly associated with the solids.

Sample generation

Samples are prepared by mixing flocculant and coagulant into 300 grams of FFT (at its initial solids content of 34%) using a metal cylinder cup equipped with four baffles. The cylinder cup has a diameter of 11 cm and a height of 8 cm, with each baffle measuring 1 cm in width. An overhead stirrer is employed to ensure thorough mixing. The stirrer has a single rectangular blade 7.6 cm wide and 2.5 cm deep. The flocculant and coagulant solutions are introduced using syringes.

The same flocculant, NRG 1000 (SNF), was used to prepare all polymer-amended FFT samples. First, 2.25 grams of NRG 1000 polymer was accurately weighed in a plastic weighing dish. The polymer was then transferred into a 1,000 ml glass beaker, and the volume was adjusted to 498 ml with bleed water. The solution was stirred using a jar tester at 300 revolutions per minute (rpm) for 30 minutes to ensure thorough mixing. After stirring, the polymer solution was allowed to mature for 15 minutes, enabling full hydration and activation.

Coagulation: Coagulant solutions are prepared by mixing concentrated coagulant with process water, to target the doses (In terms of mass of coagulant per mass of solid tailings) shown in Table 2. Coagulant solution is added to the mixing chamber when the mixer is set to 300 rpm. Mixing at 300 rpm occurs for 1 minute and 10 seconds and the speed is reduced 80 rpm for 12 minutes. The decrease in torque emulates the resistance to shear observed in a pipeline as the raw FFT becomes more viscous.

Flocculation: In the second step, the flocculant solution is injected while the mixer speed is 300 rpm. The duration of mixing is controlled in this step through monitoring the torque of the mixer. The mixing is

stopped after a peak torque is reached and the torque begins to noticeably decline, which can be generally detected within 2 seconds of the peak being reached.

Shearing Step: The third step simulates pipeline transport of the tailings. The mixing speed is set to 320 rpm and tailings are sheared for 10 minutes.

The shearing step may seem counter-intuitive in the sense that the floc size is being increased by flocculation and then subsequently decreased; however, the flocculation process is important to maximize readily released water and to minimize uncaptured fine particles- these phenomena will have a positive effect on dewatering and consolidation despite the subsequent reduction in floc size by simulated pipeline transport.

In this study, the type and dosage of coagulants are varied. The base treatment, named ADW, using metal-based coagulant (Alum) with the polymer FLOPAM™ NRG 1000 as a flocculant. Two other polymer-based coagulants were employed, termed FLOQUAT™ FL 4150 and FLOQUAT™ FL 2949. Table 2 presents the different doses of each coagulant examined. Optimum refers to optimum dose based on CST only.

Table 2: The different dose of the coagulant and flocculant used in the experiment

Flocculant Dose	Type of the Flocculant	Coagulant Dose	Type of coagulant
1,700 ppm (or g/t)	NRG 1000	1,000 ppm	Metal Base Alum
1,600 ppm	NRG 1000	1,000 ppm	Metal Base Alum
1,800 ppm	NRG 1000	1,000 ppm	Metal Base Alum
1,200 ppm	NRG 1000	1,250 ppm	Polymer FL 4150
1,260 ppm	NRG 1000	1,250 ppm	Polymer FL 4150
1,320 ppm	NRG 1000	1,250 ppm	Polymer FL 4150
1,140 ppm	NRG 1000	1,250 ppm	Polymer FL 4150
1,200 ppm	NRG 1000	2,265 ppm	Polymer FL 2949

CST tests

CST, or Capillary Suction Time (ASTM 2170 G), is a test used for short-term observation and quality control of flocculated tailings. It provides a simple and precise measure of the rate at which water is released from a treated tailing. It is based on the rate at which water is absorbed from the tailings sample by a particular filter paper (Whatman 4). Both the hydraulic conductivity of the tailings, and the viscosity of the release water (which will be affected by residual non-captured fines) controls this rate. In this set of experiments, the objective is to achieve a dewatering time about 40 seconds or less – this criteria is based on operator feedback on full-scale performance of tailings in the field.

Settlement tests

600 ml of treated tailings are deposited into a graduated cylinder of diameter 67 mm and left undisturbed for a period of 100 days. Settlement is monitored using a video camera. After 100 days, the sample is destructively tested, by removing the bleed water slowly, and then the tailings cm by cm. After each removal of ~1 cm of tailings, the whole column is weighed, while the gravimetric water content of the removed small sample is determined by oven drying. This double method of estimating the water content at specific elevations generally shows good agreement between the two estimates, indicating little mass is left behind on the cylinder walls. Assuming 100% degree of saturation, this allows for calculation of a final void ratio profile with elevation. Qi and Simms (2020) show a previous application of this methodology.

Oscillatory rheometry

Oscillatory rheometry tests were performed on samples after flocculation and pipeline shear modeling. These tests aimed to study the rheological properties, specifically the elastic modulus (G') and viscous modulus (G"), which were measured at a controlled, increasing shear stress amplitude (Aldaeef et al., 2022). G’ measurement at the very low shear stresses below the true elastic limit of the material enable by this instrument, allows for tracking of thixotropy in a sample with minimal disturbance.

The oscillatory time sweep involved applying a gradually increasing oscillation stress at a consistent angular frequency of 10 rad/s (equivalent to 1.6 Hz) (Mizani et al., 2017). This test characterizes the thixotropic /ageing behaviour of the tailings, which can have implications for long term dewatering (Salam et al., 2023). In particular, there is a given coefficient of rigidity (the ratio between G’ and the undrained shear strength), and a constant ratio between G’ and the pre-consolidation pressure for a given treatment of FFT.

Other tests part of this study but not reported in the paper include the oedometer tests and other consolidation tests. In this paper, the reported consolidation properties are those estimated from the settlement test data – these estimates will be compared with other measurements of compressibility (oedometer test) and hydraulic conductivity that our currently ongoing.

Results

CST

The CST results, are depicted in Figure 1. It is evident that polymer-based coagulants allow to somewhat lower CST and therefore lead to better dewatering performance in the short term. The time in the CST test indicates the time water takes to be transported through the filter paper; therefore, a low CST indicates some combination of the capacity of the sample to release water, but also is affected by the viscosity of the water released, which depends on the efficiency of the capture of small particles during flocculation-coagulation. Both these factors indicate desirable properties; therefore, lower CST is positive. "Overdoses" are shown that indicate no significant gain in CST despite additional chemical additions.

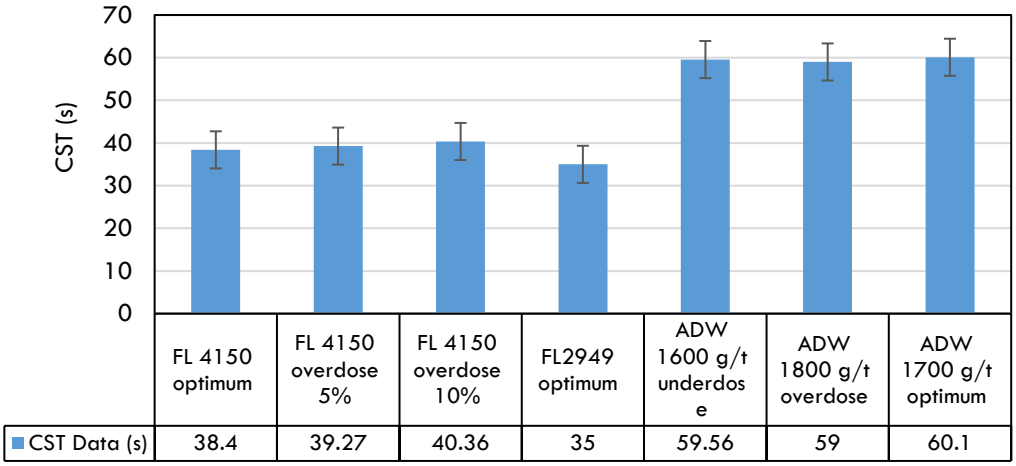

Figure 1: CST of each treatment

Settlement data

Figures 2 through 4 show the settlement data observed in the graduated cylinders. Figure 4 shows the data for all doses. Figures 3 and 4 show only data from three samples: ADW and FL 4150 optimum, and an overdosed FL 4150 sample.

Figure 3 shows the data in log time, which illustrates some differences between the FL4150 and the ADW treatments. The optimum FL 4150 has some initially faster settlement than the ADW, suggesting an initially higher hydraulic conductivity at its initial void ratio compared to the ADW treatment, but reaches a plateau and a definite final settlement by about 30 days. In contrast, the ADW samples show an almost log-linear behavior from 20 to 100 days. This suggests that the ADW treatments experience substantially more creep than the FL 4150 treatments. Pore-water pressure measurements show completion of primary consolidation before 20 days for all samples.

Figure 4 shows the settlement behavior during the first week, in linear time. Here it is clear that the settlement rate and consequently the hydraulic conductivity at high void ratios is higher in the FL 4150 optimum sample. This is confirmed quantitatively in the analysis presented in the next section.

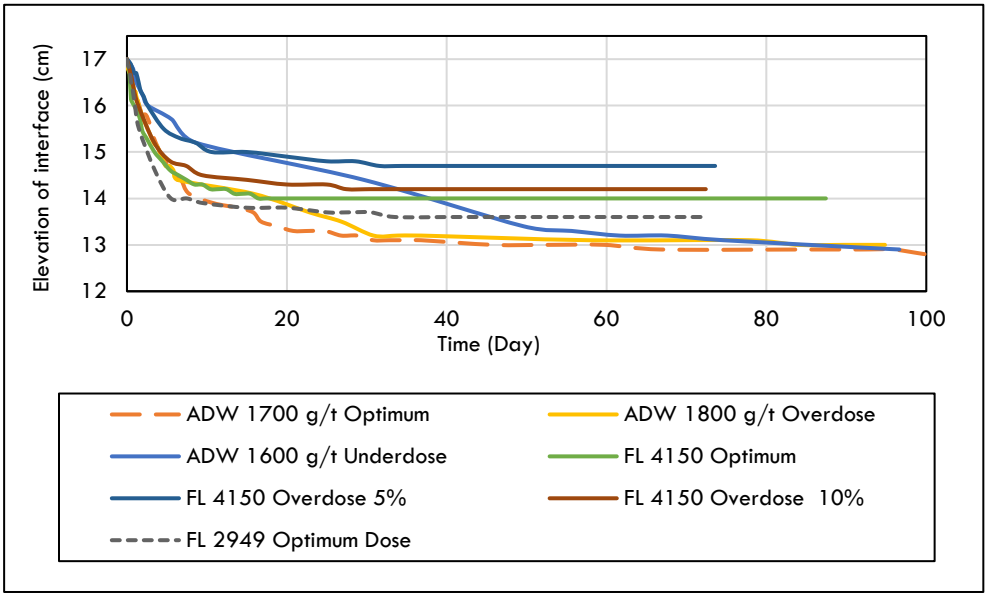

Figure 2: Settlement data for polymer-based coagulants and metal-based coagulant

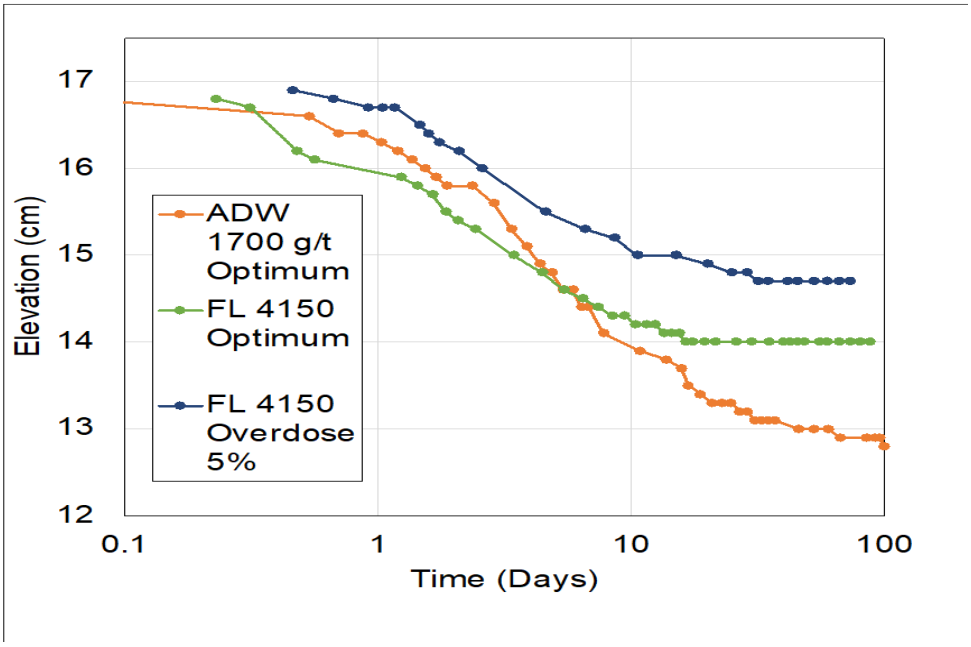

Figure 3: Settlement data for ADW optimum and two doses of FL4150

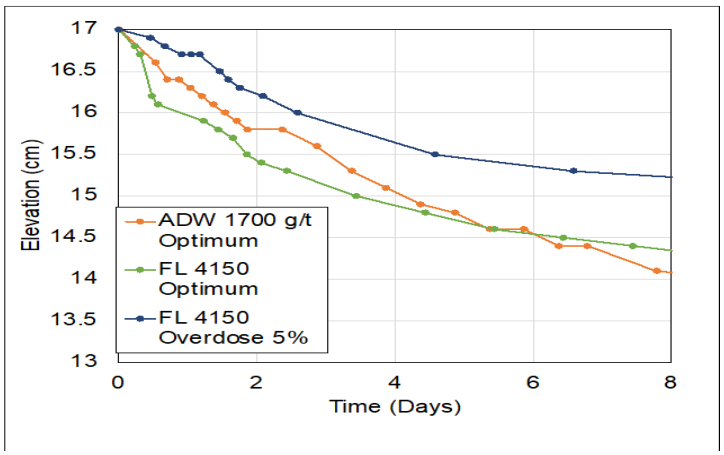

Figure 4: Early settlement data for ADW optimum and FL4150

Importantly, these data in Figures 2 through 4 should be interpreted considering difference in water content post-treatment when the FFT is deposited into the cylinder. For example, the FL 4150 samples post treatment water contents are at 230% whereas the ADW samples are at 240%.

Oscillatory rheometry

Figure 5 shows the measurement of G' over 100 days for the ADW and FL 4150 optimum doses and for the overdosed sample. The increase in G' in the first 7 days or so is attributed to consolidation, which is tracked by pore-water pressure measurements in duplicate samples. The remaining increase is due to thixotropy, reaching a plateau by about 100 days – this behavior is the same as reported for FFT by Salam et al. (2023) and by Patel et al. (2021).

It is very apparent that the FL 4150 shows a much higher value of G' from the end of consolidation and at later times, despite being at a higher void ratio than the ADW post-consolidation. The flocs or floc network produced by the FL 4150 process are thus stronger and stiffer. This is correlated with the decreased settlement in the long term observed for these samples (Figures 2 through 4).

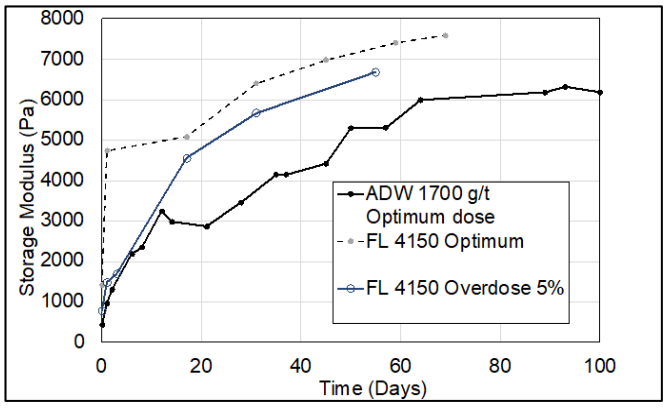

Figure 5: G' values of ADW optimum and FL4150 optimum, and overdose

Estimating the consolidation properties

Compressibility

The compressibility curve may be estimated by fitting the following equation to the measured distribution of void ratio with depth from the graduated cylinders (Qi and Simms 2020).

$$\xi = \frac{1}{\Upsilon}\left[\left(\frac{e}{a}\right)^{\frac{1}{b}}\left(\frac{e}{b+1}+1\right) - c\left(\frac{ac^b}{b+1}+1\right)\right] \quad \text{(Equation 1)}$$

Where the symbol ξ is elevation (m); a, b, c, are the parameters of the compressibility equation in modified power form ($e = a(\sigma'_v+c)^b$), such that the void ratio at zero vertical effective stress (e_c) is given by $e_c = ac^b$. The symbol Y is the submerged unit weight.

Figure 6 illustrates the measured and estimated void ratios of the tailings treated with 1700 g/t and the Alum and Polymer based coagulant FL 4150 at optimum doses and the FL 4150 overdose.

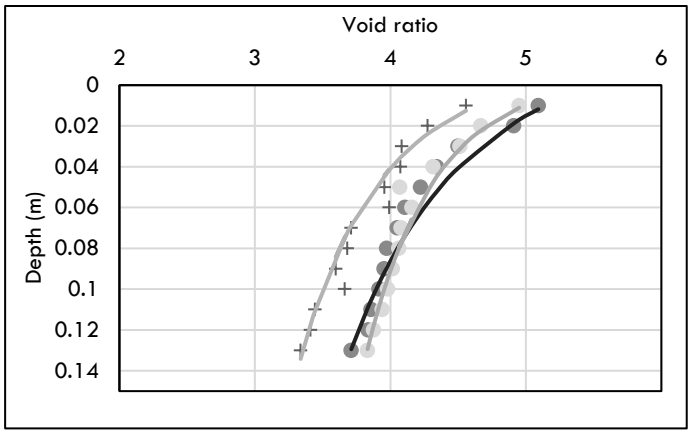

Figure 6: The measured and estimated void ratio after 100 days from the graduate cylinder of the optimum dose of alum-based (+) and FL4150 optimum(dark circle) and overdose (light circle)

Hydraulic conductivity (k-e)

Assuming the power form of the dependency of the hydraulic conductivity function on void ratio:

$$k = Ce^D \quad \text{(Equation 2)}$$

The hydraulic conductivity at the initial void ratio can be calculated using the method of Pane and Schiffman (1997):

$$K = \frac{(1+e)v_s}{G_s-1} \quad \text{(Equation 3)}$$

Where G_s is the specific gravity, e is the initial void ratio and v_s is the initial settling velocity of the solids. The parameter "C" can then be determined using different assumed values of D. For this type of material

(flocculated fluid fine tailings), it is reasonable to assume the D parameter is restricted to between 5 and 8 (reported results on clayey tailings and soft clays summarized in Babaoglu and Simms 2020). The optimal D and paired C parameter can then be determined by checking which set of parameters best match the full settlement data when employing both consolidation properties in a large-strain consolidation model. Here the UNSATCON model is employed (Gheisari et al., 2023, Abdulnabi et al., 2022, Qi and Simms, 2020), though any 1D large-strain model would work.

The simulations of settlement and post-consolidation depth profile of void ratio are compared with the measured data in Figures 7 and 8. The optimal sets consolidation parameters are shown in Table 4.

Table 3: The consolidation properties of each treatment

Tests	A	B	C	C	D
ADW 1,700 ppm	2.8	-0.16	0.02	5.02E-12	7
FI 4150 Optimum	3	-0.2	0.04	1.8E-10	6
FI 4150 5% overdose	3.3	-0.12	0.01	1.8E-11	6

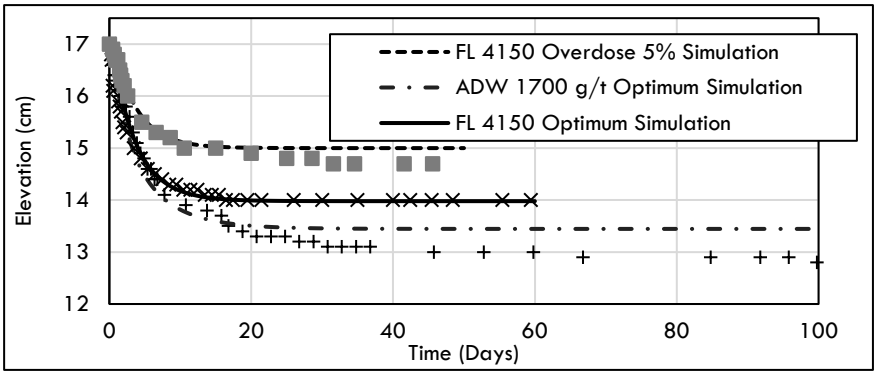

Figure 7: The simulation and the experimental data of the settlement test for 1,700 g/t optimum dose, FL 4150 optimum dose and FL 4150 5% overdose

The agreement between the modelled settlement curves and measured data is good, except for a noticeable deviation between the measured and predicted settlement after 20 days for ADW treatment. It is important to note that the end of primary consolidation predicted by the model, and the observed dissipation of pore-water pressure is good, and the remaining settlement is likely due to creep, and therefore not accounted for in the model results. It is clear that the stiffer (as indicated by G' measurements) FL4150 treatments exhibit less creep, at least for the low range of effective stresses developed in the graduated cylinders.

Hypothetical extrapolation to deposit performance

Acknowledging that future measurements will provide additional data at higher effective stresses for both

compressibility and *k-e*, nevertheless, comparative consolidation analyses are presented on a hypothetical 50 m deposit using the consolidation properties determined in the previous sections. The settlements over 50 years are presented in Figure 8.

Most remarkable is that the FL 4150 optimum and the ADW optimum show little difference in their performance, showing almost identical settlement behavior, and similar post-consolidation void ratio-elevation profiles. In reality, the magnitude of the predicted total settlement for the ADW would be larger due to creep, but the rate of settlement would be less. Looking at more in-depth analysis involving creep (Gheisari et al., 2023), the delay in consolidation due to creep is negative in the sense that there is a delay before reclamation can commence. Therefore, it is expected, though not yet confirmed, that the FL 4150 treatment would achieve a stable deposit more quickly than the standard ADW treatment, and still with a reasonable net reduction in deposit volume. Based on the stiffness (G') data, it would seem that the FL 4150 samples would also be stronger for a given void ratio.

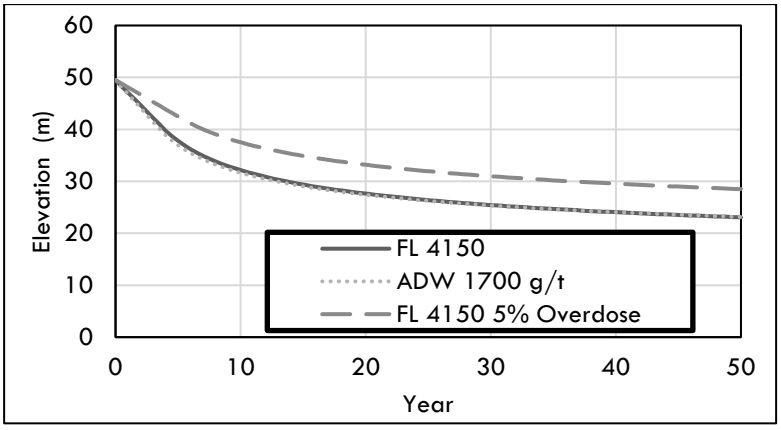

Figure 8: The settlement of a hypothetical tailings deposit over 50 years using the consolidation properties for the ADW and FL 4150 optimum dose and FL 4150 5% overdose treatments

Conclusion

1. FLOQUAT™ FL 4150 treatments provide superior and more consistent short-term dewatering than the base treatment, which is also evident from the early part of the settlement curve, indicating higher hydraulic conductivity in the 4150 optimum sample at its initial void ratio.
2. FLOQUAT™ FL 4150 treatments show a larger degree of ageing post consolidation than the base-treatment, as evidenced by the G' data; this is commensurate with the much lower degree of creep evidenced in the settlement curves.
3. Based on preliminary estimation of the compressibility properties, and employing these properties in simulation of large-strain consolidation in a 50 m deep hypothetical deposit, the FLOQUAT™ FL 4150 and base treatments provide very similar performance. However, given the larger tendency to

creep in the base treatment, which may substantially delay consolidation, the FLOQUAT™ FL 4150 may provide an advantage by achieving a sufficiently stable (minimal settlement) deposit more quickly than the base treatment.

Conclusion 3 is preliminary and must be re-evaluated once data on behaviour at higher effective stresses (the ongoing oedometer and instantaneous profile tests) becomes available.

Optimization of Operations Based on Monitoring and Construction Quality Assurance at Minera Peñasquito

Christian Armstrong, WSP, USA
Kenneth Rood, WSP, USA
Eduardo Jose Garcia Romero, Newmont Peñasquito, Mexico
Patrick Mwamba, WSP, USA

Abstract

Tailings storage facilities (TSFs) are dynamic environments that require active operational controls in order to meet the goals of physical stability, storage capacity, and other key design goals. Therefore, to operate a facility, robust construction quality assurance (CQA) and recurring field investigation programs must be performed to validate current conditions against the design. The TSF is operated as a cyclone sand, centerline raise facility with an outer shell of rockfill, with overflow tailings and whole tailings discharged into the TSF impoundment. The as-measured, in-situ properties should then inform lessons learned and be incorporated into future design and operations. The performance of the TSF at Minera Peñasquito was evaluated via a series of three significant Cone Penetration Test (CPT) programs, performed in 2014, 2019, and 2023 and two field sampling and geotechnical laboratory testing programs in 2014 and 2023, in combination with data and observations from the rolling CQA program. Results from the 2014 investigation were used to evaluate the materials properties, including changes of its characteristics due to optimization of operational and construction processes. Changes in the placement of the cyclone sand (e.g., improved water management, improved construction techniques) were evaluated by subsequent CPT programs and indicate that the cyclone sand and tailings materials are being placed in a more dense, more dilative state than previous stages of construction. The overflow and whole tailings behavior was evaluated and includes outcomes such as (a) the starter phase tailings placement resulted in a weak, fine tailings layer at depth and (b) changes in depositional management (e.g., rotating spigot deposition within the pond and removal of water near the edges of the facility) have resulted in denser/stronger materials.

Introduction

Tailings storage facilities (TSF) are inherently complex structures due to the continuous construction, scale, variability in ore characteristics, and other characteristics. Design for these structures is also based off pilot-

scale tailings generation, resulting in conditions that may vary from the in-place conditions due to variability in the ore body, operations during the initial starter and early years of deposition, and other factors. These factors are generally evaluated during the design phase by evaluating potential risks and variability and identifying potential contingencies that may be necessary. Due to this potential variability, field investigations and instrumentation are usually used to evaluate the performance of the facilities. Therefore, these tools should be used to support changes in the operations or design, which is inherently tied to the observational methodology.

The observational method has been employed throughout history by engineers and their precursors. For example, construction of the western façade of Notre Dame was halted for approximately a decade after builders observed the structure was leaning forward. They waited for settlement to reach a point where additional loading could be supported. A formalized version of the observational method was introduced to soils engineering by Karl Terzaghi and later refined and published in the seminal paper "Advantages and limitations of the observational method in applied soil mechanics" by Peck (1969). Peck argues that the observational method can be used to saved time or money by limiting overdesign of a complex structure prior to field observations that can be made during construction. Using field observations and data collected during and after construction can allow for continuous improvements to be made to the design.

The paper evaluates the use of the observational method based on information collected by the field investigations and instrumentation within the TSF at Minera Peñasquito, including the optimization of operations following the first significant field investigations.

Site background

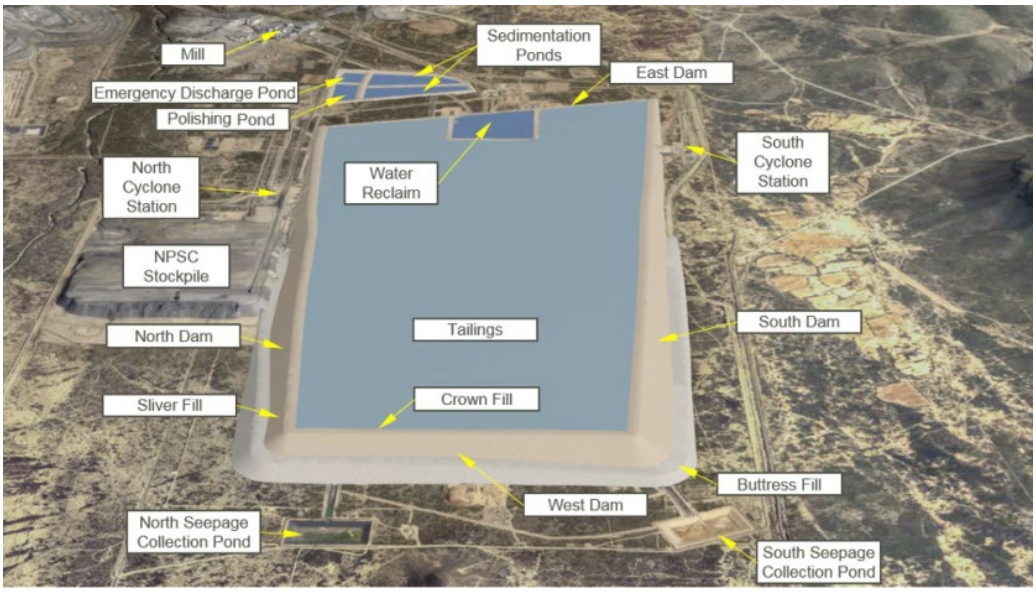

Figure 1: Key components of the TSF at Minera Peñasquito

The TSF at Minera Peñasquito tailings storage facility (TSF) is a four-sided structure with an 11 km perimeter and a current maximum height of approximately 117 m at the west embankment. The TSF receives 100,000 tons of tailings per day and has been in operation since 2009. The current design for the TSF includes a staged centerline raised to a maximum height of 134 m. Key components of the facility are presented in Figure 1.

The construction history for the Peñasquito TSF started with a 20-m-high starter dam constructed of borrowed alluvial fill with 2H:1V outer slopes (Golder, 2008, 2019). A rockfill buttress was constructed in 2011, and the dam has been raised continuously using the centerline methodology, with rockfill as the outer shell and cyclone sand as a compacted core separating the deposited tailings from the rockfill. Tailings are conveyed by gravity to cyclone stations located along the north and south dams. Cyclone underflow sand is separated from the whole tailings and used for dam construction, and cyclone overflow is deposited uniformly from the perimeter of the north, west, and south dams.

According to Golder (2019), the design and construction of the TSF has been dynamic in order to respond to changes in the availability of materials, operational experience, and shortages in quality sand production.

Construction of the TSF is separated into three activities defined as buttress fills, sliver fills, and crown fills. Buttress fills are required to stabilize the TSF dams as the facility is raised. Sliver fills are constructed over top of the buttress fills on the downstream of the centerline to allow for a widening of the dam crest, which facilitates the center line raise. Crown fills are constructed on the sliver fills to raise the elevation of the dam crest and support tailings deposition.

Operations of the facility

Construction of the TSF began in 2008 with a zoned earthfill starter dam, underdrain system, seepage collection system, starter impoundment system, and a start-up water reservoir impoundment. A technical review of the structure in 2011 found that due to insufficient quality sand production, a run of mine (ROM) rockfill buttress would be required to raise the embankment to 1,832.7 m. This construction would provide an additional two years of storage capacity, after which construction could continue as a centerline raise cyclone sand dam.

Following a 2014 technical review of the operations and TSF embankment stability, Minera Peñasquito concluded that it was not feasible to construct the facility with an embankment composed of only cyclone sand. The design was modified to make up the cyclone sand production deficit with ROM rockfill. A target crest elevation of 1862.7 m was selected as this corresponded with the maximum elevation where gravity discharge from the mill was possible. During this change in construction methods, full-time on-site engineering and construction quality assurance (CQA) services have been provided by Golder. The

CQA services included: material testing, construction oversight, dam inspections, oversight of tailings deposition, and oversight of seepage management.

Water management since 2014 has aimed to maintain a 200 m tailings beach from the centerline. Prior to this change in water management, minimum freeboard was not maintained in 2013, necessitating the construction of a temporary pipe berm. Following this event, significant improvements in construction methods and tailings deposition planning has led to a 200 m tailings beach being maintained, with only minor variances occurring. The effects of this water management can be seen in Figure 5, where the phreatic surface, observed via CPT soundings and VWP monitoring, has lowered and moved upstream in 2019 as compared to 2014.

Pipe berm construction is currently performed with the construction of temporary sand paddocks upstream of the dam centerline. As shown in Figure 2, a temporary sand paddock is constructed using existing cyclone sand, the paddocks are then filled hydraulically with underflow sand and water is allowed onto the tailings beach via a drain trench through the pipe berm. Once the sands have sufficiently drained, they are then excavated and used for quality sands at the centerline and for pipe berm raises. The quality sands are compacted using vibratory rolling to meet the design compaction specification. This construction methodology has led to an improvement in sand characteristics following 2014, with discrete variations in source materials occurring in 2020 where whole tailings and cyclone overflow sands were deposited into the paddocks.

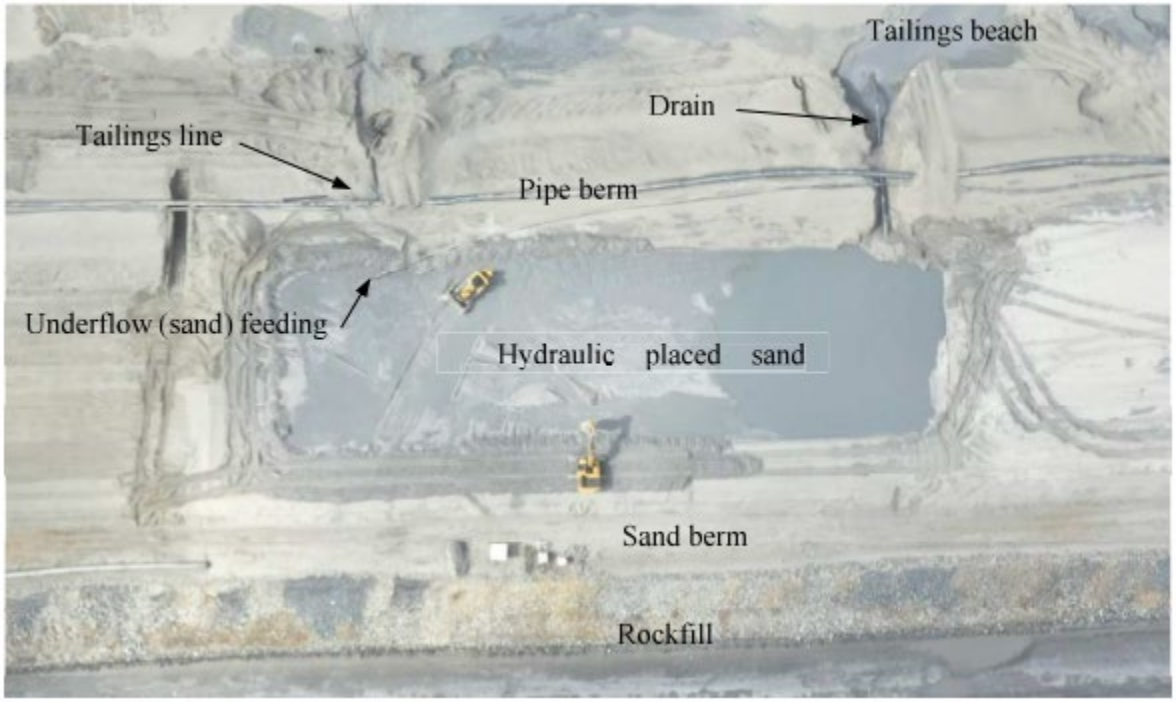

Figure 2: Aerial view of typical sand paddock construction (García and Sosa Dávila, 2020)

Analyses of seepage, stability, and consolidation have been performed to support the design changes and inform operational modifications. The 2016 buttress test fill program was instrumented and monitored to inform the maximum rate of rise achievable within the expected response of the subgrade. Since this investigation, construction of the buttress, sliver fill, and crest fill has been rotated around the perimeter of the facility to allow excess pore pressures generated by construction to dissipate before subsequent construction is performed. Additionally, tailings deposition is rotated through the spigots to maintain an even beach without the generation of localized depressions that would allow reclaim water to approach the pipe berm. The deposition is informed by visual observations, bi-weekly drone surveys, and subsurface phreatic surface monitoring. All these aspects inform a daily plan carried out by the Technical Services Planning team.

Field investigations and geotechnical testing

Field investigations were performed to evaluate the in-situ condition of the tailings versus the conditions anticipated from the detailed design analysis. In particular, the field investigations evaluated (1) the consolidation and density for a capacity analysis of the facility; (2) layering and interbedding of the tailings within the tailings beach/pond and pipe berm; (3) phreatic conditions and seepage to evaluate what flow routes are occurring within the field; (4) shear strength of the materials for modeling; and (5) critical state testing to evaluate the cyclone sand. The field investigations generally consisted of Cone Penetration Test (CPT) soundings following ASTM D5778, with additional borings performed in some investigations to support the correlated parameters. The more significant field investigations focused on the cyclone sand materials and tailings near the centerline, as these locations control the behavior of the facility, and were performed in 2014, 2019, and 2023.

The 2014 field investigation evaluated the performance of the facility following initial construction and operations using a combination of CPT soundings and seismic measurements, with a limited amount of seismic measurements, and boreholes correlated with selected locations. Results from the investigation supported the future capacity and design of the facility, including an evaluation of the phreatic conditions near the centerline of the facility, as these locations generally control stability and deformation. The vertical hydraulic gradients resulted in less than hydrostatic conditions within the cyclone sand, with a thinner saturated zone identified above the starter dam, and below hydrostatic conditions within the tailings beach materials, with closer to hydrostatic conditions further within the impoundment (see Figure 3).

However, portions of the phreatic surfaces are closer to hydrostatic in the tailings beach materials near the centerline along the west dam, indicating that the initial deposition had some variability in performance, particularly along the higher portions of the TSF near the starter facility. Perched pore pressure layers were observed within both the cyclone sand and the tailings beach. The cyclone sand is generally classified as

sand-like, with some silt-like layers, and the tailings varied from silt-like to clay-like, with heavily interbedded layers observed within the historic zone of the tailings placed behind the starter dam. These interbedded tailings generally were relatively loose and had low tip resistances.

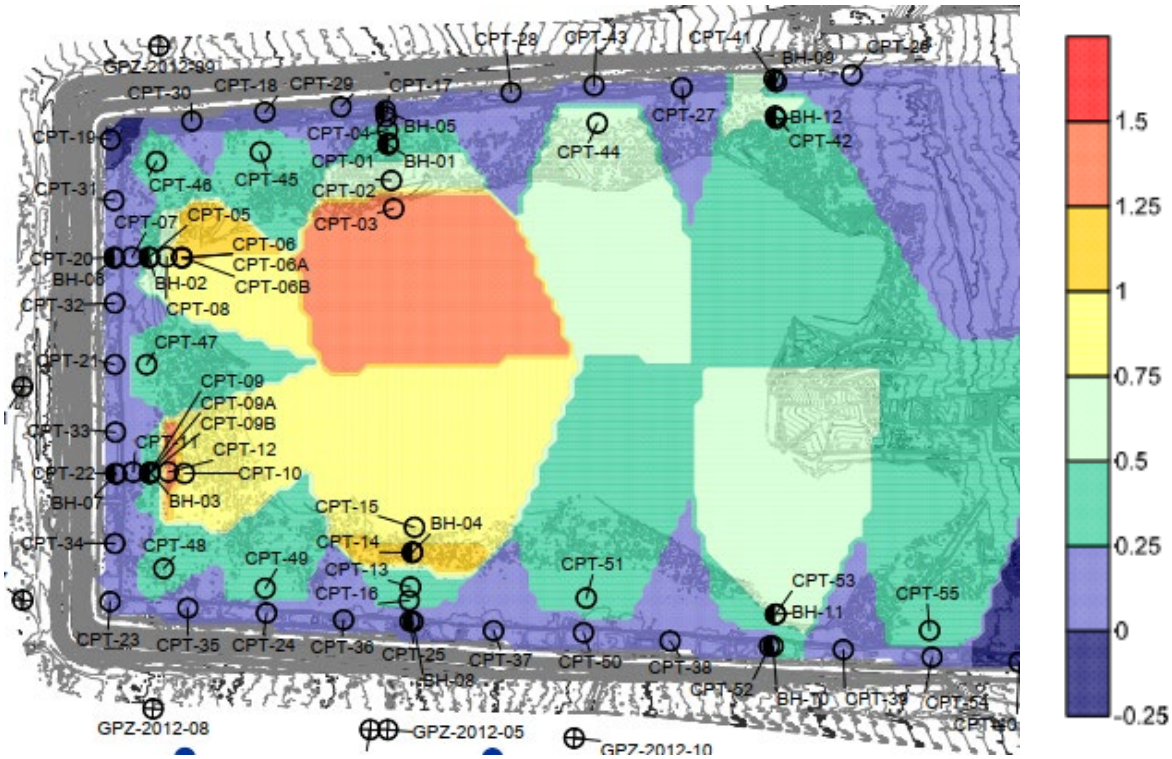

Figure 3: Vertical hydraulic gradients (unitless) within the TSF during the 2014 investigation (Golder, 2016)

The 2019 investigation was performed with CPTs and seismic measurements to evaluate how changes in operations affected the tailings, particularly the tailings beach. These changes in operations included the use of cyclone sand for the pipe berms as opposed to the reclaimed near tailings materials, and better control of the location of the decant pond. These operational changes resulted in a partially saturated cyclone sand section that was denser, with a higher shear strength, and with a more dilative correlated state parameter than observations from 2014, resulting in a performance improvement of the facility.

The better operational controls also resulted in denser tailings, as shown in Figure 4, using bulk unit weights (Robertson and Cabal, 2010) correlated from CPT data, presumably due to a higher effective stress during placement and reduced distances for consolidation pore pressures to dissipate. The change in operations also resulted in lower pore pressures near the interface between the cyclone sands and tailings beach, and in the phreatic surface moving further within the facility (Figure 5), due to discontinuing using excavated tailings beach materials to construct pipe berms. In general, the 2019 field investigations

validated the changes in operations performed following the 2014 investigation, and resulted in denser cyclone sand and tailings.

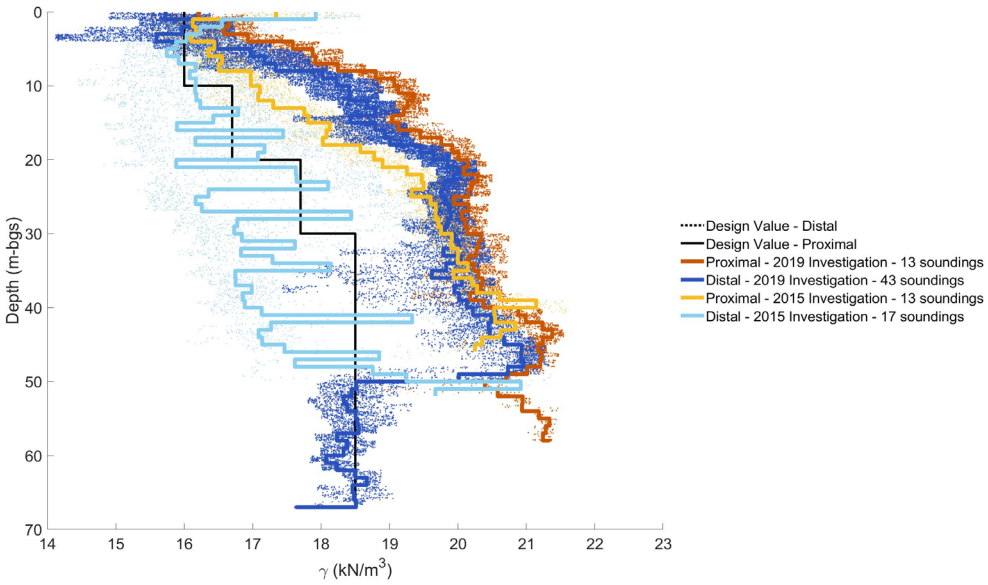

Figure 4: Correlated bulk unit weights from CPT soundings between 2015 and 2019 investigations (Golder, 2019)

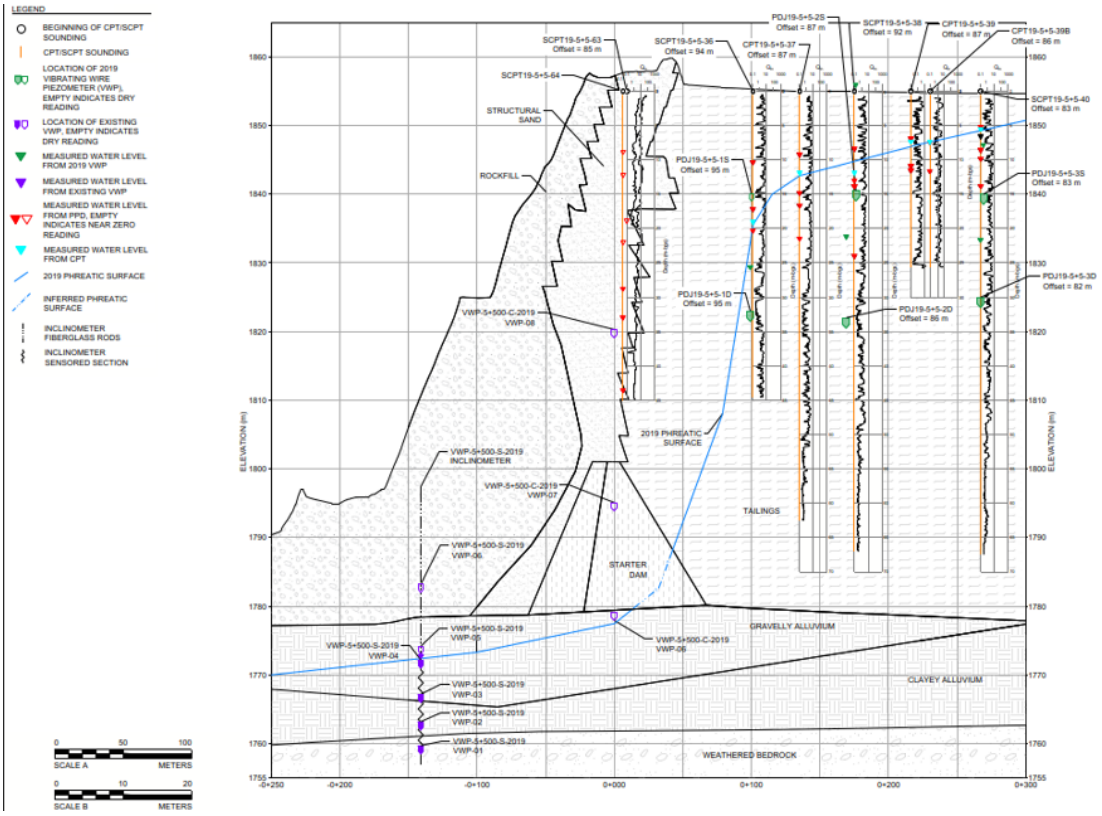

Figure 5: Generalized cross-section from 2019 field investigation (Golder, 2019)

The 2023 field investigation consisted of CPTs with seismic measurements and resistivity measurements to evaluate the saturation of materials above the inferred phreatic surface. Several soundings were co-located within the basin to evaluate changes in the material behavior over time. An example of the differences in observed behavior is presented in Figure 6 for a location within the tailings beach near the maximum cross-section. In general, the 2014 conditions were in materials classified as silt mixtures to sensitive fines, with a consistent significant excess pore water pressure generation and highly layered tailings.

The 2023 investigation indicated that these materials generally have had little densification, with similar normalized tip resistance, but materials placed in subsequent years have resulted in more sand-like to silt-like tailings behavior and reduced interbedded layers. While the initial program indicated generally near hydrostatic conditions, the operations following the 2014 investigation indicate that the phreatic conditions have shifted further within the impoundment and with lower than hydrostatic pore pressures. These changes result in tailings beach materials that are generally denser with higher shear strengths and more dilative conditions, resulting in better geotechnical performance of the facility due to the change in operations.

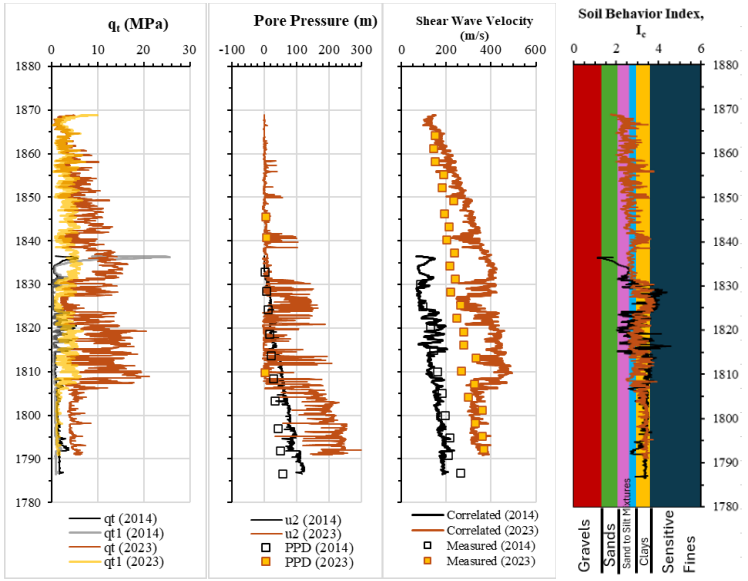

Figure 6: CPT Sounding measurements and interpretations for beach tailings from 2014 to 2023

In addition to the field investigations, robust instrumentation programs were performed, including installation of direct-push piezometers within the tailings and cyclone sands. These field instruments are an important tool to support the evaluation of the construction methodology and changes in operations. CPT soundings and corresponding Pore Pressure Dissipation (PPD) tests provide valuable information at the moment of the investigation; however, continuous monitoring provide information related to how normal operations and changes in observations can change the hydraulic performance of the materials. An array of

nested direct push vibrating wire piezometers is used to estimate the phreatic surface, to analyze the potential vertical and hydraulic gradients along with the corresponding flow paths during operations, and to generate and dissipate excess pore water pressures resulting in densification of materials via changes in response. Observations from these instruments generally are consistent with the results from the CPT investigations, indicating that the changes in operations have improved the performance of the facility by shifting the phreatic surface further within the impoundment via lowering the phreatic surface to below the elevation of the starter dam (Garcia and Sosa Dávila, 2020).

The field investigations also included various geotechnical laboratory tests on intact and bulk specimens recovered from the field. These tests were then used to evaluate the in-situ material properties and to evaluate whether assumptions made prior to design were consistent with the in-situ performance. Some examples of this testing used to support operations include testing on the cyclone sands prior to and during the 2014 investigation, evaluation of the large-strain consolidation characteristics, evaluation of saturated permeabilities, and critical state testing to evaluate and support the CPT investigations. Results from the geotechnical laboratory testing and field CQA testing of the cyclone sand prior to 2014 indicated that the material did have a higher fines content than anticipated during start-up and during the initial years of operations.

This observation was subsequently used to evaluate the placement of the cyclone sand and to determine how to adjust the operations to meet the specifications and design intent. The geotechnical laboratory program was also used to support volumetric analyses using in-place unit weight testing from intact specimens, bulk volumetric analyses from CQA records, and observations from piezometers to calibrate large-strain and normal consolidation results to models that better represented the field conditions by creating composite material properties. Composited parameters better represented the overall storage of the facility, as excessively fine resolution models may result in simulations that are heavily calibrated to a moment in time, as opposed to capturing variability observed during deposition due to changes or fluctuations in the ore body, operations, and other factors. Hydraulic testing in the field was used to estimate changes in the permeability for varying densities and confinement, and were also compared to interpreted PPD results to support hydraulic modeling. Testing evaluated the geotechnical characteristics and, to improve the accuracy of the interpreted state parameters, a critical state program was performed to evaluate the critical state behavior for coarser and finer cyclone sand and to use the CPTWidget to better interpret the in-situ state of the tailings.

Conclusion

TSFs are complex structures that inherently require the use of observational methodology, which involves designing facilities based on provided information and assessing risk prior to construction to design

contingencies. During operations, rigorous CQA monitoring, geotechnical instrumentation and monitoring, and field and laboratory investigations are needed to support the evaluation of these facilities. Observations and interpretations from these tools should be used together with operations to evaluate whether the TSF is currently meeting the design intention and whether any additional contingencies are necessary to design or implement. The field data should be evaluated using the state of the practice methodology, and previous analyses should be re-evaluated based on further advancement in the field, such as the development of additional or novel methodologies to estimate the residual shear strength and in-situ strength. Additionally, instrumentation provides a strong basis to reassess the conditions and performance of a facility and should be used to evaluate between field investigations, which may take upwards of a year to design, implement, and interpret results from. The focus of this paper has been on the geotechnical aspects, but geochemical, hydraulic, and other considerations are necessary as well.

From Minera Peñasquito, the operational changes to the materials used to construct pipe berms and maintain proper control of the operational pond indicate the inherent link between design and operations and how these groups should be in constant communication. Operators in the field provide valuable guidance into the actual behavior of the facility, while the design and planning teams can help support the evaluation and implementation of any additional contingencies. Good communication between these parties can result in significantly improved performance of the facilities, which reduces risks and helps to meet or exceed the design intent.

The flexible design of the TSF has allowed for the observational method to be employed effectively since 2014. This has proved beneficial, as design changes in the materials used to construct the dam embankment (moving from exclusively cyclone sand to a hybrid of rockfill and sand) allowed for construction to continue as the material production assumptions made during the initial design proved to be false. The use of the observational method in this project is limited, as Peck (1969) writes, to "The essential ingredient … the visualization of all possible eventualities and the preparation in advance of courses of action to whatever situation develops." It is only possible to observe for material responses to construction if a clear and comprehensive model of the facility and the surrounding geology is understood. Operational lessons include targeting field investigations and material analyses at credible failure mechanisms; clear understanding of regional geology and of the genesis of subsurface materials; periodic updates to material models (specifically tailings) as source materials change (pit host rock changing with depth, milling processes, etc.); and maintaining a design that is adaptable to these changes.

How Many Triaxial Tests Do You Actually Need to Get a Critical State Line?

Marcos Arroyo, CIMNE-UPC, Spain
Lluis Monforte, CIMNE-UPC, Spain
Stefano Collico, DMT, Germany

Abstract

Geotechnical analyses of tailing storage facilities (TSF) are nowadays very frequently based on critical state soil mechanics concepts. Obtaining a critical state line (CSL) for the different materials identified in the TSF is thus a necessary task. Given the large variability of materials commonly found in TSFs, that task may become onerous as several good quality triaxial tests are usually employed for each CSL, identifying the critical state condition attained in each triaxial test.

In this paper we explore an alternative approach, in which the effect of critical state properties on all the measured triaxial response of the soil is leveraged to minimize the amount of tests necessary to calibrate the CSL. For this purpose, we frame CSL calibration as a Bayesian updating problem, in which a generic "a priori" distribution of CSL parameters is updated with the results of a single triaxial test. Using examples from a well-known case history (Brumadinho) we show that, in some cases, the information embedded in a single test may provide close CSL calibrations to those obtained with the traditional procedure.

Introduction

Most tailings are deposited in a relatively loose condition and full saturation of the material is either present from the beginning or possible in the future. As a result, liquefaction is frequently a major consideration in the geotechnical analysis of TSFs. In the last decades a new paradigm has emerged (Jefferies and Been, 2006) in which analysis and management of liquefaction risks is informed by models and tools grounded on critical state soil mechanics. For instance, models incorporating critical state concepts have been used as tools in forensic analyses addressing the immediate cause of several landmark tailings storage facility (TSF) failures such as Fundão (Morgenstern et al., 2016), Cadia (Morgenstern et al., 2019) or Brumadinho (Arroyo and Gens, 2021). Similar models are increasingly employed in practice as predictive tools to help face a variety of design problems (e.g., Barrero et al., 2015; Halliday et al., 2022; Torres et al., 2023; Vargas-Moreno et al., 2023). All those models need as basic input a description of the critical state properties of

tailings. At a more fundamental level, many procedures currently employed to assess liquefaction susceptibility of a particular deposit from CPTu tests are reliant on critical state concepts and require an evaluation of critical state properties if they are to perform well (Torres Cruz, 2021; Shuttle and Jefferies, 2016). As a result, the determination of critical state properties for tailings has now become central in many geotechnical characterization campaigns for TSFs (e.g., Hone, 2023; Masengo et al., 2023; Toyra et al., 2023; Vieira Carneiro et al., 2023).

In the framework of critical state soil mechanics, critical state properties are described using a critical state line (CSL), i.e., the locus of void ratio-mean effective stress-deviatoric stress at which the soil shears at constant effective stress and void ratio. The relative position of the current state of the soil with respect to the CSL in the compression plane fully determines whether the soil will be contractive or dilative.

Current guidelines (Been and Olivera, 2016) recommend determining the CSL by means of drained and undrained triaxial tests on loose samples at different confining stresses. Triaxial testing on dense samples is discouraged, as these samples tend to develop localization planes during shearing, resulting in inhomogeneous stresses and strains in the sample (Desrues et al., 1996). The number of tests employed to define the CSL is influenced by budgetary and schedule restrictions in addition to the importance of the project. Been and Olivera (2016) propose a minimum of 4 tests to characterize the CSL within the range of 10-700 kPa, using undrained tests to characterize the low stress range and drained tests for the upper range. However, more than 4 tests are likely to be needed in most circumstances. In a recent round-robin exercise aimed at gauging the repeatability of CSL across geotechnical laboratories (Reid et al., 2021), the laboratories that achieved repeatable results performed 5.7 tests on average to determine the CSL.

While the number of triaxial tests required for a single CSL may not seem excessive, the problem is that a single CSL is frequently not enough. Materials deposited in TSFs are far from homogeneous, typically covering a wide range of gradations and frequently presenting also significant variability in terms of other fundamental properties, such as unit weight or plasticity. CSLs are known to vary significantly with material gradation or plasticity (Macedo and Vergaray, 2021) so the CSL characterization problem is likely to increase rapidly in size, if a realistic description of the deposit is sought. As the required testing procedures are not trivial (Reid et al., 2021) and the number of well-trained personnel and well-equipped laboratories available for CSL determination is never superabundant, critical state characterization may become a choke-point for some projects.

In this work we describe one approach to reduce or manage this problem by means of Bayesian statistics. The fundamental idea that is explored here is that information about critical state properties is present (but hidden) in all the datapoints that may be obtained from a triaxial test and not just on a few selected points. Exploiting that hidden information should allow us to obtain reliable estimates of CSL parameters using fewer tests.

Methodology

Critical state line formulation and determination in current practice

The most frequently employed formulation for CSL in current practice has a straight line in the triaxial compression plane, with slope given by the parameter M

$$q_c = M\ p'_c \qquad \text{(Equation 1)}$$

In the compression plane a straight line is also employed in the semilogarithmic compression plane, so that the CSL is given by

$$e_c = \Gamma_{100} - \lambda \ln \frac{p'}{p'_{ref}} \qquad \text{(Equation 2)}$$

where the parameters introduced to describe the CSL are λ, the plastic compressibility and Γ_{100}, the value of the void ratio in the CSL when the mean effective stress p' is equal to a reference value, p'_{ref}. In this work the reference mean stress value is taken as 100 kPa (Torres-Cruz and Santamarina, 2020).

It is widely accepted that this CSL straight line formulation in the semilogarithmic compression plane is an approximation, only valid in a restricted stress-range. More general curved CSL formulations are also available (Fourie et al., 2020). Their use would not change the argument presented here, although it would add some complication, unnecessary at this stage.

To determine parameters M, λ, and Γ_{100} current practice generally relies on identifying critical state conditions in different triaxial tests and fitting those points in the two reference planes. Because attaining critical state conditions requires the imposition of large strains and that may be challenging in practice, alternative methods that facilitate extrapolation to critical state conditions are also in use, like the use of stress-dilatancy plots (Ghafghazi and Shuttle, 2009).

CASM

CSL parameters are employed in constitutive models that, when correctly formulated, should be able to predict the whole response of the soil observed during the test. For a triaxial compression test in which axial deformation is imposed under constant confining stress, that response includes the deviatoric stress and the volume or pore pressure changes, respectively, if drained or undrained. There are several constitutive models that are able to replicate the triaxial response of triaxial tests employed to measure CSL. In this work we will use a modified version of the Clay and Sand Model (CASM; Yu, 1998). Note, however, that the methodology presented is not necessarily reliant on CASM; any other constitutive model with similar predictive capabilities may be employed.

CASM is an elasto-plastic isotropic critical state-based model, conceived to represent a wide range of soil behaviour, including the undrained softening characteristic of flow liquefaction. CASM has been

applied, with success, to analyze liquefaction failure in TSFs (Arroyo and Gens, 2021; Mánica et al, 2022) and to simulate CPTu in liquefiable soils (Monforte et al., 2019; Boschi et al., 2024). A detailed description of the CASM version used here can be found in those references. For the purposes of this work, it is enough to recall that, apart from the three CSL parameters, M, λ, and Γ_{100}, CASM features five more. Two of them, the Poisson ratio υ, and swelling index, κ, describe elastic response in the same terms as classical Cam-clay models. The remaining parameters are original to CASM. Two of them, n and r, appear on the yield surface formulation

$$f = \left(\frac{q}{Mp'}\right)^n + \left(\frac{\psi}{\psi_R} - 1\right) = \left(\frac{q}{Mp'}\right)^n + \left(\frac{\psi}{(\lambda - \kappa)\ln r} - 1\right) \qquad \text{(Equation 3)}$$

where ψ_R is the reference state parameter, value of the state parameter on the isotropic compression line (ICL), which is assumed parallel to the CSL. Because of this parallelism, determining the CSL value Γ_{100} is equivalent to determining e_{100}, the void ratio at the reference pressure in the ICL.

A final parameter m appears in the stress-dilatancy formulation derived from the plastic potential,

$$d^p = \frac{(m-1)}{m}\frac{\left(M^m - \eta^m\right)}{\eta^{m-1}} \qquad \text{(Equation 4)}$$

Manica et al. (2022) present several relations that simplify CASM calibration. They show that m is directly linked to the at-rest coefficient of earth pressure, K_0, and that, for normally consolidates materials, undrained peak and residual strengths are also directly linked to n and r.

Bayesian identification of constitutive parameters

Bayesian analysis has become increasingly popular in geotechnical engineering. From a Bayesian perspective, probability expresses a degree of belief on the outcome of an event or truth of a proposition, given some related evidence (Vick 2002). Bayesian analysis is thus able to integrate, in a systematic and rational manner, existing prior information, sometimes subjective, with observed data. It is also easily adaptable to sequential procedures, incorporating the result of new observations as they become available. For instance, Llano-Serna et al. (2022) used Bayesian inference to calibrate models of tailings compressibility combining oedometer results and field observations.

The Bayesian perspective on probability is different from the more traditional frequentist one. As explained by Contreras et al. (2018), frequentists treat statistical parameters (e.g., mean and standard deviation of error incurred by a geotechnical predictive model) as unknown fixed quantities, whereas observations are treated as realizations of random variables. On the contrary, from a Bayesian perspective, parameters of statistical models are unknown random variables, and observations are fixed known quantities.

In our case the observations are those obtained during one -or more- triaxial tests. For each axial deformation value recorded during the test, $\epsilon^i_{a\ obs}$, we have a set of observations $\boldsymbol{D}_i = [p^{i'}_{obs}, q^i_{obs}, e^i_{obs}]$; that is, the mean effective stress, the deviatoric stress and the void ratio. As unknown random variables we consider a set of CASM constitutive parameters $\boldsymbol{\alpha} = [\lambda, e_{100}, \phi, n, r, \nu, m\ ]$. For any possible value of those parameters a triaxial response may be simulated and the error incurred at any point in the triaxial path computed. We assumed that the model predictions are unbiased, so that those prediction errors are random, normally distributed variables, with zero mean. This is expressed as

$$\frac{p^{i'}_{obs} - p^{i'}_{sim}}{\max(p_{obs})} \sim N(0, \sigma_\sigma) \tag{5}$$

$$\frac{q^i_{obs} - q^i_{sim}}{\max(q_{obs})} \sim N(0, \sigma_\sigma) \tag{6}$$

$$e^i_{obs} - e^i_{sim} \sim N(0, \sigma_e) \tag{7}$$

where $p^{i'}_{sim}$, q^i_{sim} and e^i_{sim} are the model predictions of mean effective stress, deviatoric stress and void ratio computed with parameters $\boldsymbol{\alpha}$ and σ^2_σ and σ^2_e are the random model error variances for stress and void ratio measurements. These error variances are also considered as random variables.

A Bayesian inference scheme can thus be set-up. Calling $\boldsymbol{\theta} = [\boldsymbol{\alpha}, \sigma_\sigma, \sigma_e]$ the whole vector of random variables, we are interested in obtaining the statistical distribution of those random variables that best honors the test observations. Such distribution is known as the posterior distribution $P(\Theta|D)$, obtained by means of Bayes theorem as

$$P(\ \boldsymbol{\theta}\ |\boldsymbol{D}\ ) \sim L(\boldsymbol{D}|\boldsymbol{\theta})\ p(\boldsymbol{\theta}) \tag{8}$$

where $p(\boldsymbol{\theta})$ is the prior probability distribution of the inference variables, expressing previous knowledge or beliefs about them, and $L(\boldsymbol{D}|\boldsymbol{\theta})$ is the likelihood distribution: the probability of observing $\boldsymbol{D}$ given some model parameters. We define the likelihood function assuming that the errors incurred in the three triaxial predicted variables are independent, so that the joint probability of erroneous observation is:

$$L(\boldsymbol{D}|\boldsymbol{\theta}) = \prod_{i=1}^{N} \phi\left(\frac{p^{i'}_{obs} - p^{i'}_{sim}}{\max(p_{obs})\ \sigma_\sigma}\right) \phi\left(\frac{q^i_{obs} - q^i_{sim}}{\max(q_{obs})\ \sigma_\sigma}\right) \phi\left(\frac{e^i_{obs} - e^i_{sim}}{\sigma_e}\right) \tag{9}$$

where ϕ is the standard normal distribution.

To evaluate the posterior distributions numerical integration is required. In this work, a parallel version of the Transitional Markov Chain Monte Carlo method (TMCMC) (Ching and Chen, 2007) is employed to draw samples of the posterior distribution. TMCMC iteratively constructs a sequence of samples that transition from the prior to the posterior distribution by combining a sequential particle filter

method and Markov Chain Monte Carlo sampling (Ching and Chen, 2007; Betz et al, 2016). TMCMC has been used in many applications, including site geotechnical characterization based on CPTu (Ching and Wang 2016; Collico et al. 2022). The choice of prior distributions for the different random variables is explained in the next section.

Application example

Example dataset

A series of triaxial tests on reconstituted samples from an iron tailing recovered from Brumadinho B1 dam (Arroyo and Gens, 2021) are selected for application. The material corresponds to that described as "Type 2" tailings by Viana de Fonseca et al, (2022). The tests analyzed include five isotropically consolidated triaxial tests on loose specimens, four sheared drained and one undrained, as well as one isotropic, drained triaxial test on a dense specimen.

Figure 1 reports the main outputs of these triaxial tests. On first inspection, the end points of all loose specimens seem to define a straight CSL roughly parallel to the ICL - defined from the end-of consolidation points- on the compression plane. The exception is the dense specimen whose trajectory in the compression plane is not congruent with those obtained with the loose specimens. This discrepancy can be attributed to strain inhomogeneity as shear localization planes developed in the specimen prior to failure.

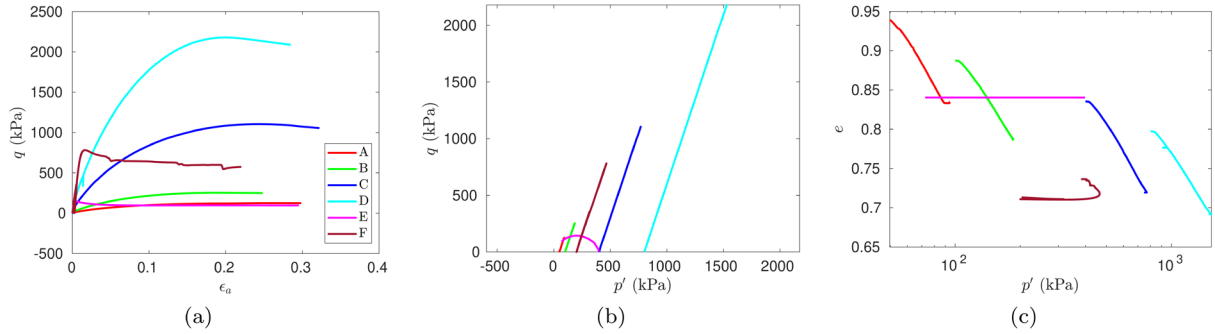

Figure 1: Triaxial compression test results for the example dataset (a) deviator stress vs axial strain (b) stress paths (c) compression paths

Figure 2 illustrates the traditional or "manual" calibration, in which the initial and final points of the 5 triaxial tests on loose specimens have been considered as points on the ICL and CSL respectively. The values $e_{100} = 0.901$ $\Gamma_{100} = 0.824$ and $\lambda = 0.049$ were estimated by minimizing the error on the predicted void ratio using Equations (1) and (2). The slope of the CSL on the triaxial plane M was estimated using a stress-dilatancy plot. A critical state friction angle $\phi = 35^{o}$ is obtained from the stress ratio at critical state using the relation $M = 6\sin(\phi)/(3 - \sin(\phi))$.

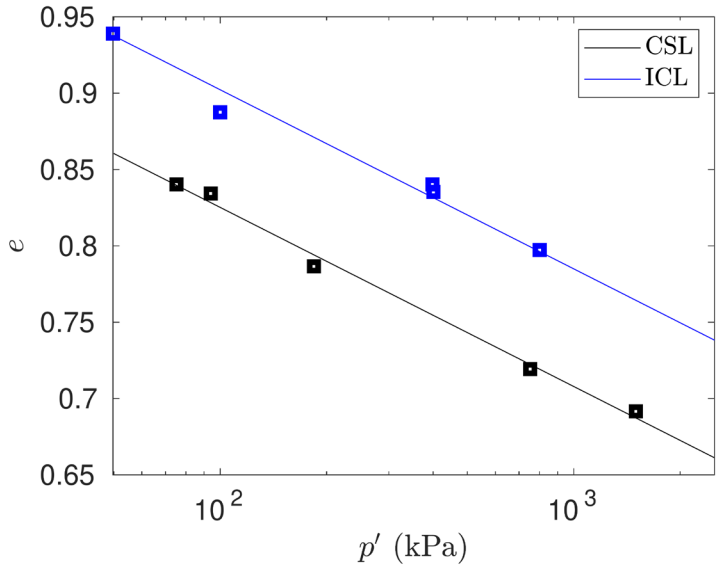

Figure 2: Manual fitting of the CSL and ICL on the compression plane

Prior distributions

All constitutive parameters of the model are calibrated except for the swelling slope, for which a value of 0.008 was adopted based on isotropic unloading tests (Viana de Fonseca, 2022). The prior distributions are always continuous uniform distributions. The limits of these distributions, shown in Table 1, have been chosen partly based on the database of Macedo and Vergaray (2022) and partly on visual inspection of the experimental data. For instance, the limits of the uniform distribution of the friction angle are equal to that inferred from the end of the test stress state ± 3º; likewise, the vertical position of the ICL at the mean effective stress corresponding to the test start is equal the experimental data ±0.03; on the other hand, the prior of λ is based on the consolidation phase performed before triaxial shearing (Figure 3). For other variables, such as n and r, large, uninformative priors are employed.

Table 1: Limits of distributions

	ϕ	λ	ν	n	r	m	e_{p_i}	σ_σ	σ_ϵ
Lower bound	ϕ_{EOF} −3°	0.04	0.2	1.1	2	1.7	e_i − 0.03	0	0
Upper bound	ϕ_{EOF}+3°	0.075	0.35	4	185	2.5	e_i + 0.03	0.05	0.01

Simulated triaxial test response

The Bayesian inference scheme was run independently using each one of the six available triaxial tests. CASM model prediction of triaxial response were computed using a constitutive driver based on Sloan et al (2001). Figure 4 and Figure 5 report the outputs of each model calibration alongside the experimental

data. For the simulated outputs we report the expected value in addition to the 95% credible interval (CI). Those CI are obtained combining, for a certain value of axial deformation ϵ_a^i , the variance of the predicted test outputs and the estimated model prediction error (through the calibrated variances σ_σ^2 and σ_e^2).

In all cases a very good match between the mean of the predictions and the laboratory test result was found, both in the compression plane and in the axial deformation-deviatoric stress plot. For the loose specimens, the error bands given by the CI are rather small, but they are significantly wider for the dense dilatant specimen. For this test, the model was adjusted including also the value of the initial overconsolidation ratio amongst the predicted variables. A value around 14.2, with a low variance, was estimated.

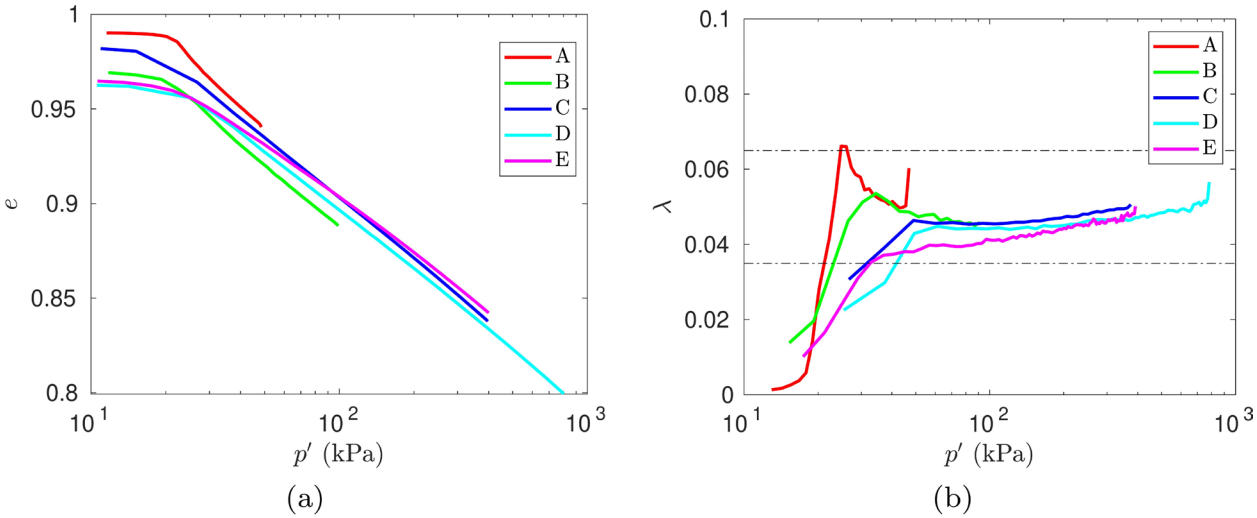

Figure 3: Isotropic compression paths and tangent approximation of plastic compressibility along the path

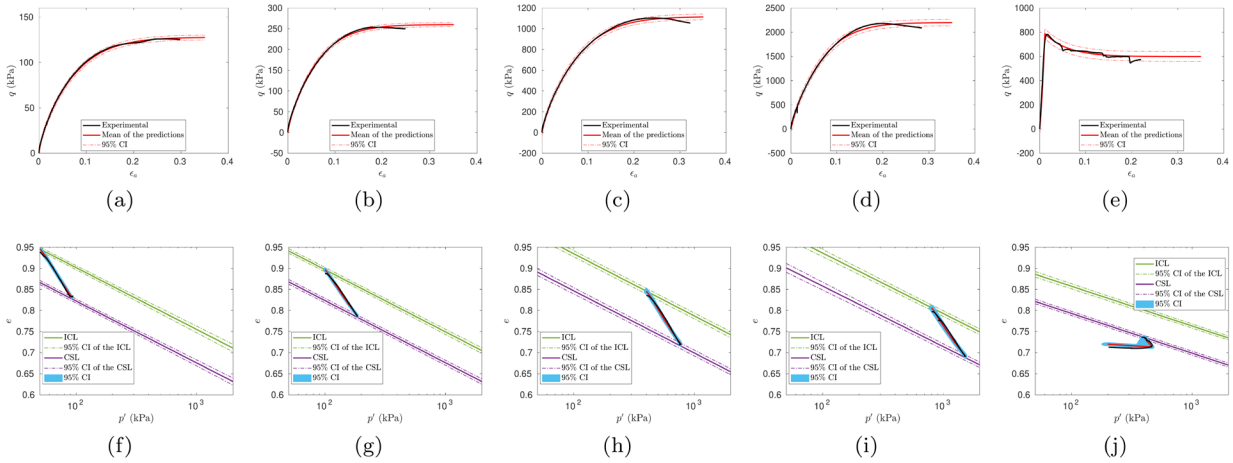

Figure 4: Outputs of model calibrations based on each separate drained triaxial test

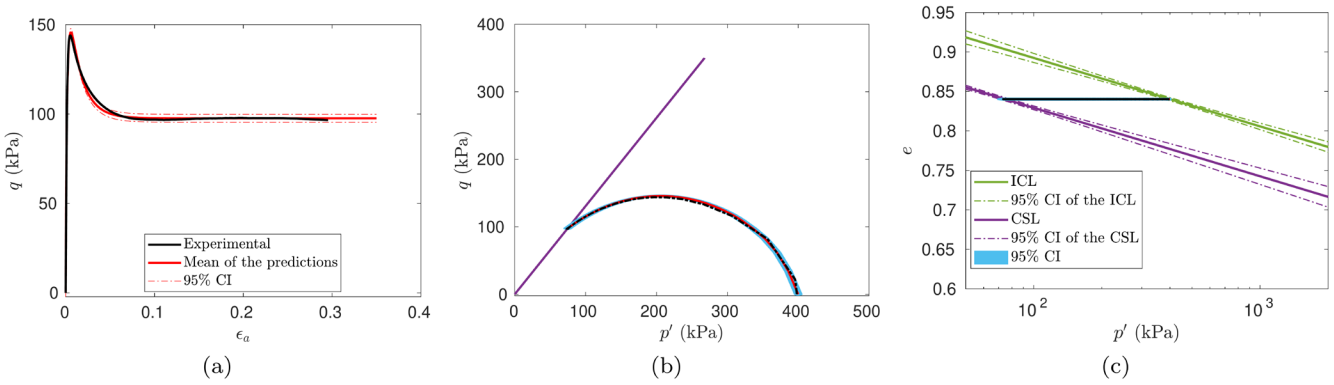

Figure 5: Outputs of model calibration based on the undrained triaxial test

CSL estimations

The Bayesian scheme produces a full probabilistic calibration of all the model parameters. Focusing only on CSL parameters, the posterior distributions obtained from each triaxial test through the Bayesian inference scheme are presented in Figure 6. The central (mean) estimates of CSL in the compression plane are presented in Figure 7. Examining these results, it can be observed that

- the central estimates obtained using a single test are never very distant from for the manual estimate obtained with all the loose tests (A to E). For the position of the critical state line Γ_{100} the differences with the manual estimate are within 0.03; for the slope of the critical state line within 0.012; for the critical state friction angle within 2.5°
- results obtained with the drained dilatant test (F) are clearly different from those obtained with the loose tests: it estimates a lower and flatter CSL and higher friction. Still, for a test that localized and where boundary stress and strain are not necessarily representative the results are surprisingly close.
- results obtained for the undrained test (E) are also distinctive in some respects: it estimates a flatter CSL and the lowest critical state friction angle.

Conclusion

Although more systematic exploration of the method is necessary, the exploratory results here obtained appear promising. Bayesian inference may be usefully employed to leverage the hidden constitutive information contained in every triaxial tests and thus facilitate the task of CSL determination. The methodology presented has the added advantage of being easily automated, thus reducing the scope for subjective estimation of CSL parameters.

Holden Mine Post Closure Monitoring – a Statistical Method for Developing Trigger Action Levels

Summer Y. Sun, Stantec Consulting Service, USA
Ray Dorow, Stantec Consulting Service, USA
Paul Pellicer, Stantec Consulting Service, USA
Mohammad Rashidi, Stantec Consulting Service, USA
Phillip Crouse, Stantec Consulting Service, USA

Abstract

How do we know the effectiveness of closure implementation in meeting the closure objectives and success criteria? This paper provides a case study on a deterministic and statistical method for establishing trigger action levels for monitoring the physical stability of the Holden Mine tailings piles. Determining these thresholds is a multifaceted challenge, influenced by factors such as site-specific conditions, instrument characteristics, and potential failure modes. This paper will present a methodology using programming software tools such as Python or R, developing trigger action levels to determine triggers and appropriate actions so that the tailings piles maintain the physical stability criteria and document the physical behavior of the tailings piles to achieve the success criteria of safe closure.

Our methodology integrates deterministic and statistical analyses to establish thresholds. Initially, deterministic analysis identifies acceptable conditions, assesses associated risks, and informs the relative importance of geotechnical instruments across various locations within the tailings piles. Subsequently, statistical analysis tracks readings over time, identifying anomalies and evaluating data distribution. Leveraging programming tools, particularly Python or R, automates data processing tasks, facilitating rapid iteration and sensitivity analysis. This integration of deterministic and statistical approaches, augmented by programming software, enables engineers to explore a wide range of threshold scenarios efficiently, leading to informed decision-making.

To demonstrate the practical application of our methodology, we present a detailed case study focusing on a TSF. In this case, slope inclinometers and piezometers are deployed to monitor ground movements and pore water pressures. Through the application of our methodology and programming software, optimal Trigger Action Response Plan (TARP) thresholds are determined for the site. Notably,

we introduce sub-TARP levels tailored to the specific characteristics of the TSF, enabling stakeholders to detect changes at smaller increments and providing early warnings of potential issues before they escalate.

This case study underscores the importance of tailored threshold determination strategies, accounting for the unique characteristics of each project. By leveraging programming software, engineers can streamline the threshold determination process, saving time and resources while enhancing the overall effectiveness of geotechnical instrumentation and monitoring projects. Our findings contribute to the advancement of methodologies for establishing TARP thresholds, particularly in the context of mine waste facility closure, and highlight the significance of integrating geotechnical instruments with programming software for improved monitoring and risk management.

Introduction

The closure of a mine requires meticulous planning and execution to meet closure objectives and success criteria. A crucial aspect of this process is the establishment of trigger action levels (TALs) for monitoring closure performance. Trigger thresholds are essential for early detection of trends in the performance of the mine closure components for initiating timely remedial actions. Closed tailings storage facilities are a component of a mine closure that can require monitoring for physical stability years after the mine has closed. Past studies were performed to use deterministic and statistical approaches to evaluate the TAL for tailings facilities (Clarkson et al., 2020; Carvalho Nunes et al., 2023).

This paper presents a case study on the Holden Mine tailings piles, illustrating a combined deterministic and statistical approach to establishing TALs. The methodology utilizes programming tools such as Python or R to streamline the process, allowing for efficient and comprehensive analysis. The methodology can also be provided for developing TALs for other mine components such as waste rock piles, pit slopes, etc. This method is not only applicable to closure mine sites but also for active facilities.

Site background information

The Holden Mine site is situated in Chelan County, within the remote Cascade Mountains of the Wenatchee National Forest in North Central Washington. The initial mining claim was made in 1896–1897, identifying a significant copper resource. Mining operations began 20 years after the death of the man who staked a claim. It produced copper from 1937 to 1957 and generated around eight and a half million tons of tailings, which were stored in three tailings piles, TP-1, TP-2, and TP-3, as shown in Figure 1. After its closure, the mine's interests were transferred in 1961 to the Lutheran Bible Institute, which now operates the site as Holden Village, a nonprofit ministry. Holden Village, located on the north side of the project site, maintains about 20 structures and hosts approximately 40 to 60 year-round residents.

Since 2008–2009, significant reclamation and reshaping efforts have been undertaken. A fully penetrating groundwater containment barrier wall and collection system were constructed around TP-1, Lower West Area, and a portion of TP-2. The collected water is conveyed to a mine water treatment plant (MWTP) for treatment and release back to Railroad Creek.

In 2023, Rio Tinto installed piezometers and inclinometers with telemetry to facilitate automated data collection. These systems include vibrating wire piezometers and slope indicators, with data transmitted to the mine water treatment plant and accessible remotely via the Internet. The system is designed for expandability to integrate additional instruments into the remote monitoring system, enhancing safety and data collection at the site.

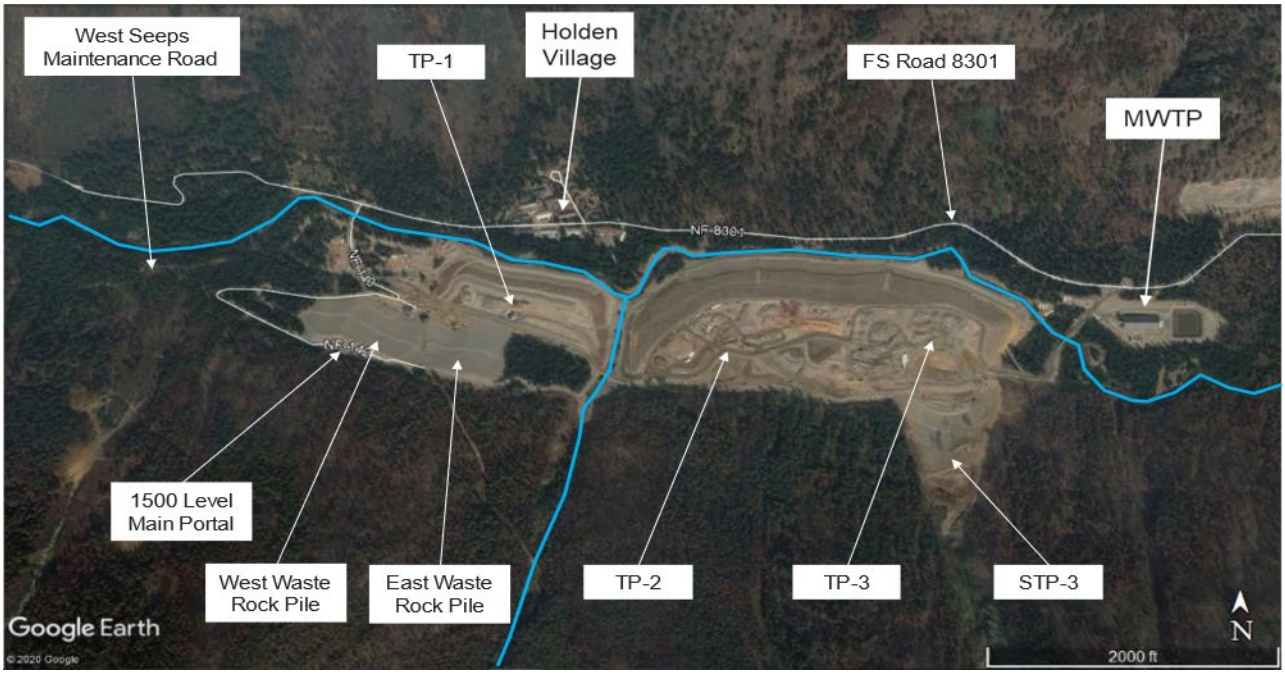

Figure 1: Site map of Holden Mine

Telemetry system

The telemetry system installed at Holden Mine consists of 63 vibrating wire piezometers (VWP) and 7 in-place slope inclinometers (SI). Figure 2 shows one of the monitoring stations, with a central datalogger mounted on a pole and connected to one or multiple VWP or SI sensors. The yellow bollards surrounding the station provide protection against accidental damage. The vibrating wire piezometers measure pore water pressures within the tailings and foundation soils. These sensors are strategically placed to cover various depths and locations across the site, ensuring thorough coverage and accurate data collection.

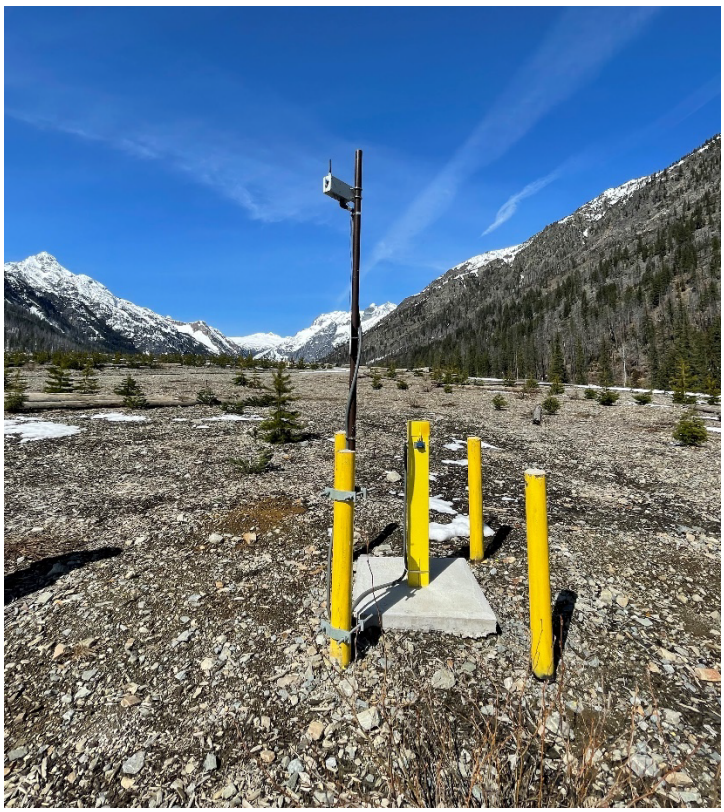

Figure 2: Monitoring station with Datalogger

Figure 3 presents a diagram of the telemetry system at Holden Mine. It shows the flow of data from the sensors (VWP or SI) through the Wireless Data Loggers to the central Gateway, and then to the Router, which connects to the internet via Starlink. The telemetry is configured this way because the site is outside of cellular coverage. By using Starlink connection, the telemetry system can transmit data via satellite internet. This allows for continuous, real-time monitoring and remote data access, even in remote locations where cellular service is unavailable.

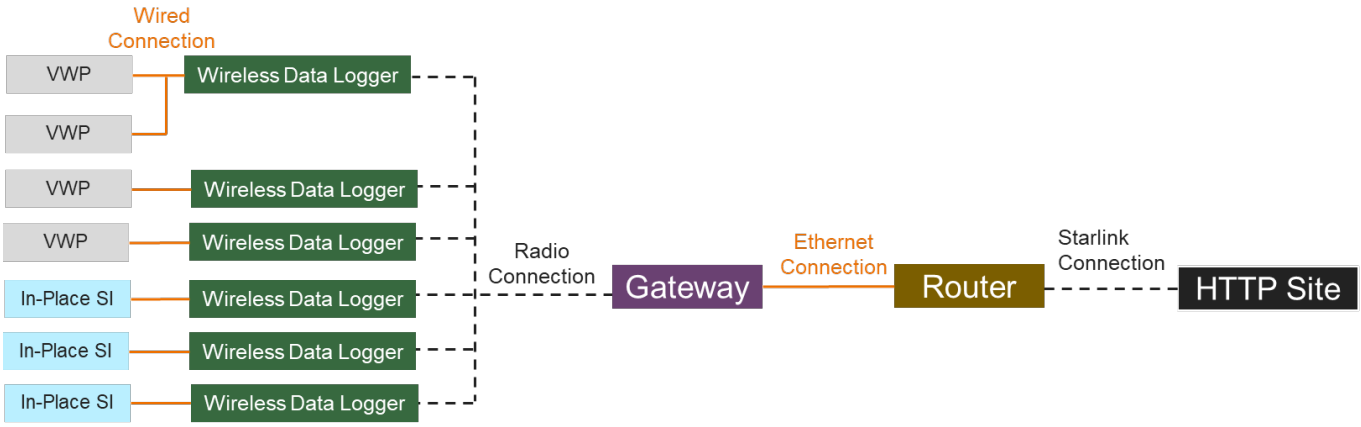

Figure 3: Holden Mine telemetry diagram

Methodologies

Establishing TARP thresholds using a deterministic analysis approach involves identifying normal conditions for the tailings pile closure performance parameters based on site-specific conditions and potential failure modes. The statistical analysis approach complements the deterministic analysis by tracking instrument readings over time to identify trends, anomalies, and deviations from expected behavior. Programming aids both approaches by:

- Data integration: combining data from multiple instruments and sources for comprehensive analysis.
- Data processing: streamlining the analysis workflow to efficiently handle large datasets.
- Anomaly detection: using statistical methods to identify outliers and unexpected trends in the data.
- Threshold refinement: adjusting TALs based on observed data distributions and statistical analysis.

The following subsections discuss the process of defining the trigger level thresholds for the VWPs as well as the SIs.

Defining trigger level thresholds for VWPs

Figure 4 provides the locations of selected existing monitoring wells and newly installed monitoring instruments within a tailings management facility. The upper part of Figure 4 shows the historical monitoring well locations, marked with purple dots, which indicate the positions of the existing piezometers. The lower part of Figure 4 highlights the newly installed vibrating wire piezometers and slope inclinometers, divided into four distinct zones: Area 1 (Mountain Side), Area 2 (Middle), Area 3 (Crest), and Area 4 (Intermediate Bench). Each type of instrument is color-coded for clarity, with new vibrating wire piezometers represented by blue dots and new slope inclinometers by green dots.

The readings from the existing piezometers play a crucial role in predicting TARP thresholds for the new piezometers. By analyzing historical data from these existing instruments, we calculated baseline conditions, the maximum and minimum readings in the past. This historical data helps establish initial TARP thresholds for the new piezometers, ensuring they are tailored to site-specific conditions. Future integration of real-time data from the new piezometers with historical data will enable refinement of these thresholds, enhancing the overall safety and effectiveness of the tailings management system.

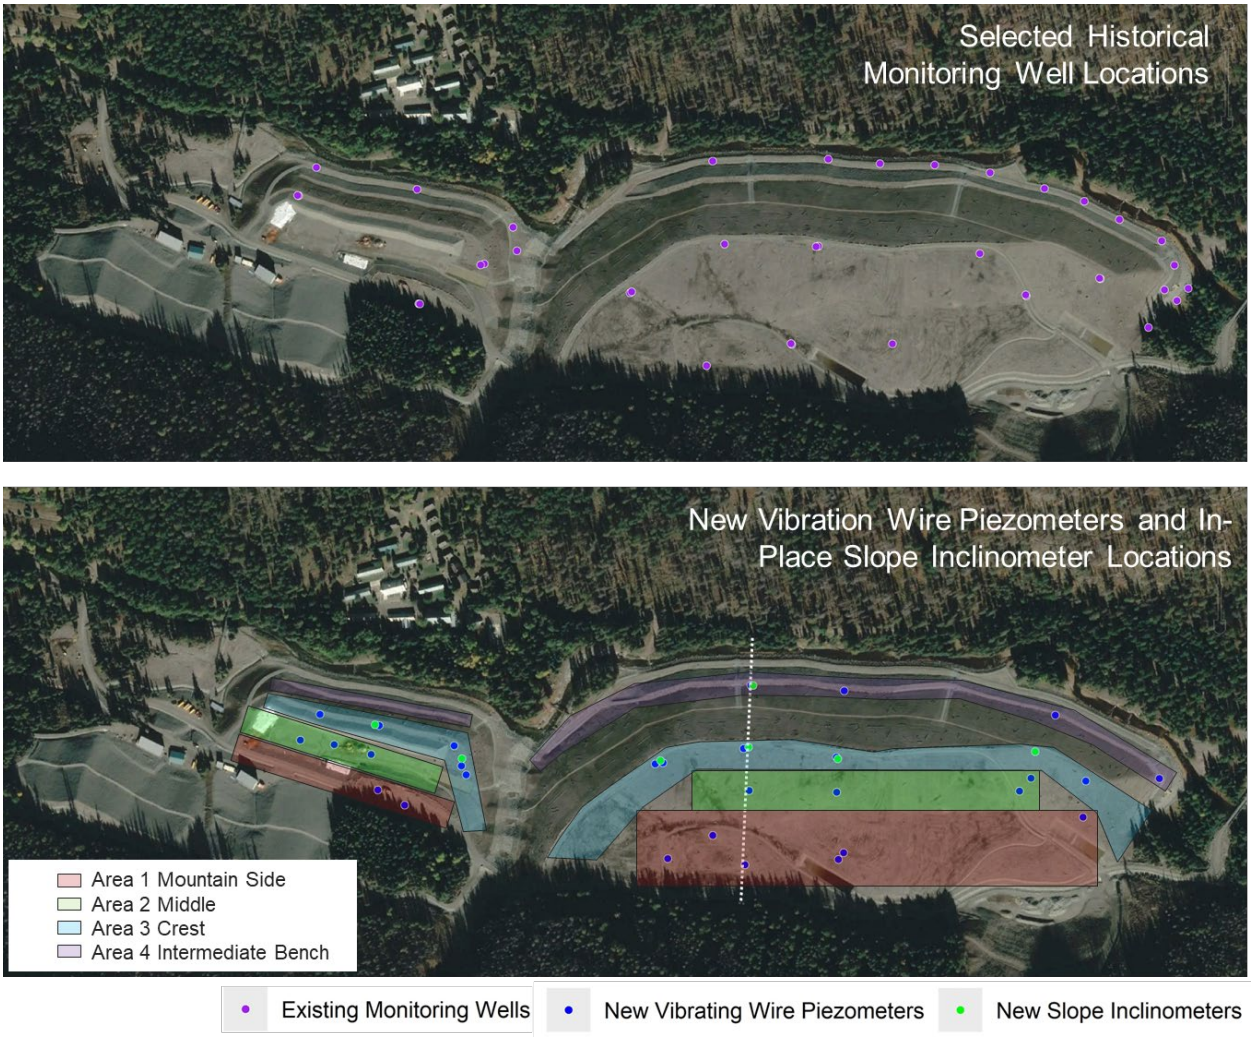

Figure 4: Vibration wire piezometer location maps

Figure 5 presents a detailed cross-sectional view of the tailings facility, corresponding to the dotted line location indicated in Figure 4. It illustrates the nested configuration of piezometers and the placement of slope inclinometers within various stratified materials. At each designated location, piezometers are nested, meaning there are either two or three piezometers installed at different depths, specifically targeting alluvium and fine-grained tailings (Group E), and intermediate fine-grained and coarse-grained tailings (Groups C and D). Coarse-grained tailings (Groups A and B) are considered faster drained and therefore are not targeted by the VWPs. This stratified approach allows for comprehensive monitoring of pore pressures across different material layers within the tailings structure.

Additionally, slope inclinometers are strategically placed at the crest and intermediate bench to monitor both overall stability of the entire slope and local toe slope stability. The blue lines in the figure represent historical monitoring data from previous piezometers, indicating historical maximum, average,

and minimum readings of pore pressure or water levels. These historical benchmarks provide a crucial reference for comparing current readings from the new piezometers, allowing engineers to assess current conditions against historical norms and identify any anomalies. The slope inclinometers contribute by detecting shifts or movements within the slope, offering early warnings for potential stability issues.

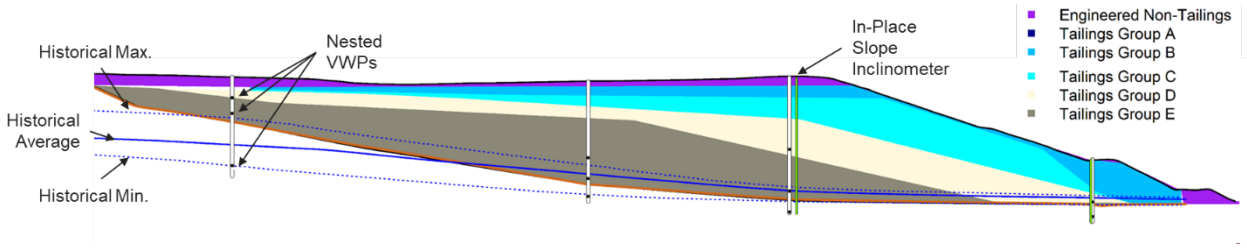

Figure 5: Example cross-section of Holden tailings pile and instruments

Figure 6 illustrates the rational for setting the VWP thresholds. The TARP for Holden Mine includes Normal, Alert, Watch, and Warning levels, each with associated response plans. The deterministic approach involves iteratively evaluating the factor of safety by raising the water table. Slope stability analyses were performed to verify if raising the water table alone would result in a factor of safety lower than the design criteria during both drained and undrained loading conditions. For the stability cross-sections analyzed, we were unable to reduce the factor of safety to a point where it did not meet the design criteria (FOS = 1.5) for slope stability of the global slope at a ratio of 3H:1V. Therefore, we adopted a statistical approach, where the alert trigger corresponds to readings that exceed the historical maximum readings. For VWPs within the intermediate bench area that is within the toe slope stability slip surface, the stability of the toe slope of 2H:1V determines the trigger for the Watch threshold.

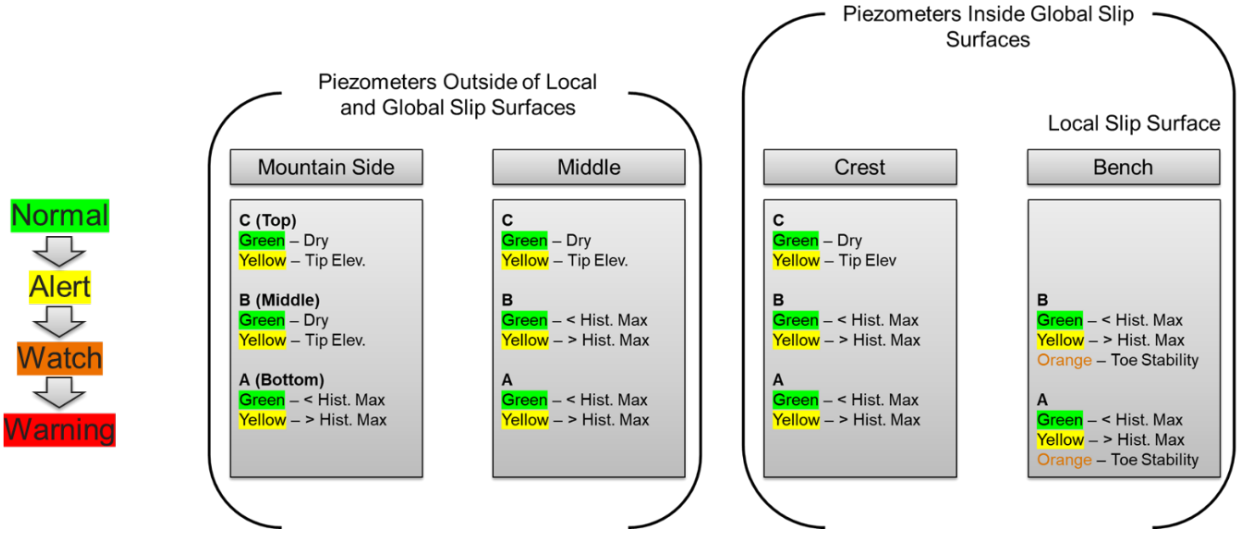

Figure 6: Rationale for setting vibrating wire piezometer thresholds

Defining trigger level thresholds for in-place slope inclinometers

To define the thresholds of the slope inclinometers, our first exercise was to collect readings over the first six months and analyze the trends. We used programming languages to process the data collected every hour. Figure 7 presents the readings from Holden's slope inclinometers along one of the axes during these six months. Defining "time zero" is crucial for interpreting inclinometer readings because it establishes a baseline reference point for all subsequent measurements. Without a clear baseline, initial readings can be influenced by various factors that might cause shifts, making the data unreliable. These factors include installation disturbances, and initial soil consolidation, or settling, which can cause erroneous movements not indicative of actual slope conditions. External factors such as weather changes, vibrations from nearby construction, or even the natural adjustment of the instrument in its casing can also affect initial readings. By setting a precise time zero, these initial variances are accounted for, ensuring that subsequent measurements reflect true changes in slope stability rather than installation-related anomalies or environmental influences. Based on Figure 7, the time zero for the inclinometers were set at January 1st.

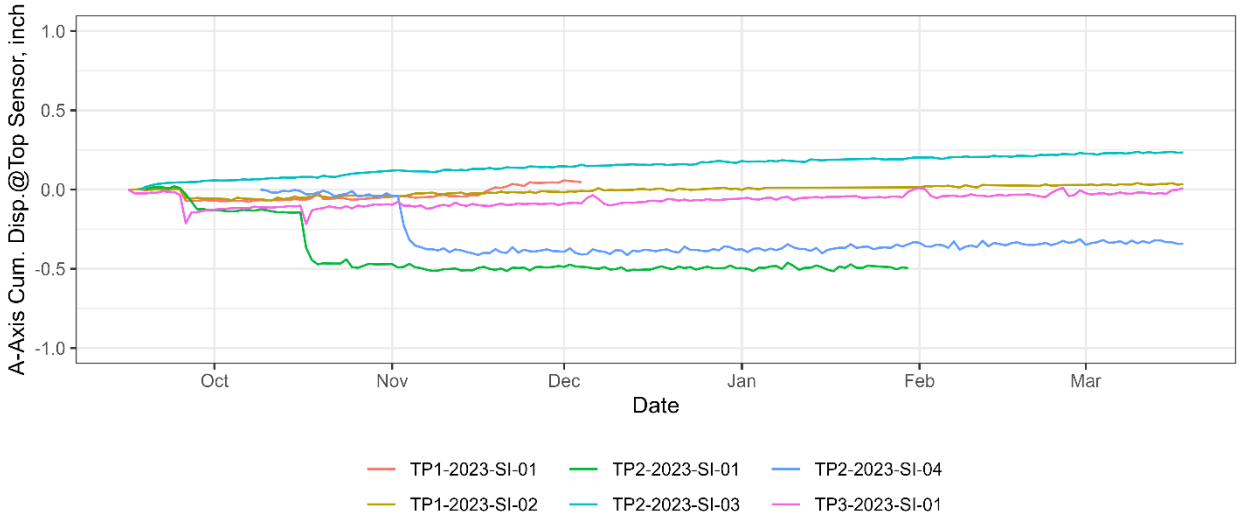

Figure 7: Initial readings of first six months from slope inclinometers

The alert trigger levels for the inclinometers were determined based on the predicted shear deformation from seismic deformation analysis over the shear bands and the peak strain observed in laboratory tests. We defined two key metrics: incremental displacement (displacement between two adjacent sensors) and cumulative displacement (displacement between the bottom fixity and the top sensor). Figure 8 illustrates the direct shear test results for Group E tailings, where most deformation is predicted to occur, according to seismic deformation analysis. The shear strain at peak stress is approximately 2%. Based on this, we set the threshold for incremental displacement between two sensors to 0.2 inches per foot.

Figure 9 presents the shear band color maps for a 1/10,000 year earthquake scenario. The shear band, which aligns with the fine-grained (Group E) tailings, is defined as the region where materials reach a 2% strain. The thickness of this shear band is about 15 feet. Consequently, the cumulative displacement threshold from the bottom fixity to the top of the SI (Slope Inclinometer) is determined to be 3 inches.

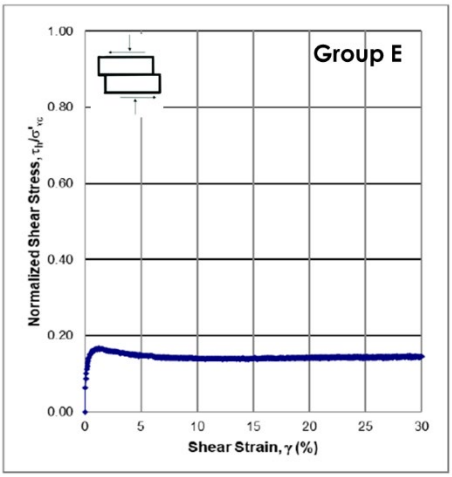

Figure 8: Direct simple shear test of group E tailings

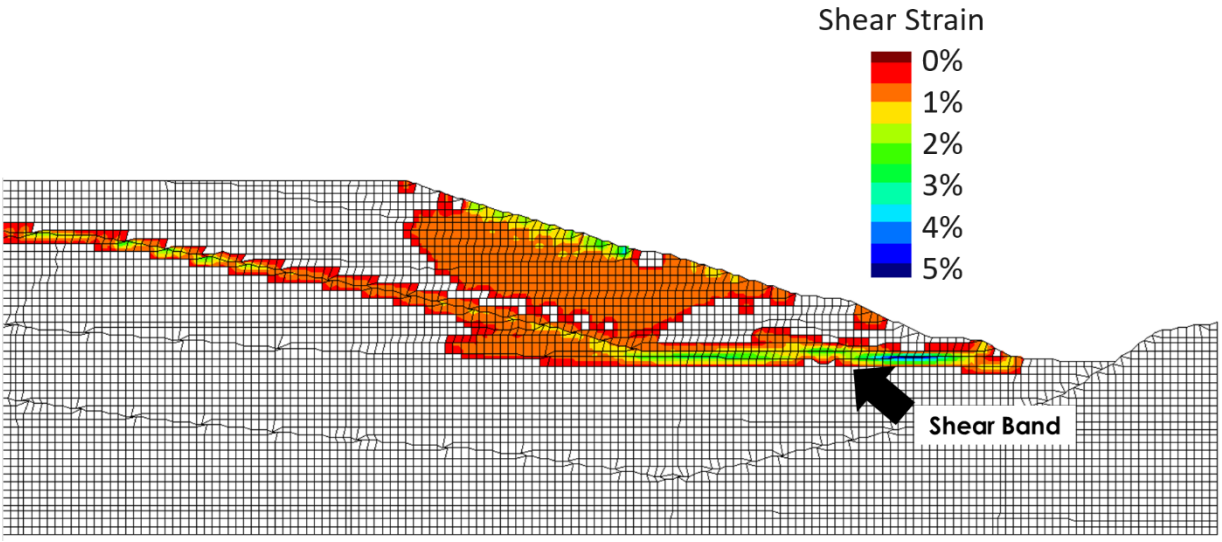

Figure 9: Shear band in seismic deformation analysis

Benefits of data automation and batch processing

Figures 10 through 13 show some examples.

Deciphering flow characteristics in tailings using a nested piezometer system

Figure 10 illustrates the effectiveness of a nested piezometer system in distinguishing between surface

infiltration and groundwater upwelling as sources of tailings saturation. The system involves installing multiple piezometers at various depths within the same borehole, enabling the measurement of pore water pressures across different strata within the tailings and underlying materials.

- Bottom piezometer: the bottom piezometer showed no significant rise in water pressure, indicating that groundwater from beneath did not upwell into the tailings.
- Top piezometer: the top piezometer transitioned from dry to saturated at the beginning of April, following snowmelt at the site, suggesting surface infiltration as the cause of saturation.
- Middle piezometer: the middle piezometer became saturated after the top piezometer, further indicating a top-to-bottom direction of water flow.

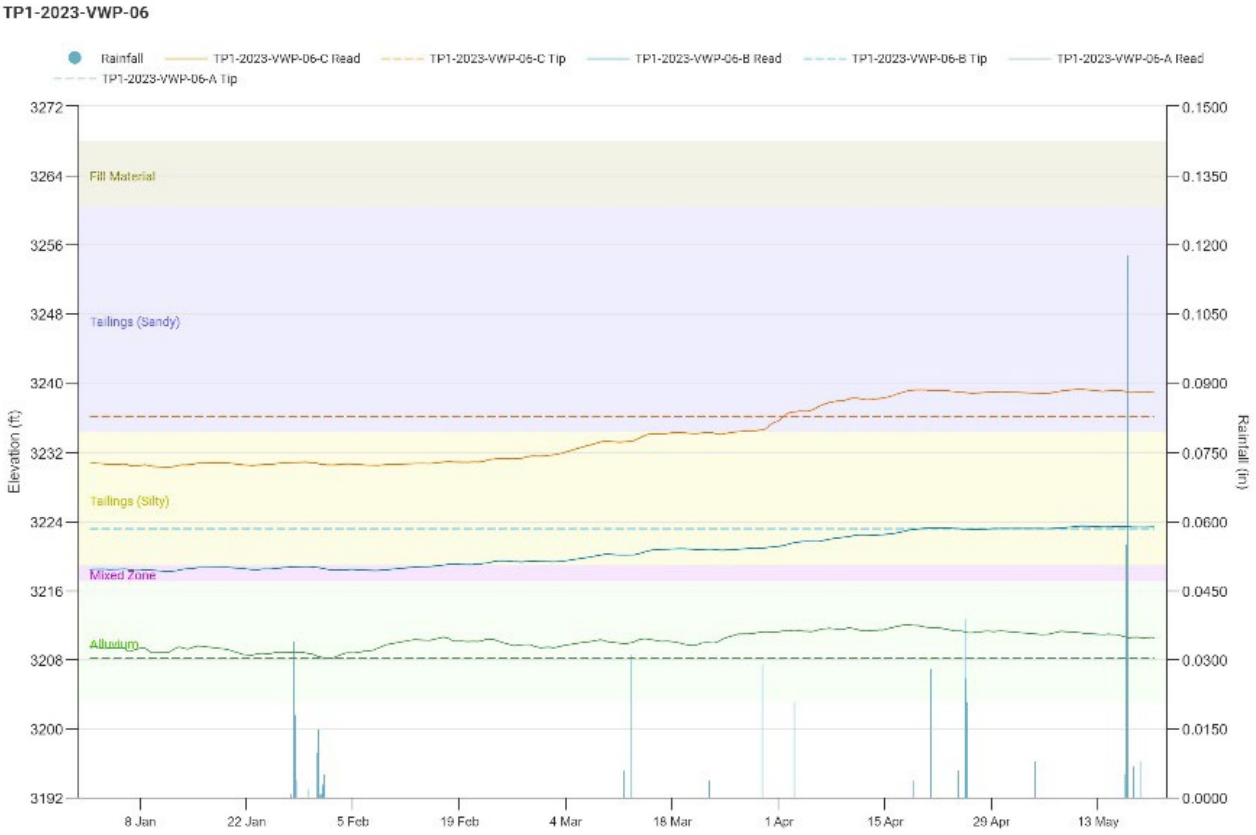

Figure 10: Readings of nested piezometers in the context of lithography

Assessing material conductivity and drainage characteristics through continuous piezometer readings

Figure 11 is an example that shows that continuous readings from piezometers provide valuable insights into how materials respond to changes in hydraulic conditions, distinguishing between fast-draining and slow-draining materials. Fast-draining materials exhibit rapid fluctuations in water pressure, while slow-

draining materials show more gradual responses. These continuous measurements are essential for assessing material conductivity and drainage characteristics, aiding in effective site management and risk assessment. Specifically, the lower piezometer responds more quickly to changes in the groundwater table, indicating fast-draining properties, whereas the upper piezometers respond more slowly, reflecting the behavior of slow-draining materials.

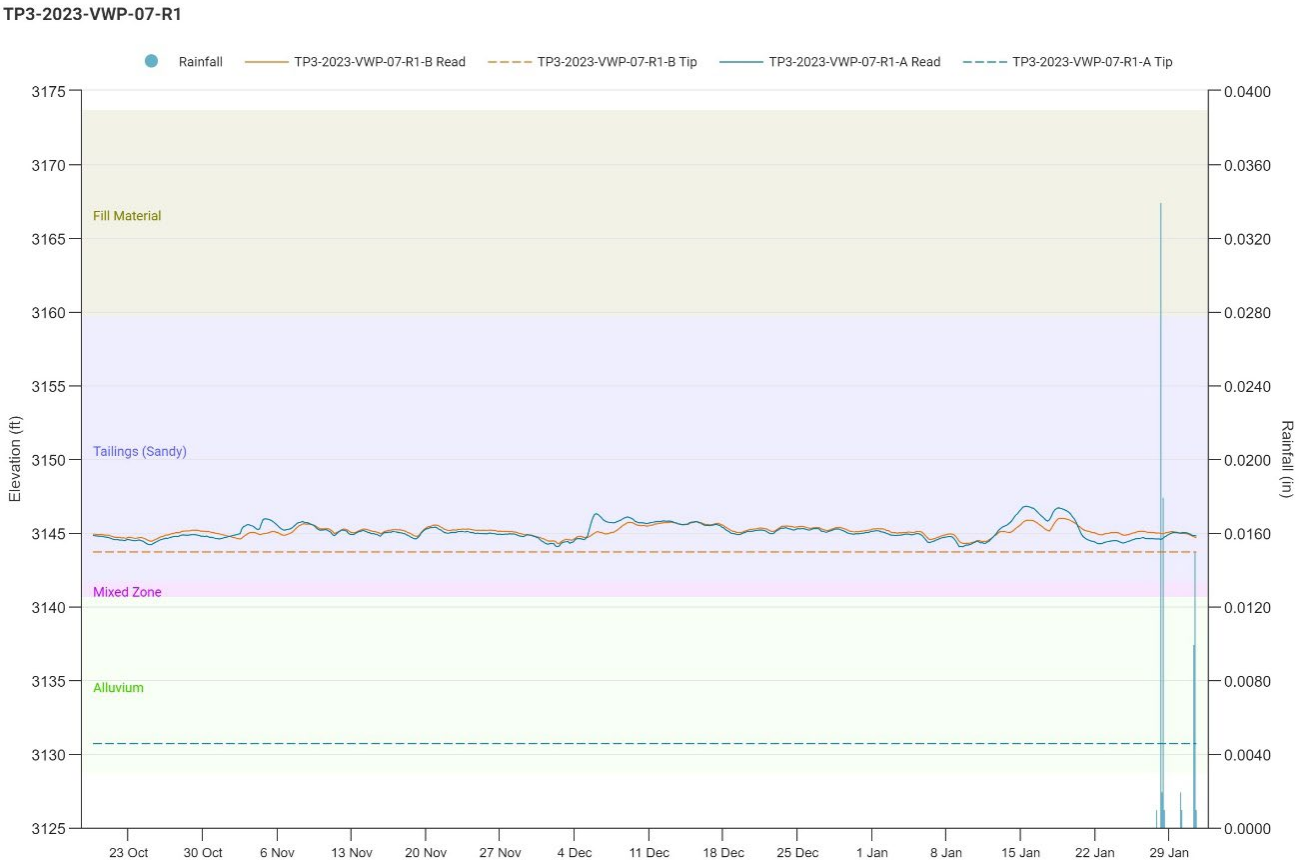

Figure 11: Different responses of piezometer sensor within different material types

Developing sub-TARP trigger levels for early warning and risk mitigation

Sub-TARP trigger levels are essential for providing early warning signs of potential issues or deviations from expected conditions within the facility. These trigger levels act as thresholds that, when reached or exceeded, prompt further investigation or action to prevent or mitigate risks such as slope instability, overtopping, or seepage. By establishing sub-TARP trigger levels, operators can proactively monitor specific parameters, such as pore water pressures or settlement rates, to detect trends or anomalies that may indicate emerging problems. This proactive approach allows for timely interventions and adjustments, ensuring the safety and integrity of the facilities and reducing the likelihood of accidents or environmental impacts.

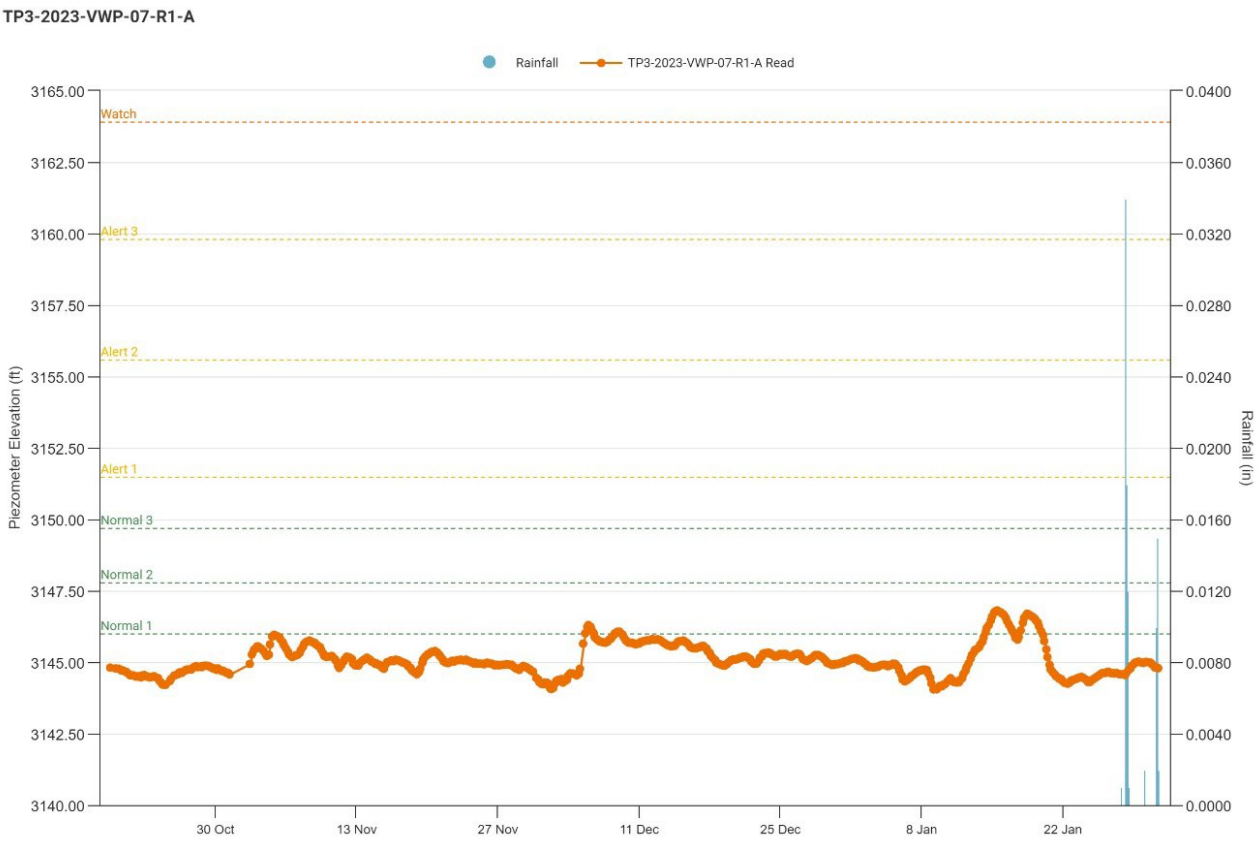

Figure 12: Sub-TARP trigger levels for piezometer readings

Advantages of continuous groundwater table monitoring over sporadic manual data collection

Piezometers are essential tools for identifying fluctuations in groundwater tables. By continuously measuring water pressure at various depths, piezometers provide real-time data on changes in groundwater levels. This continuous data collection is crucial as it captures the dynamic nature of groundwater systems, reflecting both short-term variations due to events like rainfall or snowmelt and long-term trends resulting from seasonal changes or human activities.

Unlike sporadic manual data collection, which might miss critical fluctuations and provide only a fragmented view, continuous monitoring ensures a comprehensive and accurate record of groundwater behavior. This continuous data is vital for understanding the complex interactions within the subsurface environment, enabling more precise predictions and better-informed management decisions regarding water resources and environmental protection.

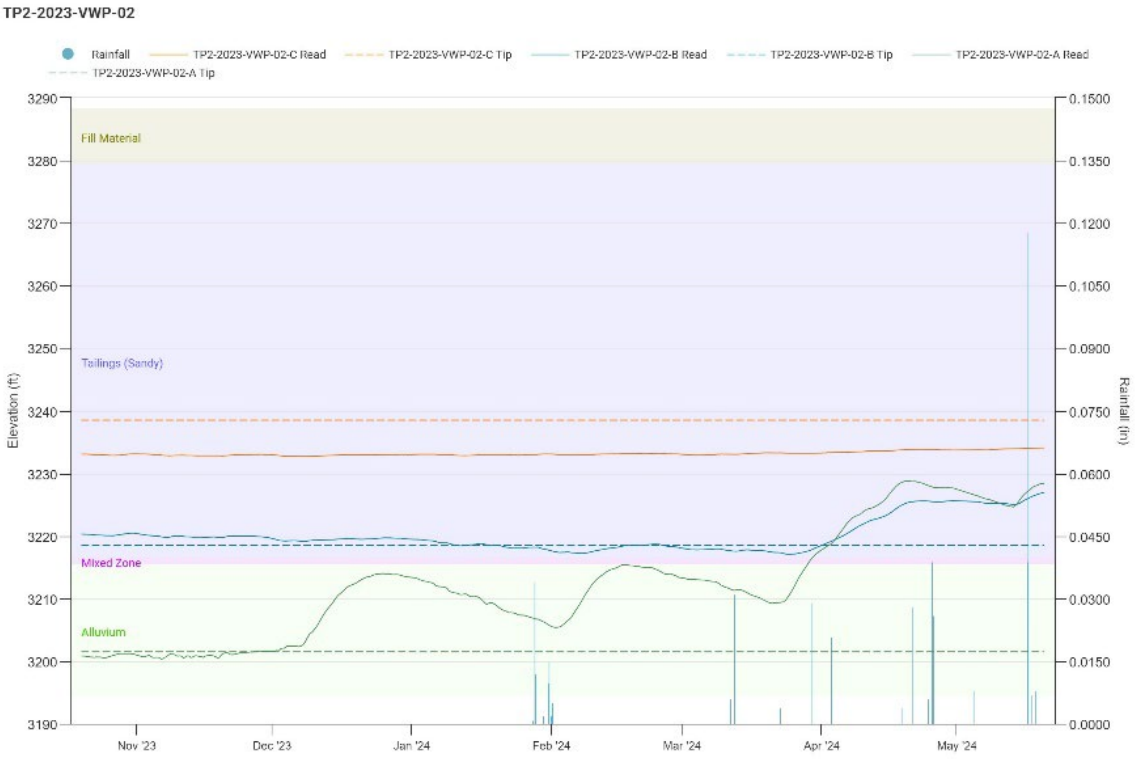

Figure 13: Fluctuating groundwater table as a result of changing conditions

Conclusion

The methodology detailed in this study combines deterministic and statistical analyses to establish TARP thresholds for monitoring mine tailings piles. Deterministic analysis identifies acceptable conditions and informs the significance of geotechnical instruments based on site-specific conditions, while statistical analysis tracks instrument readings over time to detect anomalies and trends. Programming tools like Python or R facilitate efficient data processing and real-time monitoring, ensuring precise thresholds and enhancing mine closure safety and effectiveness.

This approach can be broadly applied to other facilities and instruments requiring meticulous monitoring, such as waste rock piles, pit slopes, and various geotechnical and environmental applications. Industries beyond mining, including construction, dam safety, and environmental engineering, can adopt these techniques to improve infrastructure monitoring and maintenance. By leveraging programming tools and statistical methods, organizations can streamline data processing, quickly identify potential issues, and implement timely corrective actions, thereby improving overall operational safety and efficiency.

Acknowledgements

We extend our sincere gratitude to Rio Tinto for their invaluable support and approval to publish the data

presented in this study. Their collaboration and willingness to share information have made a significant contribution to the advancement of knowledge in the mining industry. This work not only enhances our understanding of tailings monitoring but also sets a precedent for future research and innovation in geotechnical and environmental instrumentation. We believe that the insights gained from this study will play a crucial role in improving safety, efficiency, and sustainability within the mining sector.

Shear Strength Characteristics and Joint Envelopes of Compacted Unsaturated Fine-grained Bauxite Residue

Hua Tian, The University of Queensland, Australia
David J. Williams, The University of Queensland, Australia
Keith Mandisodza, The University of Queensland, Australia

Abstract

Shear strength parameters of unsaturated compacted bauxite residue are critical for the construction and operation of upstream tailing dams. The shear strengths of unsaturated soils are commonly determined through suction-controlled direct shear or triaxial tests. However, this traditional experimental approach is apparatus-demanding, time-consuming, and relatively expensive to test in the laboratory. There have been reasonable successes in estimating shear strength parameters for the unsaturated soils when using the soil-water characteristic curve and conventional shear tests. In this study, the shear strength characteristics of the unsaturated compacted bauxite residue were investigated by carrying out a series of conventional multistage direct shear tests and flattened Brazilian tests over a broad range of water content. The water contents were interpreted to matric suction via the soil-water characteristic curve (SWCC), so the experimental results could be analyzed under the two stress state variables theory. The friction angle, ϕ', varied on different water contents due to the microstructure formed during compaction under low water contents and increased as the decrease of normal stress. The friction angle due to suction, ϕ^b, was less than the friction angle, ϕ', when the soil was nearly saturated and decreased to the negative regime before rebounding to zero as the matric suction approached the residual state. The nonlinear shear strength characteristics were described by a modified power law type joint strength envelope.

Introduction

Each year, a large amount of bauxite residue (also called red mud) is produced during the extraction of alumina from bauxite and commonly discharged in slurry pipes to an impoundment in a thin layer. Subsequently, it consolidates under its self-weight and compacts to form a tailing dam. Under climatic influences, water segregated from the slurry infiltrates into the previously deposited tailings or flows as surface runoff down to the decant pond or evaporates into the atmosphere. As a result, the surface of the tailings desiccates, creating an unsaturated zone above the phreatic surface. Therefore, using unsaturated

shear parameters is more appropriate for the actual site conditions.

Due to the smaller volume of the embankment, the upstream tailings dam is the most popular in the mining industry. In this type of dam, rising embankments are constructed directly on the dumped tailings. Given the importance of determining bearing capacity and evaluating tailing dam stability, the shear strength characteristics of bauxite residue have received extensive research attention (Jitsangiam and Nikraz, 2013; Rubinos et al., 2015; Alam et al., 2017; Reddy et al., 2021). However, most of these studies focused on saturated conditions. Until now, there has been little research regarding unsaturated conditions.

The mutual changes between tensile stress and compressive stress states occur during the soil failure process (Kong et al., 2022). Consequently, shear failure may occur under either compressive or tensile normal stress. To ensure the stability of constructed tailings dams, there is a need to comprehensively incorporate tensile strength into shear characteristics and establish a joint strength envelope considering both tensile and compressive normal stresses. Several pioneering studies (Toyota et al., 2003, 2004; Vesga 2009; Namikawa et al., 2017) have attempted to establish such a joint strength envelope for unsaturated soils. However, much of the existing research has been limited to narrow water content ranges and has not considered the nonlinearity in shear strength resulting from matric suction and normal stress.

To address the limitations in the current research, this study aimed to determine the soil-water characteristic curve (SWCC) to establish the relationship between water content and soil suction for subsequent analyses. Following this, multistage direct shear tests were conducted to understand the variation of shear strength characteristics across a broad range of water content and soil suction. Subsequently, to comprehensively and reasonably describe the shear strength characteristics of unsaturated bauxite residue, a nonlinear joint shear strength envelope for unsaturated soils was proposed by coupling the tensile strength obtained from flattened Brazilian tests.

Literature review

Fredlund et al. (1978) extended the Mohr-Coulomb theory to unsaturated soils by two independent stress state variables:

$$\tau = c' + (\sigma_n - u_a)\, tan\, \phi' + (u_a - u_w)\, tan\, \phi^b \qquad 1$$

Where, $(\sigma_n - u_a)$ is the effective normal stress; $(\sigma_a - u_w)$ is the matric suction; c' is the effective apparent cohesion; $\phi'$and ϕ^b are the friction angles indicating the rate of increase in shear strength relative to effective normal stress and matric suction respectively.

Suction-controlled direct shear and triaxial tests, in which matric suction is controlled by applying the axis-translation or osmotic technique, are two commonly used laboratory techniques for measuring the shear strength parameters of the extended Mohr-Coulomb theory (Ng et al., 2007). However, the traditional approaches mentioned above require sophisticated apparatus and are time-consuming, especially for clayey

soil due to its low permeability (Escario and Sáez, 1986; Gan et al., 1988; Khalili and Khabbaz, 1998). Alternatively, the variation in effective stress due to soil suction can be interpreted from and quantified in terms of water content through the SWCC. Therefore, conventional shear testing techniques developed within the framework of saturated soils mechanics remain effective in unsaturated soils.

Furthermore, it is widely accepted that the constant water content test is more suitable for engineering practice (Walton-Macaulay, 2015). This is because excess pore water pressure is expected to dissipate slowly, especially for clays that tend to retain water under loading, while excess pore air pressure is anticipated to dissipate almost instantaneously (Ma et al., 2013). The persistent nature of excess pore water pressure is a crucial aspect of geotechnical engineering problems, as it could be the cause of slope failure and long-term settlements (Thu et al., 2006). Therefore, the alternative approach using conventional shear tests and SWCC to determine the shear parameters of unsaturated soils is more practical in engineering practice. Its acceptability has been demonstrated through theoretical analysis (Oloo and Fredlund, 1996) and extensive experimental practices (Oloo and Fredlund, 1996; Bai and Liu, 2012; Chowdhury and Azam, 2016; Xing et al., 2016).

Cohesionless soils, such as sand (Kim and Sture, 2008; Lu et al., 2009; Yin and Vanapalli, 2018); hard rock tailings (Narvaez et al., 2015) exhibit significant tensile strength under unsaturated conditions due to negative pore water pressure and surface tension (Yin and Vanapalli, 2018). There are two types of methods applied to measure the tensile strength of unsaturated soils, namely direct and indirect methods.

In the direct method, the tensile strength of the soil is usually directly measured under uniaxial tensile strength conditions, in which the soil specimen is tested under tensile load directly applied normally to one principal plane, with zero loads applied to corresponding orthogonal planes (Lu et al., 2009). For the indirect method, mainly including the Brazilian test (ASTM, 2016a) and flexure beam test (ASTM, 2019), the specimen is split under compression loads, which are measured and then calculated into tensile strength through various functions developed based on specific testing conditions and assumptions. Originally developed for rocks, the Brazilian test was found to be able to determine the tensile strength of soils (Krishnayya and Eisenstein, 1974; Dexter and Kroesbergen, 1985; Beckett et al., 2015). Its low cost and convenience make it ideal for bulk testing of cover material (Beckett et al., 2015).

It is worth mentioning that the intersection of the shear strength envelope to the normal stress axis is the theoretical isotropic tensile strength derived from inherent material variables and independent of loading conditions (Lu et al., 2009). However, it should be recognized that the tensile strength obtained by most contemporary laboratory testing techniques was closer to the uniaxial condition rather than the isotropic condition (Lu et al., 2009). Li and Wong (2013) demonstrated that the measured tensile strength in the Brazilian tests is equal to the uniaxial tensile strength. Thus, in this research, the uniaxial tensile strength from the flattened Brazilian tests was used to approximate the tensile strength in the shear strength envelope.

The current paper applied the theory and test techniques of unsaturated soil mechanics to compacted unsaturated bauxite residue and developed a physical understanding regarding the shear strength characteristics and the shear strength envelope ranging from tensile to compressive normal stress of such fine-grained tailings.

Material and preparation

The bauxite residue investigated in this study was collected from a local tailings storage facility located in north Queensland, Australia. A series of laboratory tests were conducted to characterize the bauxite residue. According to the results of particle size distribution analysis, the bauxite residue consisted of a significant presence of clay-sized particles (54.43%), followed by silt-sized particles (43.25%), with the remainder (2.32%) in the sand range. The maximum dry density was 1.26 g/cm3 with an optimum water content of 34.5%. The investigated bauxite residue was classified as lean clay (CL) according to the Unified Soil Classification System (ASTM 2020), based on the testing results of plastic limit (33.5%), liquid limit (47.9%), and plasticity index (14.4).

The quantitative mineralogy (relative abundance) was estimated by X-ray diffraction (XRD) analyses. The bauxite residue was featured with the presence of significant quantities of hematite (Fe_2O_3) (36%) and nosean ($Na_8Al_6Si_6O_{24}(SO_4)$) (14%), with small quantities (2%) of clay mineral presenting as kaolinite ($Al_2Si_2O_5(OH)_4$).

To prepare the testing specimens, the collected bauxite residue was completely oven-dried at 60°C. After that, the aggregations of large particles were pulverized by a rubber mallet and sieved through an 850 BS sieve. Then, the predetermined amount of distilled water was added to the dried bauxite residue to reach a broad range of target moisture contents (4, 8, 12, 16, 20, 24, 28, and 32%). Next, the mixtures were sieved using an 1180 BS sieve to thoroughly mix the soil and prevent any conglomeration. After being placed in sealed jars for 2 days to reach water equilibrium, the well-moistened soils were ready for use.

Testing program

The testing program consisted of (i) SWCC test to establish the relationship between the water content and matric suction, (ii) multistage constant-water-content direct shear tests on unsaturated specimens, and (iii) flattened Brazilian tests on unsaturated specimens to determine the tensile strength.

SWCC

The water characteristic curves for bauxite residue under drying conditions were established using the GCTS pressure plate apparatus according to ASTM standard D6836-16 (ASTM, 2016b). The bauxite residue was compacted to a predetermined dry density of 1.23 g/cm^3 in the sample ring and then saturated

by soaking water from the bottom. Fully saturated specimens were then placed directly on the porous plates in the pressure chamber. To obtain a smooth curve, several pressure intervals (5, 10, 20, 40, 80, 160, 320, and 500 kPa) were tested.

Flattened Brazilian testing

A series of flattened Brazilian tests under a broad range of water contents (4%, 8%, 12%, 16%, 20%, 24%, 28%, and 32%) were conducted in the load frame manufactured by INSTRON. The specimens used in this research were 100 mm in diameter and 50 mm in length, as suggested by Beckett et al. (2015).

Initially, the predetermined moistened bauxite residue was placed in a split mold of 100 mm in diameter and compacted to a height of 50 mm in one layer. After compaction, the specimen was carefully removed from the split mold and sealed in plastic bags for 4 days for moisture equilibration. Subsequently, the specimen was tested by applying compressive forces with a constant loading rate of 0.02 mm/min, as suggested by Stirling et al. (2015), until failure. The tensile strength (σ_{tu}) was determined by the equation:

$$\boldsymbol{\sigma_{tu} = \frac{P}{\pi R L}} \qquad 2$$

where P, R, and L are the peak applied vertical load, the specimen radius, and length, respectively.

Multistage direct shear testing

A series of multi-stage direct shear tests under different water contents ranging from 4% to nearly saturated was carried out on a large-scale direct shear apparatus manufactured by WILLE to obtain the shear strength parameters under compressive normal stresses. The top and bottom porous stones were replaced with plastic plates, so the specimens were under constant water-content conditions during shearing.

The dimensions of the specimens used in this research were 150 mm × 150 mm × 150 mm (length × width × height). Firstly, the predetermined well-mixed moistened bauxite residue was compacted in the shear box to the target dry density of 1.23 g/cm³ in five layers, allowing a uniform distribution of density and moisture throughout the specimen.

Subsequently, the specimens were tested by applying shearing forces with a constant loading rate of 0.02 mm/min, as suggested by Suzuki et al.,(2001) , until failure. The applied effective normal stresses were chosen to be 5 kPa, 25 kPa, 50 kPa, and 100 kPa, representing the shallow depths of unsaturated zones in the tailings dam of approximately 0.3 m, 1.6 m, 3.1 m, and 6.3 m, respectively (assuming an in-situ unit weight of 16 kN/m³). A maximum shear displacement of 7.5 mm (10% shear strains) was controlled for every stage.

During the shearing tests, displacements and forces were measured and recorded at time intervals of 15s. After testing, water contents of the failure surface were checked to ensure the differential was less than 0.25%.

Presentation of test results

Measurements obtained from the stress plate apparatus are shown in Figure 1. The widely used empirical equation proposed by van Genuchten (1980) was used to approximate the SWCC in this study. The relation between the degree of saturation and suction is:

$$\frac{S - S_r}{1 - S_r} = \frac{1}{\{1 + [a(u_a - u_w)]^n\}^m} \quad 3$$

where S is the degree of saturation, a is approximately the air entry value (AEV), m and n control the slope at the inflection point on the SWCC. Fitting parameters a, m, and n values were given in Figure 1. The residual degree of saturation (S_r) corresponding to the residual suction and the capillary degree of saturation (S_c) corresponding to the AEV, which is the low bound of saturation to the boundary effect zone, was also obtained from the SWCC.

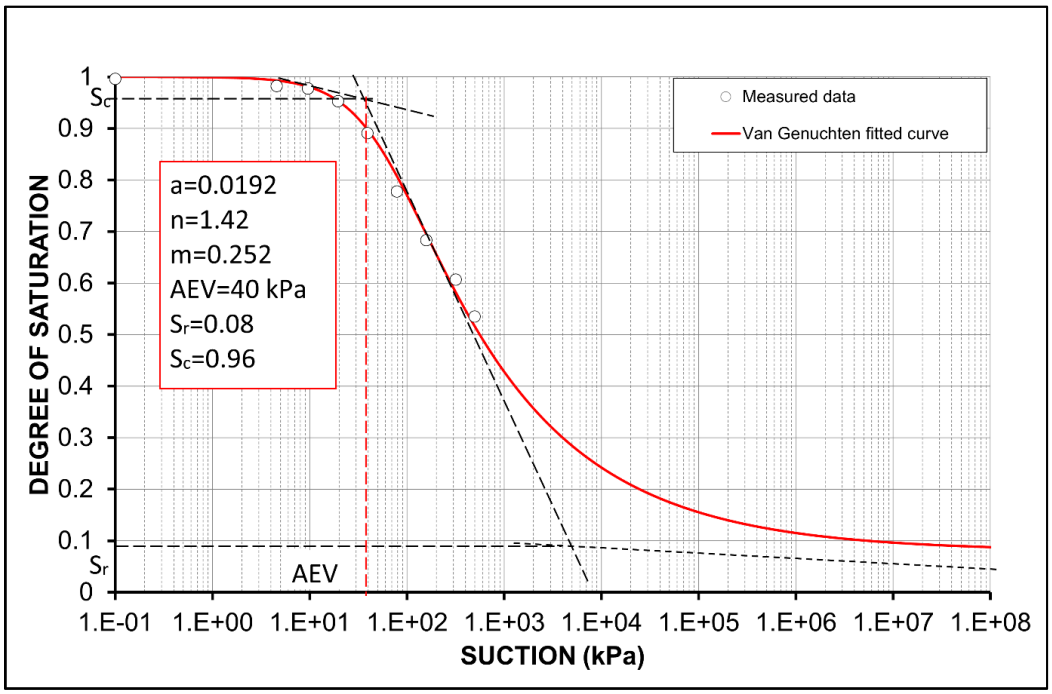

Figure 1: The best fitting SWCC and the experimental data of bauxite residue

The SWCC is defined as the relationship between water content and suction for the soil (Williams, 1982), through which the water contents defining the amount of water contained within the voids of the soil could be interpreted into soil suctions (Fredlund and Xing, 1994). The water contents and the corresponding suction in this research were presented in Table 1, based on which the measured shear strength was represented as points with different signs in Figure 2, together with the strength-suction curves.

Table 1: Results of suctions and strength

Water content (%)	Degree of saturation	Matric suction (kPa)	Tensile strength (kPa)	Shear strength (kPa)			
				5 kPa	25 kPa	50 kPa	100 kPa
4%	0.0838	242732015	-13.70	18.66	29.51	48.54	88.44
8%	0.166	37259	-15.73	20.38	29.78	49.79	91.56
12%	0.251	5703	-17.91	22.20	34.89	53.99	95.38
16%	0.335	1868	-19.96	25.17	38.63	56.89	97.92
20%	0.419	837	-28.63	29.86	49.28	67.98	104.67
24%	0.503	443	-28.28	28.22	46.94	66.52	102.30
28%	0.586	258	-23.38	20.20	36.37	54.32	85.85

nearly saturated	1.0	40*	–	6.07	15.11	28.43	51.68

*The AEV was used for the suction of nearly saturated condition

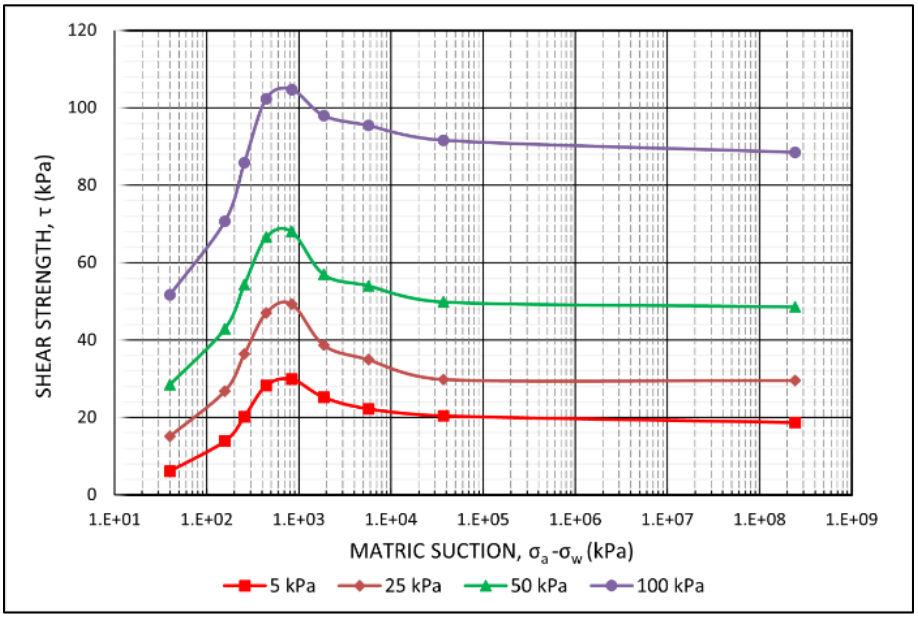

Figure 2: Shear strength plotted against the matric suction

As seen, the agreement was very satisfactory in general, despite the differences in applied normal stress. The strength-suction curves indicated that the shear strength depended significantly on suction. As the suction increased, the shear strength increased quickly before a critical suction was reached, which corresponds to the peak value of shear strength. From there on, the shear strength gradually decreased to the residual value with further increases in suction. The nonlinearity of the strength-suction curves was attributed to the diminishing contribution of matric suction to the shear strength, as the water content of the soil approached its residual value (Oloo and Fredlund, 1996).

The preceding observation shows an important conceptual change to the previous theories or findings wherein the effective shear strength of coarse-grained soils started to decrease beyond residual suction value (Donald 1957; Vanapalli 2009). However, a significant decrease in shear strength was not observed for fine-grained soils when tested over a broad range of suctions (Escario et al., 1989; Khalili and Khabbaz, 1998; Vanapalli et al., 2000; Huat et al., 2005; Vanapalli, 2009; Schnellmann et al., 2013) or water contents (Bai and Liu, 2012; Chowdhury and Azam, 2016; Xing et al., 2016), as shown in Figure 3.

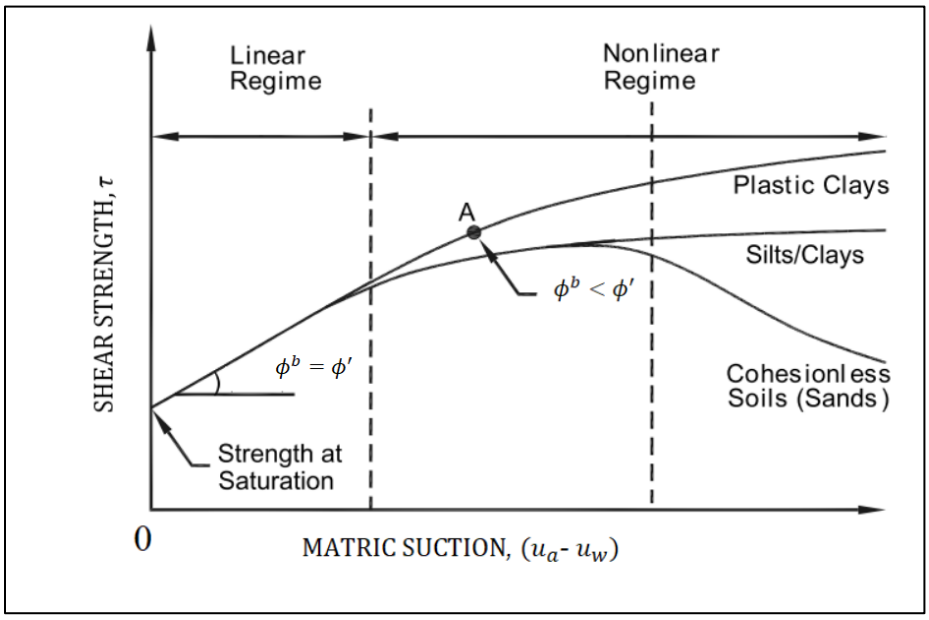

Figure 3: Typical unsaturated shear strength envelopes for different soil types, modified from (Vanapalli, 2009)

The high residual shear strength of fine-grained soils under excessively dry conditions could be attributed to the greater frictional resistance of soil aggregates resulting from cementation and/or shrinkage of the clayey mass, thus enhancing shear strength (Matsushi and Matsukura, 2006). In fine tailings such as bauxite residue, although particle size distribution analysis indicated a large presence of clay-sized or silt-sized particles, XRD patterns verified only a slight appearance of clay minerals. Consequently, slight cementation and/or shrinkage bonding provided by these clay minerals may contribute to shear strength.

The close agreement in the tendency of shear strength under residual suction between fine-grained bauxite residue and coarse-grained sand indicates that both particle size and mineralogy contribute to the shear strength of unsaturated soils. The absence of dominant clay minerals influenced the residual shear strength characteristics of fine-grained tailings (bauxite residue) in this research.

The load-displacement curves of flattened Brazilian tests under different water contents were shown in Figure 4a. The tensile strength was determined through Eq. (2) and presented in 4b.

Discussion of test results

Shear strength characteristics under compressive normal stresses

In this research, the matric suction, $(\sigma_a - u_w)$ had been deduced from the SWCC of the bauxite residue, so the results of shear strength of unsaturated bauxite residue obtained from the conventional multistage direct shear tests could be analyzed in two planes (i.e., the τ versus $(\sigma_n - u_a)$ plane, and the τ versus $(u_a - u_w)$ plane) separately under the frame of the two independent stress state variables theory, as stated in Eq. (1). By assuming the pore-air pressure at failure was equal to the atmospheric pressure, the effective normal stress, $(\sigma_n - u_a)$, could be approximated to the applied normal stress, σ_n, due to its effectiveness nature. Thus, Eq. (1) could be revised as:

$$\tau = c' + \sigma_n \tan\phi' + (\sigma_a - u_w)\tan\phi^b \qquad 4$$

The shear strengths from the multistage direct shear tests were presented in Table 1, in which the water contents of the specimens at failure and the corresponding matric suctions estimated from the SWCC shown in Figure 1 were also provided.

The contribution of matric suction to the shear strength ($(\sigma_a - u_w)\tan\phi^b$) could be viewed in terms of being either part of the frictional component of shear strength or part of the cohesional component of shear strength (Gan et al., 1988). As part of the cohesional component, the failure surface could be projected to the shear strength versus normal stress plane ($\tau: \sigma_n$) at zero matric suction, and the internal friction angle ϕ' could be evaluated from the slope of the shear strength envelope. In the current research, the measured shear strengths were plotted against the applied effective normal stresses in Figure 4. The variation of the measured shear strengths with the applied normal stresses (i.e., the shear strength envelope) could be approximated by a linear Mohr-Coulomb strength envelope for each water content. The friction angle, ϕ', of strength envelope and the apparent cohesions, c', determined by extrapolating the strength envelope to the shear strength axis associated with different water contents were also present in Table 2.

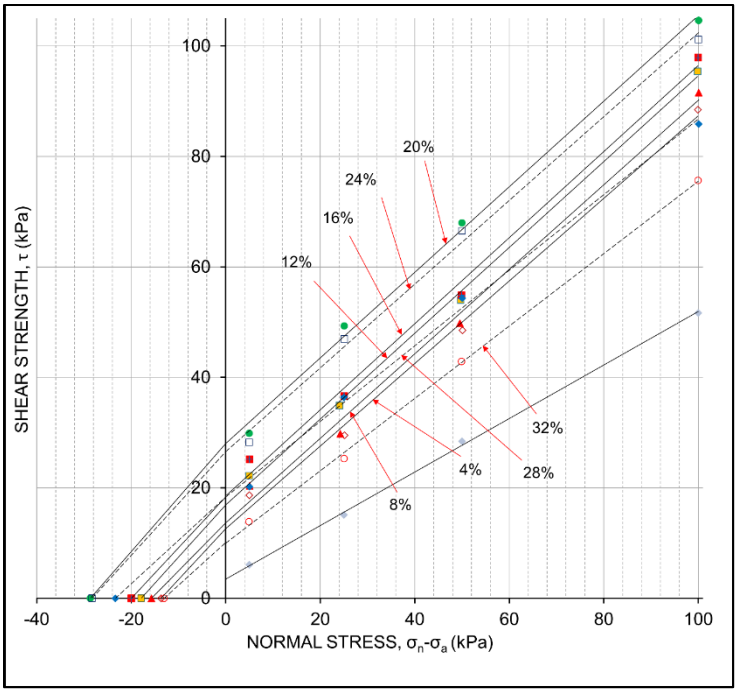

Figure 5: Shear strength plotted against the applied normal stress

It can be observed from Figure 5 that there is a tendency for divergence at increasing normal stresses in the shear strength envelope. As presented in Table 2, the apparent friction angle slightly increased from 36.80° at a water content of 4% to a plateau of 37.93° at a water content of 16%, with increasing water content. It then remained at a high level (greater than 37.0°) at water contents ranging from 20% to 24%. Beyond this point, a significant decreasing trend to a value of 25.86° in ϕ' was observed with further increases in water content (decreases in suction). It can be concluded that the friction angle, ϕ', under relatively low water content (high suction) was significantly higher than that at high water content (nearly saturated).

Earlier research (Fredlund et al., 1978; Krahn et al., 1989; Rahardjo et al., 2004; Thu et al., 2006), in an attempt to simplify the conditions, assumed that the strength envelopes for different water contents (or suctions) were parallel and that the friction angle was constant. However, extensive published works (Escario and Sáez, 1986; Cokca et al., 2004; Huat et al., 2005; Bai and Liu, 2012; Schnellmann et al., 2013; Chowdhury and Azam, 2016; Xing et al., 2016) correlated well with the divergent envelopes observed in this research. For example, Chowdhury and Azam (2016) reported that the friction angle for compacted expansive clay decreased from 44° to 27% for a water content range from 18% to 30%. The divergence became less significant in clayey/silty sand (Escario and Sáez, 1986; Schnellmann et al., 2013), where the observed variation in the friction angle due to suction (water content) change was considerably smaller. The particle size distribution (PSD) analysis verified high clay-sized contents in the bauxite residue used

in this research; thus, the variation of strength envelopes over water contents may highlight a close relationship between the bauxite residue and clayey soils in terms of frictional characteristics during shearing.

The scanning electron microscopy (SEM) and mercury intrusion porosimetry (MIP) techniques revealed that fine-grained soils compacted at low water content display a well-developed microstructure characterized by larger clusters formed by the gathering of small particles and dispersed grains surrounding them, while soils compacted at high water content exhibit dispersed grains with fewer or no clusters (Delage et al., 1996; Romero and Simms, 2008; Romero, 2013; Zabielska-Adamska et al., 2019). The clusters were agglomerated from small particles through the summation of interparticle actions. The interparticle actions contributing to the internal cohesion in unsaturated soil include (1) capillary force, (2) van der Waals attraction at the particle contacts, (3) electrical double layer force near the particle contacts, and (4) cementation bonding from chemical compounds. Cementation bonding is considered constant and negligible in cohesionless soils. Advances have been made in recent decades on the semiquantitative understanding of the magnitudes of the first three interparticle actions in unsaturated granular media (Lu and Likos 2006). Under the same degree of saturation, the first three interparticle actions are generally inversely proportional to particle size and separation distance.

For example, the capillary force could increase from several kilopascals among 0.075 mm particles to be as high as several hundred kilopascals among 0.002 mm particles. Therefore, internal cohesion within the clusters originating from the interparticle actions among fine particles with a short separation distance, which is the case within the clusters, is considerably stronger than that among the relatively large clusters. During loading, the clusters can withstand external loads as a whole instead of completely breaking down due to the strong internal cohesion. At low water content, the overall external loads are mainly resisted by the interaction transmitted from cluster to cluster. The internal frictional resistance of compacted bauxite residue at relatively low water content is derived from the interaction between clusters, which can be approximated by the internal friction of an equivalent granular material consisting of particles of the same size and shape as the clusters (Tang et al., 2015).

Normally, in granular material, the internal friction, made up of the resistance to sliding on the surface of the soil particles and the interlock between the soil particles, increases with particle size (Vangla and Latha, 2015). Because the interlock is proportional to particle size to some degree, the clusters formed under low water contents give rise to a higher interlock than dispersed particles, which is the case with high water contents. Consequently, the friction angle under low water contents is higher than that under high water contents.

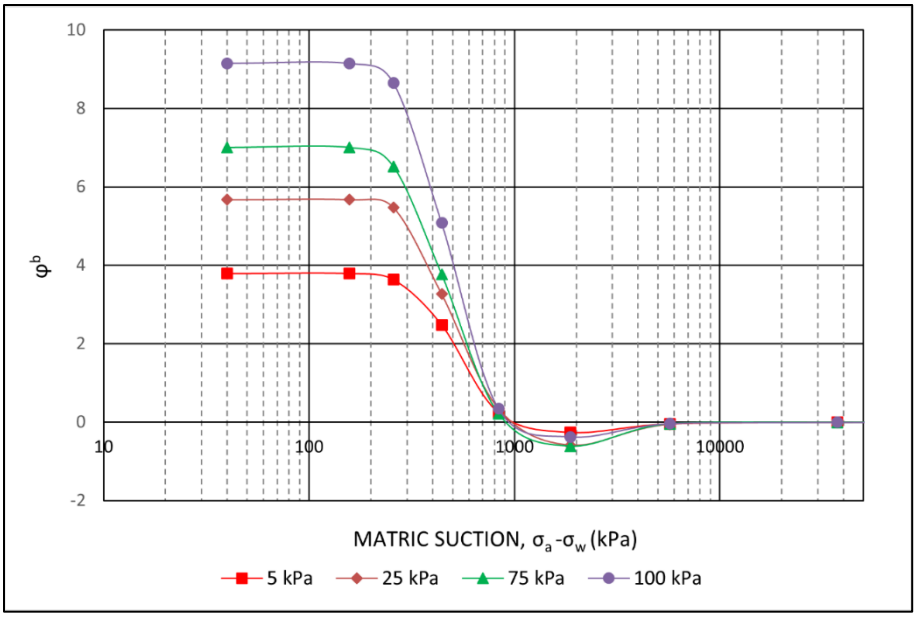

Figure 6: The friction angle due to suction, ϕ^b, against the matric suction

The material variable, ϕ^b, introduced by Fredlund et al. (1978) to capture the increase in shear strength with increasing matric suction, was defined as the slope describing the shear strength versus matric suction curve. The friction angle due to suction, ϕ^b, followed an S-shaped curve when plotted with respect to matric suction in Figure 7. The maximum value occurred at the commencement of the curve (nearly saturated), then ϕ^bdropped sharply from the initial peak value to a negative value as matric suction increased. From there, it gradually rebounded to zero as suction approached the residual saturation state. A good agreement was observed between the shapes of ϕ^b curves under different normal stresses. A similar shape had also been observed in clays by several previous researchers (Vanapalli, 2009; Bai and Liu, 2012; Chowdhury and Azam, 2016). The ϕ^b values were less than the ϕ' values, which was consistent with the shear strength parameters in most previous research.

Nonlinear joint shear strength envelope

The strength envelope that can describe the shear failure in both the compressive and tensile regimes is generally called the joint shear strength envelope. To establish the joint shear strength envelope, the measured tensile strengths were plotted together with the maximum shear stresses under the same water content in the shear strength versus normal stress (τ: σ_n) plane in Figure 5. For analysis purposes, the Mohr-coulomb envelope was handled by dividing into two linear portions, the first extending from the point of tensile strength to the apparent cohesion with a slope of ϕ_t, and the second extending beyond the apparent cohesion with a slope equal to ϕ'. By comparing the value of ϕ_t and ϕ' presented in Table 2, a significant discrepancy was observed, indicating a single linear Mohr-coulomb envelope couldn't accurately represent

the joint shear strength envelope of bauxite residue under partially saturated conditions, nor did the Fredlund envelope extended from the Mohr-coulomb envelope. This observation was consistent with experimental evidence of cohesionless saturated sands for small magnitudes of compressive stress (e.g., Sture et al., 1998; Kim, 2001) where the ratio of shear stress to normal stress typically increased significantly when the normal stress was approaching the far left point of shear strength envelope.

Due to the symmetry of Mohr circles and envelopes with respect to the normal stress axis, the derivative of the shear strength envelope is continuous at the intersection of the strength envelope to the normal stress axis, thus, the tangential friction angle interpreted from the derivative of the shear strength envelope should equal 90° at this point. However, the Mohr-Columb strength envelope implies the derivative is discontinuous here, therefore, many publications utilized the power law relation (Charles and Soares, 1984b, a; Jiang et al., 2003; Baker, 2004; Eid, 2014) to describe an increase in friction angle with decreasing normal stress. The generalization of this power law relationship can be expressed in the form:

$$\tau = P_a A \left(\frac{\sigma_n}{P_a}\right)^B, \left(\frac{1}{2} < B < 1\right) \quad 5$$

Where, P_a is boundary normal stress of low and normal compression, and usually taken as the atmosphere pressure; A and B are constants. A is a scale parameter controlling the magnitude of shear strength, and B controls the curvature of the envelope.

The situation became more complex in the unsaturated granular materials, which was the case in this research, where the van der Waals attractions, electrical double layer forces, and capillarity provided an additional component of interparticle bonding strength (Lu et al., 2007) giving rise to the tensile strength defined as the intercept of the strength envelope to the normal stress axis in the shear stress versus normal stress ($\tau: \sigma_n$) plane. This feature could be incorporated by considering the additional tensile strength (negative) as part of the effective normal stress, as:

$$\sigma' = \sigma_n - \sigma_t \quad 6$$

where σ_t is the tensile strength, σ_n is the normal stress, the difference between them is the unified effective normal stress.

Legitimate values of normal stress were restricted to range from the tensile strength rather than zero. The shear strength envelope for compacted unsaturated soils went through the tensile strength point and could be rewritten as:

$$\tau = P_a A \left(\frac{\sigma_n - \sigma_t}{P_a}\right)^B, \left(\frac{1}{2} < B < 1\right) \quad 7$$

The tangential friction angle was defined by the relation:

$$tan\, \phi_t = AB \left(\frac{\sigma_n - \sigma_t}{P_a}\right)^{B-1} \quad 8$$

As suggested in previous research (Lu and Likos 2006; Yin and Vanapalli 2018), the tensile strength in the unsaturated cohesionless soils could be considered as a function of matric suction:

$$\sigma_t = f(u_a - u_w) \quad 9$$

Thus, Eq. (7) could be written as:

$$\tau = P_a A \left(\frac{\sigma_n - f(u_a - u_w)}{P_a}\right)^B, \left(\frac{1}{2} < B < 1\right) \quad 10$$

The parameters A and B in the proposed strength envelope could be estimated by fitting the experimental results from tensile tests and shear tests. The fitting results of the proposed strength envelope for experimental results in this research were presented in Table 2. The comparison between a few typical experimental results and the corresponding fitted nonlinear envelopes was shown on the diagram in Figure 7, indicating the proposed strength envelope in Eq. (10) provided a reasonable approximation for the experimental results of unsaturated bauxite residue within the experimental normal stress range.

Table 2: Fitting parameters of nonlinear envelope

Water content (%)	Parameters of nonlinear envelope		Parameters of Fredlund envelope		
	A	B	Friction angle φ_t (tensive zone)	Apparent cohesion	Friction angle φ' (compressive zone)
4%	0.756	0.906	42.67	12.62	36.80
8%	0.773	0.906	40.97	14.65	37.45
12%	0.805	0.906	43.37	16.91	37.84
16%	0.814	0.906	42.64	18.96	37.92
20%	0.836	0.906	44.29	28.04	37.76
24%	0.812	0.906	43.24	26.57	37.17
28%	0.717	0.906	38.18	18.37	34.39
32%	0.663	0.906	37.73	10.48	33.25
nearly saturated	–	–	–	3.48	25.86

Figure 7 also displayed the alternative Fredlund shear strength envelopes fitted from the direct shear tests data. As may be seen, the proposed strength envelope provided more conservative strength estimations than those provided by the Fredlund envelope under small magnitudes of normal stress, particularly in the tensile stress regime. It is axiomatic that engineering models are best if accurate, acceptable if conservative, and unacceptable if neither (Travis et al., 2010). The conservative nature of the proposed strength envelope made it practically suitable for shallow slope failures occurring within the vadose zone under partially saturated soil conditions with significant tensile strength.

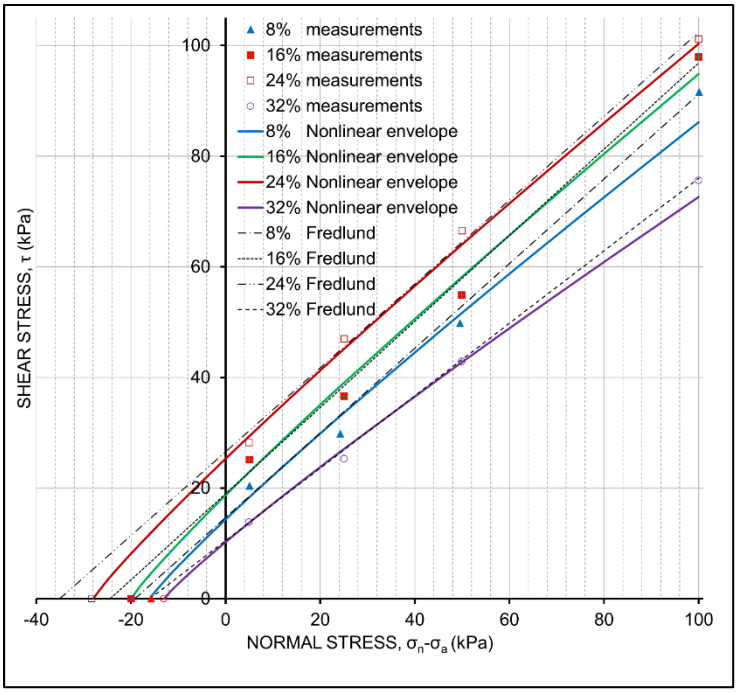

Figure 7: Comparisons of the measured shear strength and fitted envelope

Conclusion

Understanding the shear strength characteristics of compacted bauxite residue is essential for the construction and operation of upstream tailings dams due to their relationships to lateral earth pressure and bearing capacity for raised embankments. Based on the results of a comprehensive testing program on typical local bauxite residue presented and discussed in this paper, the following conclusions can be drawn:

- The shear strength characteristics of fine-grained bauxite residue neither agreed with those of coarse-grained sand nor with those of fine-grained silt/clay. This discrepancy could be attributed to the independent influences of both particle size and mineralogy on shear strength characteristics. The particle size led to divergence in shear strength envelopes due to the microstructure formed during compaction under low water content, while the mineralogy caused a significant drop in shear strength under residual suction due to the lack of clay minerals and the corresponding cementation and/or shrinkage bonding effect.
- The friction angle due to suction, ϕ^b, defined as the incremental shear strength on the incremental suction, peaked near the critical situation and then decreased to a negative value before rebounding to zero. The maximum value of the friction angle due to suction, ϕ^b, was less than the friction angle, ϕ', measured under saturation conditions, which did not comply with earlier unsaturated soil mechanics, but correlated well with extensive recent experimental results.

- The ratio of shear strength to normal stress increased as the normal stress approached the tensile strength, which was well captured by the modified power law type strength envelope established by considering the additional tensile strength of unsaturated cohesionless soils as part of effective normal stress. The proposed nonlinear envelope provided a more conservative strength estimation than that provided by the Fredlund envelope under small magnitudes of normal stress and particularly in the tensile stress regime, making it particularly suitable for geotechnical engineering practice in the shallow unsaturated zone.

Abstract

Rheological properties of colloidal suspensions such as clay-based tailings are complex and can be difficult to measure due to their non-Newtonian state. Viscosity and yield stress are valuable to tailings operators as they are relied upon to inform dredging operations, model interactions between pond fluids and subsequently deposited sands, mixing characteristics, and dam breach modeling exercises to determine run out and impacts in emergency planning. Currently, rheological properties of tailings are measured ex situ in a laboratory environment. Errors are introduced through the sampling and transport processes, and real-time decision making based on results is not possible.

NAIT (the Northern Alberta Institute of Technology) and ConeTec developed two experimental vane shear testing protocols applied to a variable rate field vane shear testing apparatus (VR-eVST), patent pending. Field VR-eVST tests using each testing protocol were conducted at five testing locations and multiple depths at an operating mine near Fort McKay, Alberta, Canada. Following each test, a tailings sample was retrieved from the tested location and shipped to NAIT's laboratory in Edmonton for laboratory rheology measurements and index testing. Each VR-eVST test was paired with a Gamma Piezo-Cone Penetration Test (GCPTu). NAIT applied the Bingham fluid rheological model to calculate fluid properties from the field VR-eVST data. The plastic viscosity and Bingham yield stress parameters obtained from model fitting applied to the in-situ data are plausible for the type of tailings encountered in this study. Further study is required to determine the size and dynamics of the shear band during testing as well as the impacts of repeated shearing on laboratory analysis. Early work indicates that in-situ rheology measurements are promising and may add value to tailings management.

Introduction

The study of the flow and deformation of matter in response to applied shear forces is called rheology. Resistance to flow is defined as viscosity. Newtonian fluids, like water and oil, are homogenous single-phase fluids and have a constant viscosity at a constant temperature regardless of the applied stress. However, industrial slurries, and suspensions including fluid tailings, are more commonly non-Newtonian fluids. These fluids exhibit complex behaviors such as non-constant viscosity, yield stress and time- and shear- history dependent properties (Piette et al., 2022). Simultaneously, these properties are critical parameters for operators to understand, impact both operations and closure, including the efficiency of dredge operations, how tailings materials interact with sand mixing, and are required for modeling runout.

The Bingham plastic fluid model is commonly utilized to represent oil sands tailings behavior (Sanders et al., 2004; Litzenberger and Sumner, 2004). The Bingham plastic fluid is a simple rheological model that reasonably captures the behavior of tailings. It is characterized by a yield stress that must be overcome before flow is initiated and a plastic viscosity beyond that yield point. Additionally, a stepped rate approach has been applied. This involves stepping the VR-eVST rotation rate up and down; and holding at stepped speeds, to investigate the development of shear stress during variable rate testing in fluid materials. This approach has been partially inspired by the concept that a critical vane velocity exists for determining minimum undrained shear strength, as demonstrated in transitional mine tailings by Harvey et al. (2023) and originally developed by Blight (1968). This study examines whether excessively high shear stresses are observed at high rotation speeds and if they are associated with viscous effects.

Background

Currently, the best practice for measuring rheological parameters for industrial fluid tailings is to sample materials and transport them to an offsite laboratory for analysis. This process is not only costly and time-consuming, but it also has the potential to yield results that do not accurately reflect the true in-situ rheological properties (Bugg et. al., 2022). This discrepancy arises from the time- and shear history-dependent nature of non-Newtonian tailings materials. It is not uncommon for viscosity and yield stress values measured by offsite laboratories to be significantly lower than expected true in-situ values, an observation that could be explained by the thixotropic nature of tailings slurries.

The rheological properties of tailings slurries are highly susceptible to breakdown through shear history, especially if they have been previously flocculated. Previous studies, such as Sun (2018), have shown that although initially strong, clay aggregate flocs formed through polymer amendment become mechanically dissociated and revert to a near pre-flocculation state after exposure to significant shear energy. Once the polymer-amended clay aggregates are sheared apart in this manner, their strength

properties are not recoverable. The sampling, transport, and requirement to forcefully homogenize samples associated with laboratory testing induce significant shearing and potentially irreversible breakdown in rheological properties, causing the results to no longer be representative of the in-situ conditions. For these reasons, it is advantageous to measure the rheological properties in the field, in-situ, and in real time. This paper investigates the use of novel VR-eVST, like those typically used for undrained shear strength tests, with an operating protocol similar to those described by Fisher et al. (2007), to measure the viscosity of fluid tailings. Several existing studies explore modifying the operating protocol field vane shear testing to allow for variable rates (Harvey et al., 2023; Reid et al., 2023). Harvey et al. (2023) emphasize the significance of identifying optimal vane rotation rates to achieve accurate undrained shear strength measurements in mine tailings. While these studies focus on transitional soils, they show that higher rotation rates displayed increasing shear stress, which was assumed to be an effect of viscous rate effects. Stepped VR-eVST tests have been undertaken in fluid tailings to investigate the impact of variable vane rotation rates on the shear stress generated.

The testing locations (A, B, C, and D) were chosen to target materials within the fluid body with potentially complex rheological properties. All testing locations contained tailings subject to deliberate treatment, including the addition of anionic polyacrylamide flocculants to encourage dewatering. The fluid in location A was additionally subjected to significant post-flocculation shear stress, aging (likely in excess of a year), and potentially mixing with other fluid tailings streams. Location A gave the opportunity to characterize a highly variable fluid deposit under relatively challenging testing conditions. The other locations (B, C, and D) were chosen in a relatively homogenous flocculated fine tailings deposit. Flocculant was recently added at the point of deposition, with visual monitoring used to control and optimize polymer dosage. The fluid was then left to rest (< 6 months), subject only to sedimentation and self-weight consolidation, resulting in a thickened, uniform fluid. Locations B, C, and D afforded the opportunity to evaluate the test performance in a treated fluid tailings deposit where the tailings deposition plan is partially dependent on the undrained shear strength and viscous properties of the fluid to later entrain sand.

Objectives

The primary objective of this study is to develop a test protocol to accurately measure the rheological properties of fluid tailings in-situ through innovations to VR-eVST equipment and methodologies, to provide reliable, real-time data on the viscosity and yield stress, overcoming limitations associated with sample transport and laboratory testing. While vanes of this type are commonly used to measure undrained shear strength of fine-grained soils at a rotation rate of 6 degrees per second (ASTM D2573), this study investigates the industrial application of a more rapid rate of rotation in industrial slurries. To achieve this, the study tests the following hypotheses:

1. The rheological properties of fluid tailings can be effectively measured in situ using VR-eVST.
2. Modified variable, stepped rate tests will reveal a continuum in responses across different grain size materials, from transitional soils to fluid tailings, bridging the gap between geotechnical and rheological measurements.

Additionally, the study seeks to understand the in-situ measurements by comparing them with traditional laboratory results. A discrepancy between in-situ rheology and the laboratory measured rheology is expected as a result of the field conditions (Bugg et al., 2022).

Methodology

In situ

The in-situ testing was conducted using a VR-eVST developed by ConeTec and applying a testing protocol developed by NAIT. Testing was conducted at four distinct locations and five depths at two tailings storage facilities, within a single operating mine, near Ft. McKay, Alberta, Canada. A ConeTec amphibious platform and crew facilitated access to these testing sites. The detailed procedures are as follows:

1. **Gamma Piezo-Cone Penetration Test** (GCPTu) (Figure 2): At each testing site, a GCPTu was conducted for stratigraphy and selection of VR-eVST testing elevations.
2. **Initial VR-eVST**: At each elevation, an initial VR-eVST was performed ramping up from 0 to 15 RPM (90 degrees per second). The equipment subsequently ramped down to 0 RPM.
3. **Remolded VR-eVST:** Without repositioning the equipment, a second ramped VR-eVST test was conducted on the same in-situ specimen to the same RPM. This aimed to observe the behavior of the disturbed sample under the same testing conditions.
4. **Sample Collection and Analysis**: Following the VR-eVST tests, an 8-liter fluid sample of the tested tailings was collected. This sample was split into two pails:
    - The first pail was sent to a commercial laboratory for constituent analysis.
    - The second pail was delivered to NAIT for rheology testing.
5. **Stepped VR-eVST**: At approximately a 1m horizontal offset from the original test point, a third VR-eVST was performed using a step-up rate hold methodology at rotation rates between 0.3 and 90 degrees per second. This was conducted to investigate the rheological properties of the tailings under varying shear rates.

In total, the research work comprised fifteen VR-eVST tests (three of which are presented in Figure 1), the collection of five fluid samples, and three GCPTu (one of which is presented in Figure 2). It is important to acknowledge that the data set is relatively small and limited to a single operating mine.

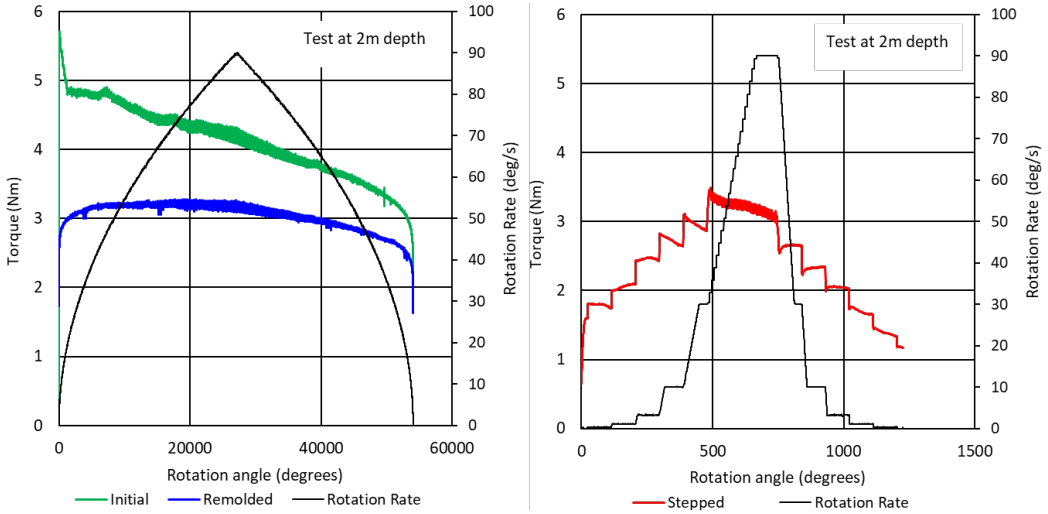

Figure 1: Example VR-eVST rotation curves from ramped test (left) and stepped test (right)

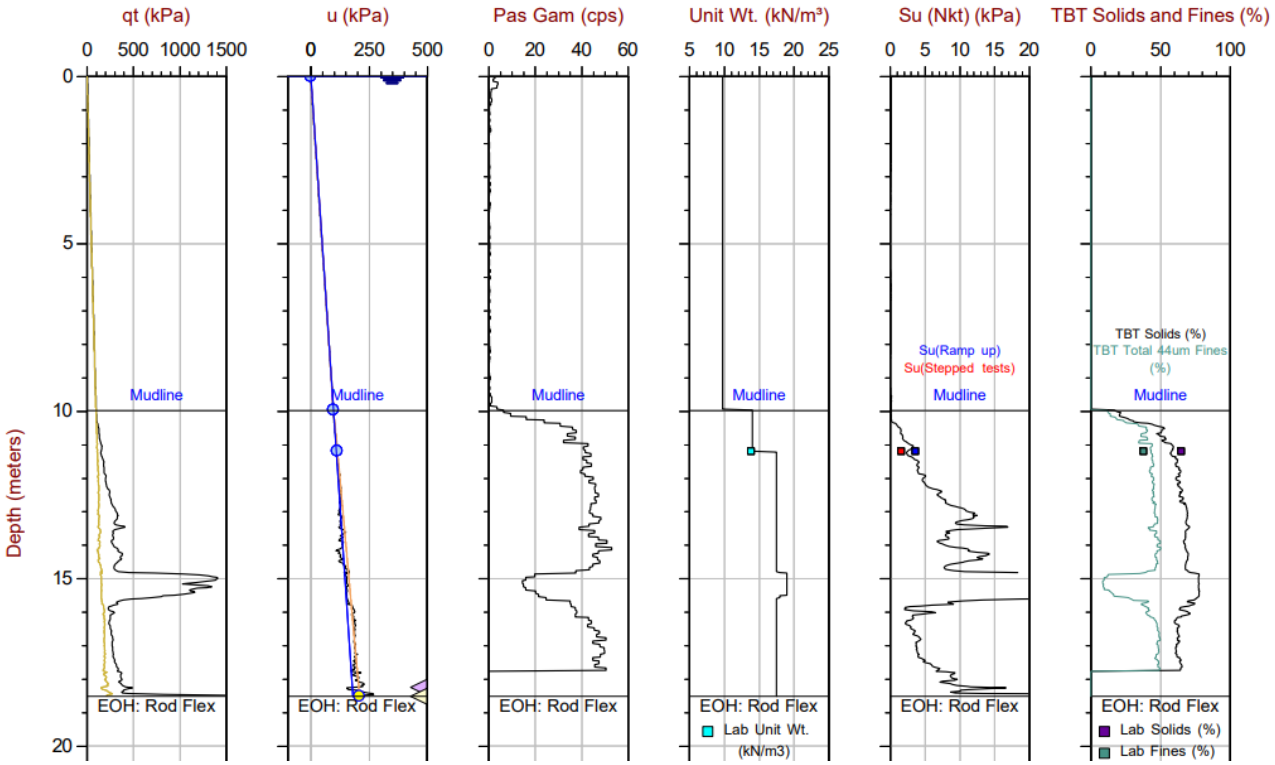

Figure 2: Example GCPTu Plot with annotated key features at location D.
Unit weights were determined using the equilibrium fluid pressure in fluid behaving materials, and soil behavior type (SBT) zones (Robertson et al., 2009) in non-fluid tailings, SBT zones 0-3 were assumed to have a unit weight of 17.5 kN/m³. Continuous profiles of solids and 44µm fines from tailings behavior type (TBT) (Entezari et al., 2023)

The VR-eVST torque load cells were calibrated ensuring a linear relationship between the load cell recorded torque and the applied torque at a rate of 1:1 (Figure 3). The lowest value on the torque calibration curve was 0.74 Nm and 0.76 Nm dependent on the instrument used, defining the sensitivity limits. The torque range for the field tests varied between 1 and 45 Nm, with the full range output of the VR-eVST being 100 Nm, indicating linearity of the torque load cell, and field measurements fell within the tool's operating range despite the low shear resistance of the fluid tailings (Figure 3).

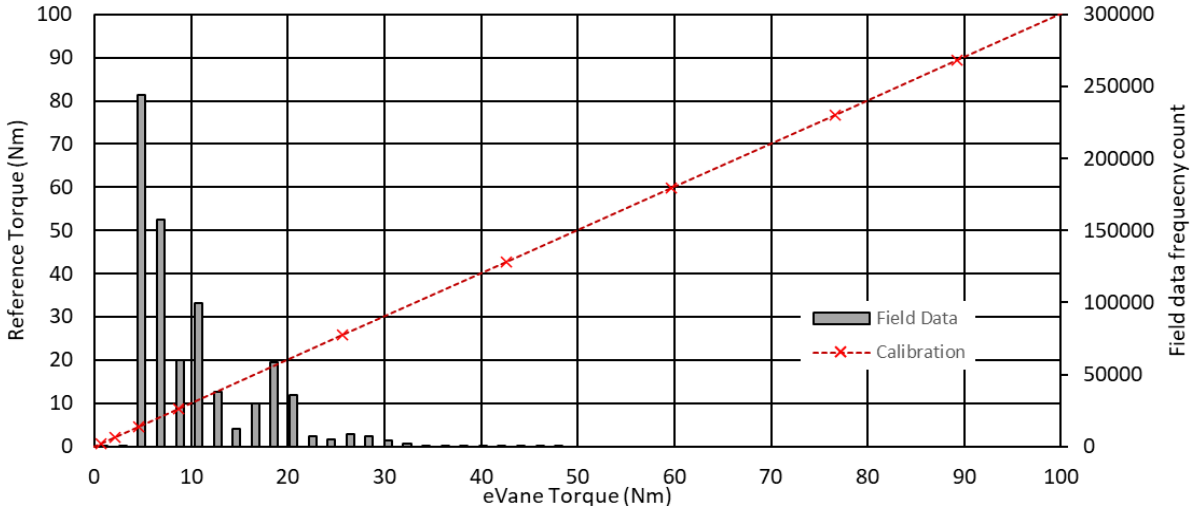

Figure 3: Vane calibration co-plotted with a histogram of the field measured torque showing the deployed ranges of the ramped VR-eVST, at all test sites

Laboratory control reference

Laboratory testing was undertaken as a control to validate the in-situ results. The samples gathered from the five test locations, were shipped and retested in a similar but scaled down shearing protocol on a Brookfield RST rheometer. The use of a slim profile blade rather than a concentric cylinder aims to minimize sample disturbance during instrument insertion reducing the impact on the shear-history dependent fluids properties. For polymer-treated materials, wall slips are a critical concern. Wall slip arises from a localized near-wall solids depletion effect, leading to artificially lowered measurements. When rotating in a fluid exhibiting a yield stress, the fluid within the vane blades rotates as a solid body. Consequently, yielding occurs within the fluid itself rather than at the boundary between the fluid and a smooth solid surface, significantly reducing the likelihood of wall slip errors (Nguyen and Boger, 1985). The majority of laboratory confirmation testing was conducted using a small vane (L = 40 mm, D = 20 mm), however a larger vane (L = 80mm, D = 70mm) was also used to conduct a portion of the tests to increase the full-scale torque (FST).

Analysis

Calculating viscosity and yield stress of non-Newtonian fluids depends heavily on measurement protocol,

geometry, and proper model fit. For this study, the Bingham Model analysis for the in-situ measurements was confined to the ramp-down data only. The thixotropic complexities of the tailings slurries had mostly been removed by a period of shearing, allowing the calculations to be performed on a relatively steady-state fluid. The data was plotted as torque response to imposed vane rotation speed and the Bingham plastic fluid model has been applied. The model is defined by Equation 1:

$$\tau = \mu_p \gamma + \tau_B \quad (1)$$

where τ= shear stress, μ_p = plastic viscosity, γ = shear rate and τ_B = Bingham yield stress.

For a rotational rheometer it is more useful to consider behavior in terms of rotational angular velocity and torque response. The equation describing Bingham plastic fluid behavior in concentric cylinder geometry is described Shook & Roco, (1991), and can be rearranged for a torque response as:

$$T=4\pi L[(R_1^2 R_2^2)/(R_2^2-R_1^2)]\mu_p\omega+4\pi L\ln(R_2/R_1)[(R_1^2 R_2^2)/(R_2^2-R_1^2)]\tau_B \quad (2)$$

where T= Torque, [N.m], L= cylinder length [m], ω = Angular velocity [rad/s], R_1= Radius of rotating inner cylinder [m] and R_2 = Radius of stationary cup [m].

By assessing the torque and angular velocity of the vane rotation at both field scale and laboratory scale, and determining the slope and y-intercept of the linear line, Equation 2 can be recognized as:

$$\text{Slope}= 4\pi L[(R_1^2 R_2^2)/(R_2^2-R_1^2)]\mu_p \quad (3)$$

$$\text{Intercept} = 4\pi L\ln(R_2/R_1)[(R_1^2 R_2^2)/(R_2^2-R_1^2)]\tau_B \quad (4)$$

Example results are presented in Figure 4, where the slope and intercept from the linear portion of have been identified. The "ramp-down" results from the "peak" rotation sweep were preferentially used in the calculations, as the initial ramp up results have inherent breakdown in tailings structure due to thixotropic effects not adequately covered by the Bingham fluid model used at this stage in research.

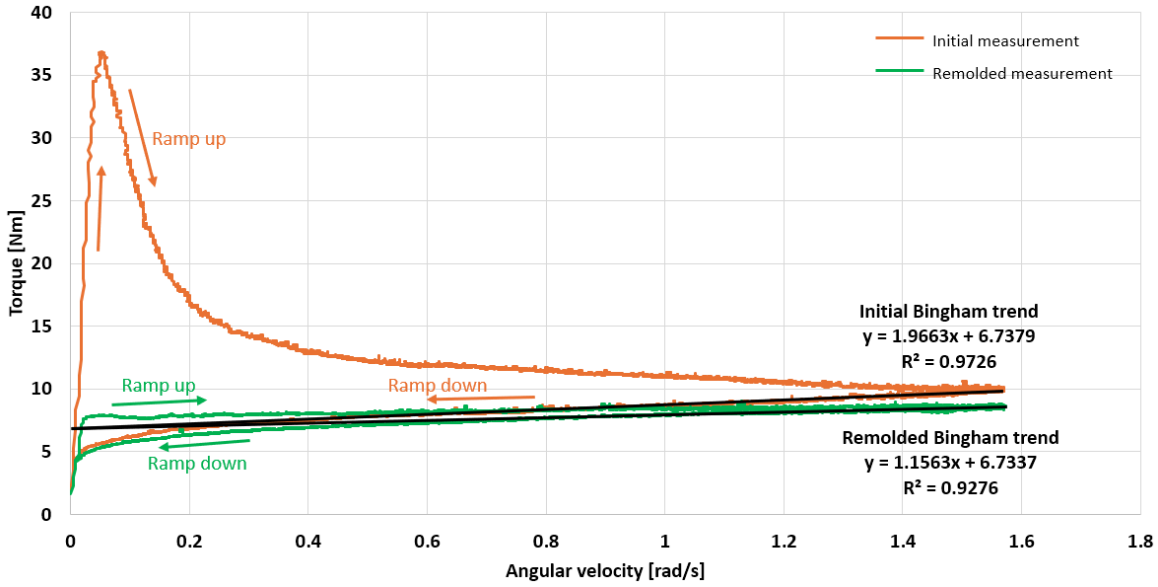

Figure 4: Interpretation of the initial VR-eVST and remolded VR-eVST at 8.3 m (Location B)

Both L and R_1 are known constants depending only on the geometry on the vane. For the laboratory case of a vane rotating within a large container, the shear at the edge of the rotating surface is a maximum, that decays exponentially outwards due to frictional losses. When the local shear stress decays past the yield stress of the fluid, the fluid at that radial position and beyond is considered to be unsheared, and essentially behaving as a solid. In the case of a vane rotating in a sufficiently large container (such as a tailings pond), where the container radius is sufficiently larger than R_2, the vane may be considered to be rotating in an infinite medium. Under these circumstances, R_2, representing the radius of the sheared area, is not clearly defined.

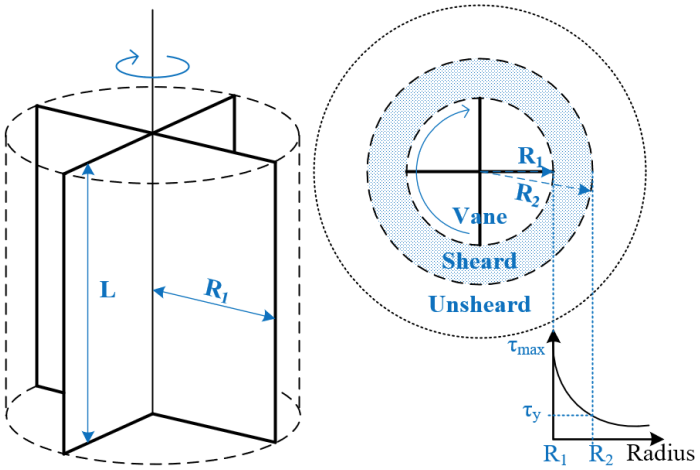

Figure 5: Representation of the vane geometry, illustrating the inner radius (R_1) and the radius of the sheared area (R_2).
Cylindrical shear profile is also shown (Fischer, 2007). Diagram is not to scale

To conduct the calculations at this preliminary stage of method development, R_2 was determined via iterative calculations to assess the relationship between an assumed value of R_2 and calculated plastic viscosity and Bingham yield stress. It was noted that both plastic viscosity and Bingham yield stress initially changed significantly for small values of R_2, but remained constant beyond a point. Assuming the calculated critical point to be R_2 allowed for the calculation of rheological properties for this early study. Using this methodology, for the field vane tests, R_2 was assumed to be 0.3 m, whereas R_2 at the laboratory scale using the small vane was assumed to be 0.02 m. A simplifying assumption was made that R_2 remained constant through the duration of testing. These assumptions for R_2 will be refined in ongoing studies.

In support of Objective 2, the stepped VR-eVST tests were analyzed to understand how shear stress develops at different rotation speeds (between 0.3 and 90 degrees per second) considering an average shear stress both increasing and decreasing rotation rates. For each rotation speed, shear stress was calculated in accordance with ASTM D2573/D2573M – 18.

Results

Viscosity and yield stress

The field VR-eVST tests conducted gave calculated values for plastic viscosity ranging between 40 Pa.s and 124 Pa.s, as presented in Table 1. These values are comparable to model suspensions of kaolinite and bentonite clay at similar compositions to the measured slurries, and other laboratory testing on true oil sands tailings (Piette et al., 2022; Shakeel et al., 2021). The calculated viscosity and yield stress aligns with plausible values with respect to the depth, location, solid content, and density of the tailings.

Table 1: Bingham plastic fluid properties calculated based on field data from initial VR-eVST

Location	Density Kg/L	Depth (m)	Initial VR-eVST field data results			Remolded VR-eVST field data results		
			Plastic Viscosity (Pa.s)	Bingham Yield Stress (Pa)	Peak Su from ramp up (kPa)	Plastic Viscosity (Pa.s)	Bingham Yield Stress (Pa)	Remolded Su from ramp up (kPa)
A	1.23	2.0	40.31	90.63	0.436	21.50	78.38	0.245
A	1.67	4.0	79.20	138.96	2.376	10.82	134.62	0.351
B	1.27	8.3	85.19	216.43	2.813	51.12	214.74	0.661
C	1.66	9.7	–	–	1.356	–	–	0.243
D	1.41	11.2	123.52	445.13	3.595	76.83	521.19	1.438

As shown by Figures 1 and 4, and Table 1, viscosity values for the tailings fluids continue to decrease after remolding shear until reaching a state of fully sheared structural equilibrium. At the current phase of study, the initial VR-eVST values were preferentially chosen as they are sufficiently stable to allow measurement, yet more representative of the in-situ characteristics of the tailings fluids. It should be noted that there was no observable trend in how much the calculated viscosity decreased following remolding. These thixotropic effects are likely sample dependent, and are influenced by solids content, clay content, flocculant content, and the water chemistry of the sample.

In contrast, the laboratory data, as presented in Table 2 seem to significantly underrepresent the viscosity and yield stress compared to the field values. The values appear erratic without trends occurring with respect to depth, location and density. The smaller vane used in laboratory testing may be partially at fault for the lower readings, as the rheometer was only able to reach 2.5% FST. For typical rheometer operations, 10-30% FST is recommended. However, viscosity values measured using the laboratory rheometer did not increase significantly after switching to the larger diameter vane, which was able to achieve 50% FST. The discrepancy between laboratory and in-situ data was expected due to the thixotropic nature of tailings slurries and shear break during the sampling, transport, and homogenization for required laboratory testing. At both field scale and laboratory scale, the sample collected from location D at 9.7m

consistently resisted measurement. This was likely due to high sand content in this sample leading to a settling, non-homogenous suspension over the duration of testing. Heterogeneous fluids are known to cause difficulties for rheological measurements due to the constantly changing solid content of the sample. In the case of a laboratory rheometer, where the vane spindle is positioned close to the vessel bottom, the formation of a sand bed may act as an additional brake to the vane rotation. It is currently undetermined at what sand-to-fines ratios rheological measurements become unstable due to settling suspensions and is an opportunity for future study.

Table 2: Bingham plastic fluid properties calculated based on laboratory data

Location	Depth (m)	Laboratory results from small vane		Laboratory results from large vane	
		Plastic Viscosity (Pa.s)	Bingham Yield Stress (Pa)	Plastic Viscosity (Pa.s)	Bingham Yield Stress (Pa)
A	2.0	1.09	55.98	0.147±0.044	72.86±1.238
A	4.0	0.52±0.009	51.69±0.366	0.431±0.020	52.21±0.086
B	8.3	1.155±0.02	24.85±1.551	–	–
C	9.7	–	–	–	–
D	11.2	2.464±0.036	149.99±2.771	–	–

When comparing the viscosity determined from VR-eVST field data from the adjacent CPTs, there is strong agreement between the cone resistance (q_t) (averaged over vane length) and viscosity values. This correlation, if supported by future studies, stands to add a valuable interpreted parameter to a CPTu test; it also suggests fluid tailings viscosity may be related to similar factors influencing penetration resistance in fluid tailings, such as stresses and fabric.

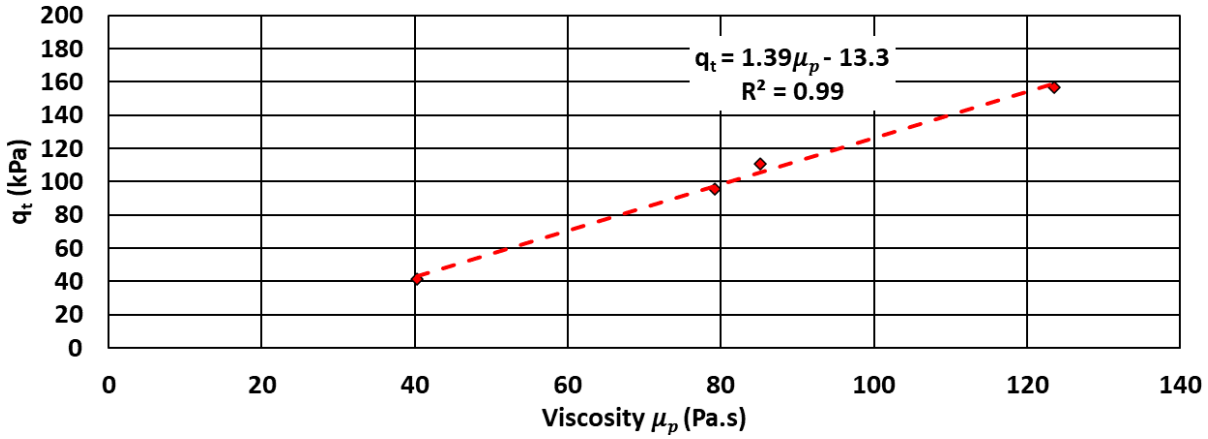

Figure 6: Relationship between viscosity from VR-eVST field data and cone resistance (qt) from adjacent CPT plots. Data is from the initial ramped VR-eVST at locations A, B, and D

Shear stress development

The results for the field VR-eVST tests, focusing on the shear stress calculated for each held vane speed have been presented in Figure 7 on a linear scale and Figure 8 on a log-log scale, both increasing speed and decreasing speed data has been considered. It is challenging to decern a trend on the linear-linear data, though some curvature towards a "U-shape" is apparent, occurring at low vane rotation speeds during the increasing speed part of the test. This trend is not apparent when the vane rotation speed is decreased.

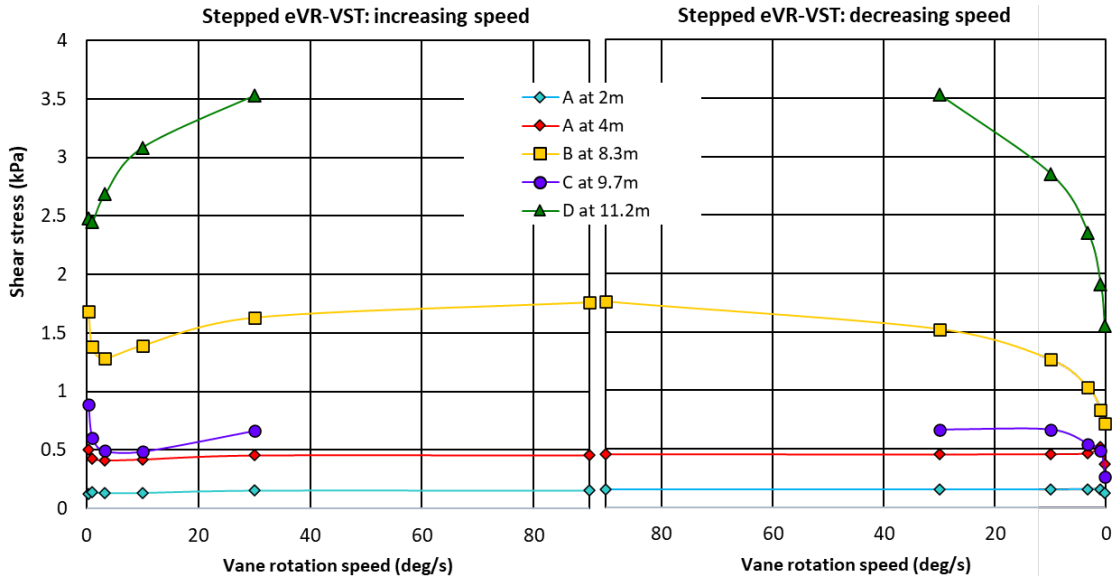

Figure 7: Comparison of the stepped eVR-VST increasing in speed and decreasing in speed

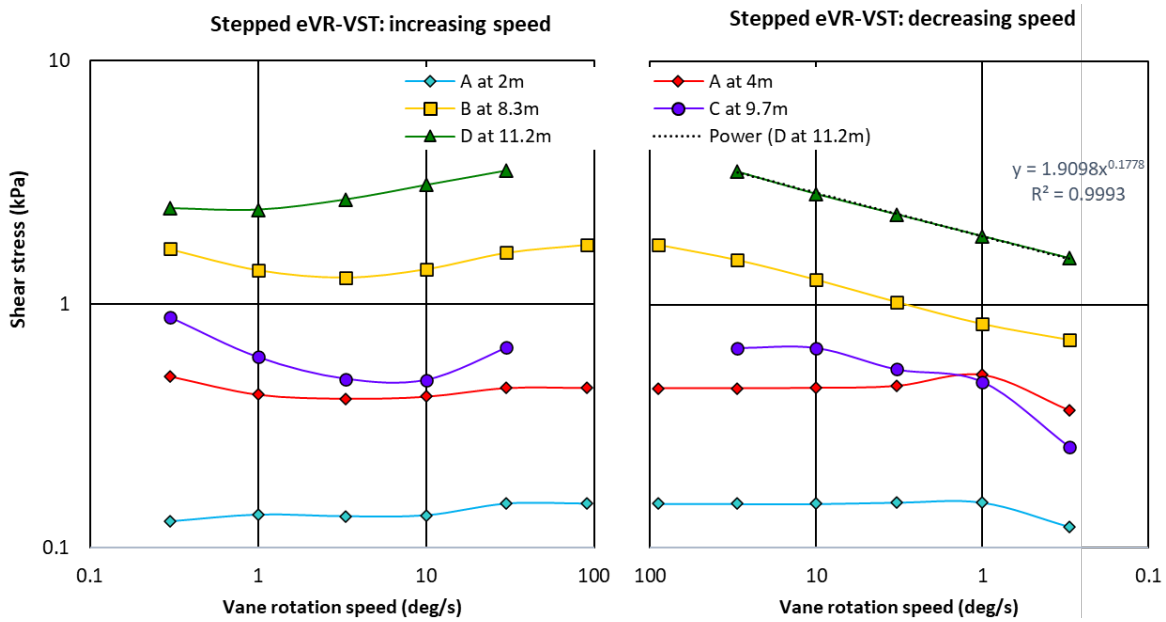

Figure 8: Comparison of the stepped eVR-VST Increasing in speed and decreasing in speed on a log-log scale. D shows the selection of the rate effect parameters

When plotted on a log-log scale, the U-shape trend becomes more apparent in tests B, C, and D during the increasing speed phase, while a linear trend is observed during the decreasing speed phase. For the two tests in location A no significant rate dependency appears to occur. This is likely due to the distinct treatment strategies between Location A and Locations B, C and D.

Work conducted by Yafrate et al., considers the rate-dependent effects on resistance for full flow penetrometers, fitting rate effect parameters to the measured data. The data obtained through decreasing the speed has been assessed in this manner. A power trendline was found most appropriate for the data that showed rate dependency. Results are presented in Table 3.

Table 3: Rate effect parameters from stepped eVR-VST considering minimum undrained shear strength

Location	Undrained Shear Strength (kPa)	Constant	Exponent	R^2
A	0.12	No significant rate dependency		
A	0.40			
B	0.71	0.85	0.16	0.99
C	*0.26 (high sand content)*	0.40	0.19	0.81
D	1.5	1.91	0.18	0.99

Discussion

Several hundred million cubic meters of oil sands tailings need to be removed from containment and treated, often with polymer flocculants, to meet existing regulatory guidelines. The rheological properties of fluid tailings have typically been assumed conservatively low. However, as an oil sands facility matures, significant proportions of coarse sand particles from beach deposition suspend within the fluid tailings, creating dense and viscous fluid tailings that can be challenging to mobilize. As per Bugg et al. (2022), understanding the flow properties of tailings can enable process engineers to plan dredge moves to support re-processing of fluid tailings from existing tailings deposits and erroneously low laboratory rheology measurements can lead to incorrect predictions of coning during dredge operations. Additionally, if not understood, rheological variability can impact flow of the fluid tailings to a single point dredge, resulting in time consuming and expensive “targeted dredging”. The dredging of tailings may also be of interest in hard rock mining where re-processing tailings is becoming increasingly attractive.

In the alternative case (in which much of the tailings can be left in place through infilling), viscous fluids have been observed to mix with infilling sand, impacting the geotechnical properties of the resultant beach. Tailings planners influence the degree of mixing by controlling the thickness of deposited thickened fluid tailings layer, allowing for ageing periods, controlling the decant water depth, and rate of coarse tailings placement. If uncontrolled, this mixing could produce low strength tailings in the beach. When

controlled, mixing has been observed to produce geotechnically competent, fines enriched mixed deposits. The in-situ rheological properties of the fluid are the primary mechanism for determining when and where mixing occurs. From a dam safety and emergency planning perspective, understanding the flow properties of the contained fluid is necessary to predict run out distances in a breach scenario.

The field trial using the VR-eVST to measure rheological properties of oil sands fluid tailings produced promising results and requires further development. Measuring viscosity in-situ using vane geometry with an infinite boundary condition may better reflect the true nature of the shear-sensitive tailings, minimally impacted by sampling, transport, and handling. The presence of polymer in all samples at least partially impacted the results, as polymer treated samples are known to show rheomalaxis (Schramm et al, 2018).

Despite plausible values for plastic viscosity and Bingham yield stress calculated from VR-eVST, laboratory verification test results were significantly lower than the field-measured values. Lower-than-expected laboratory rheological measurements of tailings fluids were previously observed in industry (Bugg et al., 2022), and is the primary motivation behind the present research. In both the study by Bugg et al. and the present research, the likely cause of low laboratory measurements is the shear-induced breakdown in rheology of tailings, exacerbated by requisite sampling, transport, storage, handling, and homogenization prior to laboratory testing. The authors are presently developing validation methods to evaluate VR-eVST performance in the laboratory.

The findings presented show a decline in plastic viscosity and yield stress with cumulative shear. Reductions in viscosity and yield stress were observed between all initial and remolded tests, which are due to the breakdown of the material structure (thixotropy) of the tailings. Shear-thinning behavior can be captured more accurately by advanced rheological models such as Herschel-Bulkley and Casson (Saasen and Ytrehus, 2020; Kelessidis and Maglione, 2006) which consider pseudoplastic behaviors. While the Bingham model is suitable for initial studies, more advanced models should be explored in future research.

The data from the stepped tests was hypothesized to show a u-shaped curve, enabling the identification of a critical velocity providing a minimum shear response above which viscous effects cause increasing shear stress response. This phenomenon was not observed, likely due to the interplay between thixotropic response (fabric destruction) and simultaneous onset of viscous effects. Further work in partially drained mine tailings or soils would be useful to further test this hypothesis. Conducting a stepped test from high to low rotation speed is likely to yield the most representative data and be most compatible with the Bingham Model, without the inclusion of complexities associated with thixotropy.

This initial proof-of-concept study has a limited sample size and further study is ongoing. This includes a second phase of testing scheduled to expand the data set in non-polymer treated tailings and consider the impact which an infinite boundary condition has on results, investigating the use of

confinement around the VR-eVST vane, therefore defining a constant R_2. When unconfined it is expected that the shear boundary around the vane (as R_2) is dynamic and likely changes with total rotation and rotation rate, and thus R_2-R_1 becomes smaller at higher speeds. Further studies will also be undertaken to assess the utility of piezometric sensors, inclinometers, and thermal compensation in the VR-eVST, with an emphasis on the critical velocity and viscous effects in tailings subject to partial drainage under standard rates of shear, such as those commonly found in hard rock mill tailings.

Conclusion

The use of novel VR-eVST with protocols to measure the rheological properties of fluid tailings in-situ shows early promise, and provided viscosity and yield stress values that were physically reasonable. This study's findings indicate that in-situ data may be more representative than laboratory measurements. Observations from the VR-eVST show viscosity and yield stress reduced with cumulative shear in the field from the initial peak to remolded properties, therefore it would be expected that laboratory results after sampling, shipping, homogenization, sub-sampling would provide the lowest bound measurement of rheological properties. Tailings are known to exhibit shear-sensitive rheological behaviors, highlighting a need for in-situ measurements which minimize error due to handling. The viscosities obtained in-situ may influence both runout modeling, mixing and dredging operations.

Although the sample size is small, VR-eVST equipment appears to have reliably and efficiently measured rheological properties in fluids with shear strengths ranging from 0.1 kPa to 3.5 kPa. Remolded strengths obtained from the stepped hold tests and remolded VR-eVST tests are comparable, suggesting either method is appropriate to determine a minimum undrained shear strength. Additionally, there appears to be a strong relationship between plastic viscosity and the CPTu q_t.

Future work should expand the data set and consider applying the method of adjacent VR-eVST, each with a unique constant speed (Harvey et al., 2023), rather than the stepped method. This approach will provide a better understanding of peak rather than remolded strength and the relationship with vane speed.

Acknowledgements

The authors would like to thank Wale Akanni, Jared Young, Trae Whorms, and Mahdi Askaripour for collecting and analyzing the data, and Alice Zheng, Vitali Sakalou, and Roque Obusan for their efforts developing the VR-eVST. Lastly, we would like to thank the mine operator involved for their support.

Mechanical Response of Plastic Fine Tailings under Constant Shear Drained Loading

Luis Vergaray-Astupina, Georgia Institute of Technology, USA
Jorge Macedo, Georgia Institute of Technology, USA

Abstract

Several case histories of tailings dam failures have highlighted that the instability onset in loose particulate materials can be triggered under prevailing drained conditions and stress paths that can be represented by constant shear drained loading. This study investigates the mechanical response of a plastic fine tailing, which has received limited research attention. The examined tailing has a fine content of 90% and a plasticity index of 14. Common coarse and intermediate materials exhibit distinct responses – either loose or dense – depending on their initial state. In contrast, this fine tailing exhibits predominantly a dense-type response, despite initial states above the critical state line (i.e., loose) due to their compressibility and states before the stress relief stage. This "mixed" response was interpreted using the critical state soil mechanics framework, and the underlying mechanism was postulated. This study advances the understanding of plastic fine tailings response, aligning with the Global Industry Standard on Tailings Management (GISTM) recommendations.

Introduction

Static liquefaction, often associated with the onset of instability in particulate materials under static loading, is commonly assessed under undrained conditions, highlighting the role of excess pore pressure development and the associated reduction in effective stresses (e.g., Jefferies and Been, 2015). However, static liquefaction can also occur under prevailing drained conditions. Previous case studies (e.g., Bishop, 1973; Zhu and Anderson, 1998; Olson et al., 2000; ICOLD, 2001; Morgenstern, 2001; Morgenstern et al., 2016, 2019) have highlighted the development of static liquefaction under prevailing drained conditions. For instance, the 1966 Sgurigrad TSF failure was caused by a pond level rise during three days of heavy rain (ICOLD, 2001). As the pond level increased, the mean effective stresses decreased, and the shear stresses changed marginally, triggering the liquefaction of the stored tailings. This process can be represented in the laboratory by considering a constant shear drained (CSD) stress path (e.g., Brand, 1981; Anderson and Sitar, 1995). The Baia Mare disaster in 2000 and the Buffalo Creek failure in 1972 are

examples of TSF failures caused by extreme weather conditions, similar to the Sgurigrad TSF failure. With global warming, extreme weather events are expected to become more frequent, increasing the risk of similar failures. Therefore, it is crucial to understand the mechanical response of mine tailings and other granular materials under unconventional loadings such as CSD stress paths.

Most previous efforts on assessing drained-type instabilities have been focused on natural sands with low or not fine contents (e.g., Skopek et al., 1994; Zhu and Anderson, 1998; Anderson and Sitar, 1995; Junaideen et al.. 2010; Wanatowski and Chu, 2010; Dong et al., 2015; Alipour and Lashkari, 2018; Rabbi et al., 2019). In contrast, previous studies considering mine tailings are scarce (e.g., Morgenstern et al., 2016; Morgenstern et al., 2019; Fotovvat et al., 2022), despite the importance of drained type instabilities in TSF case history failures. Initially, the efforts on mine tailings were limited to forensic studies after the recent failures with somewhat limited scope.

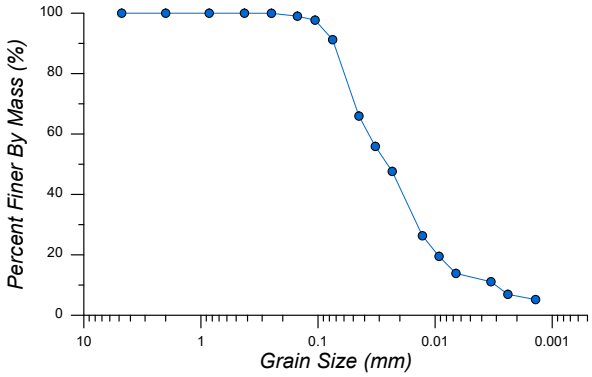
For example, Morgenstern et al. (2016) conducted three tests under CSD and LE (lateral extrusion – a variation of the CSD test where q is increased) stress paths in the assessment of the Fundão failure; Morgenstern et al. (2019) conducted 6 CSD tests in evaluating the Cadia failure. More recently, studies have increasingly assessed the response of mine tailings under CSD stress paths (e.g., Riveros and Sadrekarimi, 2021; Fotovvat et al., 2022; Fanni et al., 2022).

Riveros and Sadrekarimi (2021) evaluated the instability of gold tailings using a direct simple shear (DSS) device, finding similar instability mobilized friction angles between CSD and constant volume stress paths. Fotovvat et al. (2022) evaluated the response of two non-plastic mine tailings (fine contents of 17 and 84%) under triaxial CSD stress paths. Their study suggests that the instability stress ratios under CSD and triaxial undrained stress paths are consistent but are affected by the stress ratio (η) and state at consolidation. Fanni et al. (2022) approximated CSD conditions in a hollow cylinder to study anisotropic effects. The studies above are a step toward better understanding drained-type instabilities within the tailings community. However, given their relevance to recent TSF failures, more efforts focused on mine tailings are warranted, especially for materials with medium to high plasticity. This study contributes to this direction by studying the drained-type instability of a plastic fine tailing, by conducting experimental tests under CSD stress paths and interpreting the results under the critical state soil mechanics framework.

Investigated material

Figure 1 shows the particle size distribution of the mine tailing gradation investigated in this study. This material has a fine content (FC) of 91% and a plasticity index (PI) of 14. Using the Unified Soil Classification System (USCS), this material is classified as low to moderate plasticity clay (CL). Table 1 shows additional information on this material, including Atterberg limits, packing and particle size distribution indexes, and specific gravity. Figure 2 shows scanning electron microscope (SEM) images for

this material, showing that the fine particles dominate the matrix, with angular coarse particles floating around. X-ray diffraction analyses indicated that the material is mainly composed of quartz and chlorite, with traces of K-feldspar and other minerals (tin, copper, and molybdenum). The fine gradation has a significant amount of chlorite (a soft clay mineral), which likely caused the high PI of 14.



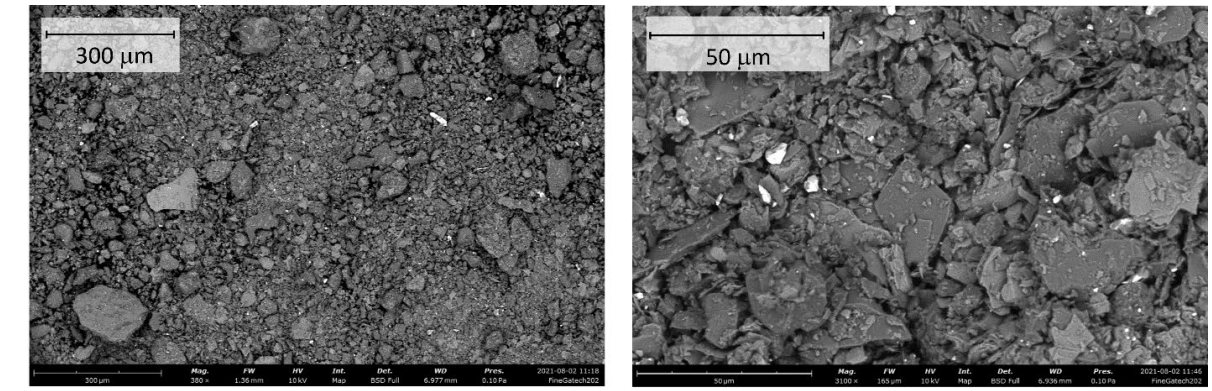


Figure 1: Particle size distribution

Coefficient of uniformity	C_u	14
Coefficient of curvature	C_{curv}	1.80
Mineralogy in %:(quartz, chlorite, and others)		57, 38, 4

Experimental setup

The equipment used in this study represents a state-of-the-art triaxial device. Two electromechanical water pumps are used to control the cell and back pressure; each of them has an electrical pressure transducer capable of controlling pressure and volume changes, with a precision of 0.2 kPa and 0.1 mm^3, respectively. The equipment also has an additional air pump to provide suction during water flushing before saturation. The data acquisition system allows automatic saturation, consolidation, and shearing for several stress paths under strain and stress-controlled conditions. The load control system is equipped with dynamic sensors, which are well suited to control stresses even at large rates of deformations. This is a desirable feature for CSD stress paths as the vertical and horizontal stresses need to be controlled, especially when approaching an instability condition where deformation rates are accelerated. This feature provides advantages relative to previous studies on CSD paths focused on sands with challenges in controlling stresses as the instability onset is approached (e.g., Rabbi et al., 2019).

Sample preparation

The samples were reconstituted using the moist tamping method (MT), with the end-of-test freezing procedure used to measure void ratios (e), as commonly used in tailings engineering (e.g., Reid et al., 2020). Specimens were prepared by mixing water to achieve a moisture content of approximately 20% , allowing the specimens to cure for about 12 hours. The specimens were then reconstituted in seven layers using the "under-compaction" method (Ladd, 1978) to achieve a uniform specimen with a targeted void ratio. The diameter of the samples is D=2.7 in, and the height-to-diameter ratio (H/D) was fixed at 2 to mitigate potential end platen effects (Lade et al., 1996). Following the recommendations of Viana da Fonseca et al. (2021), a small suction was applied to place the specimen into the triaxial cell, and a rubber suction cap was placed at the top of the specimen to avoid tilting due to misalignment. Once the specimen was placed, the cell was filled with water, and a small p' (<20 kPa) was applied. Then, the specimen was flushed with deaired water, before saturation using a back pressure ramp saturation method.

This saturation method steadily increases the cell and back pressures to avoid sample collapse while keeping a constant small p' value (<20 kPa). A back pressure of 750 kPa was used, and Skempton's B values higher than 0.98 were considered to represent saturated conditions. The saturated specimens were then consolidated, and once the desired confinement in the range of 50–350 kPa was achieved, the specimens were sheared under strain-controlled conditions in the standard triaxial tests and under stress-controlled conditions in the CSD tests. In the CSD tests, the samples were sheared in two stages. First, a triaxial loading was imposed until the desired shear stress (q) was achieved. Then, in the second stage (the

stress relief stage), the vertical and horizontal stresses were decreased by the same magnitude to decrease p' at a constant q. The samples were sheared at stress reduction rates (dp' / dt) of 0.25 kPa/min.

Response in triaxial tests and critical state line assessment

Figure 3 shows the material's stress-strain response (i.e., axial strain, ε_a, versus q) and stress paths (i.e., p' versus q and e versus p') under standard triaxial drained (TxC-CD) and undrained (TxC-CU) loadings. Macedo and Vergaray (2022) defined terminology to describe the response of mine tailings under TxC-CU loadings as i) full softening, where there is a drop from peak to residual conditions, and q is close to zero at large strains; ii) partial softening, which is similar to full softening, but q is not close to zero; iii) limited flow, when there is a transition from contractive to dilative response after the peak (i.e., q initially decreases after the peak, but then increases); and iv) non-flow when q tends to increase. The full/partial softening cases are particularly associated with static liquefaction in the literature (e.g., Jefferies and Been, 2015). In this context, the typical responses observed in the plastic fine tailing range from limited flow to non-flow, which is likely influenced by its large compressibility. The slope of the CSL (λ_e) and the PI can serve as proxies of compressibility (Macedo and Vergaray, 2022; Vergaray et al., 2023). The λ_e of this material is about two times the typical values of sands (e.g., λ_e ~ 0.02 to 0.04, see Jefferies and Been, 2015); hence, highlighting its significant compressibility.

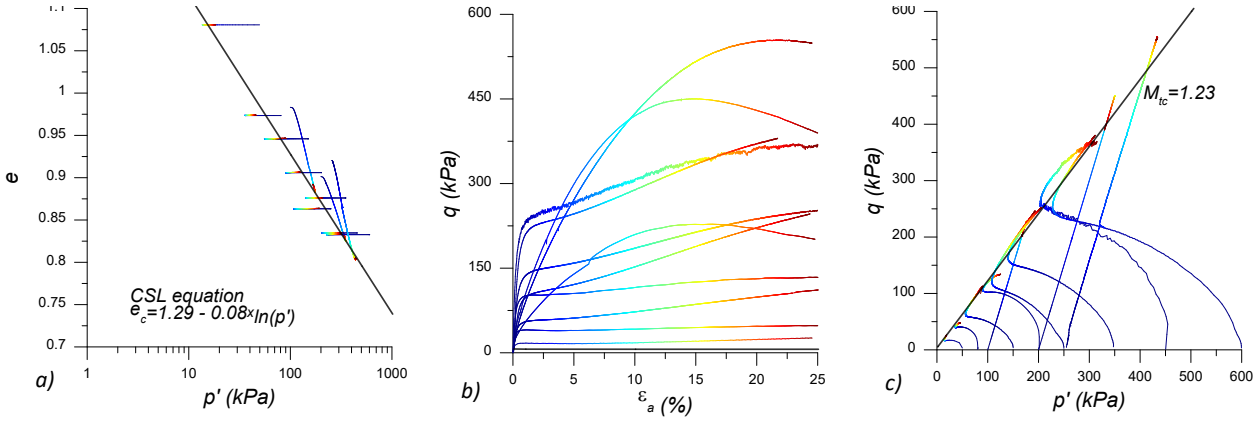

Figure 3: a) Critical state location, b) stress-strain response, and c) stress paths in the $p' - q$ space of the plastic fine tailing

Response under CSD stress paths

Figure 4 presents typical responses of CSD tests in the $e - p'$ (left column), $p' - q$ spaces (middle column), and the evolution of ε_a versus p' (right column) for the examined tailing, considering different initial states as defined by the initial state parameter (Been and Jefferies, 1985), which is expressed as $\psi_0 = e_0 - e_{cs}$, where e_0 and e_{cs} are the initial and critical state void ratios for the same p'. ψ_0 was estimated using the

CSLs defined in the previous section, which are also shown in Figure 4 for reference. Also, the instability points in Figure 4 (yellow starts) are obtained using a second-order work-based criterion (Hill, 1958) and, for now, are only presented for illustrative purposes.

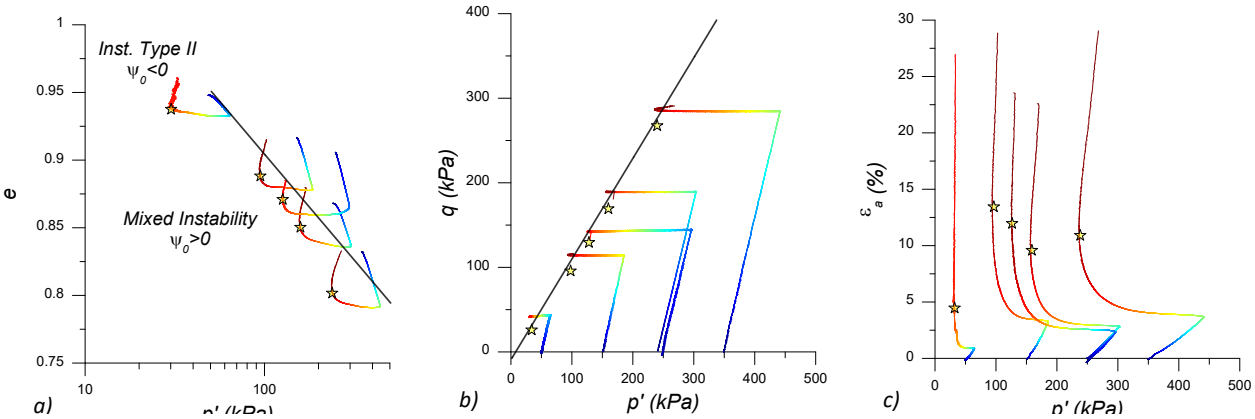

Figure 4: CSD response of the plastic fine tailing in the a) $e - p'$, b) $p' - q$, and p' versus ε_a plots

Typically, loose states (i.e., above the CSL – $\psi_0 > 0$) in sands make the initial part of the response (triaxial loading) contractive (Figure 5a). Then an initial volume increase in the stress relief stage is followed by a subsequent decrease after the instability onset, where large deformations occur. In addition, the stress path in the $e - p'$ space stays above the CSL and the instability stress ratio (η_{IL}) is lower than the critical stress ratio (M_{tc}). This type of instability has been defined as Type I by Alipour and Lashkari (2018). In initial dense samples (i.e., below the CSL – $\psi_0 < 0$) in sands, the volume mainly increases before and after the instability onset, with the stress paths in the $e - p$ space staying below the CSL and crossing the M_{tc} (Figure 5b) in the $p' - q$ space (i.e., $\eta_{IL} > M_{tc}$). As per Alipour and Lashkari (2018), this constitutes a Type II instability.

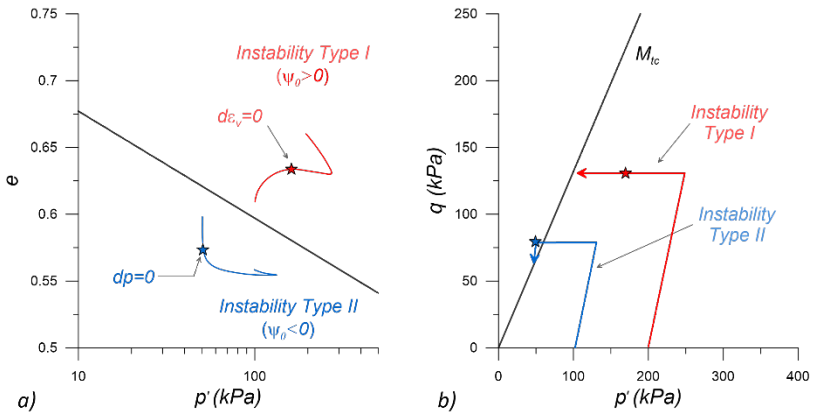

Figure 5: Instability responses (Type I and II) in CSD tests in the a) $e - p'$, and b) $p' - q$ spaces

However, the response observed on this plastic fine tailing differs from the typical response observed in clean sands (e.g., Junaideen et al., 2010; Wanatowski and Chu, 2010; Dong et al., 2015; Alipour and Lashkari, 2018; Rabbi et al., 2019), which are illustrated in Figure 5. In terms of the instability observed on the fine tailing, it is first relevant to highlight that the states after consolidation and before the CSD stress relief phase are close to the CSL, as shown in Figure 4. This is attributed to the significant compressibility reflected in a large Γ (1.29) and λ_e (0.08), which correspond to the 84th percentile of the ranges provided by Macedo and Vergaray (2022).

Thus, the "high altitude (i.e., high Γ)" of the CSL line in the $e - p'$ space and the significant compressibility result in initial states close to the CSL before the stress relief in the CSD loading, which, in turn, affects the tradeoff of $d\varepsilon_v^e$ and $d\varepsilon_v^p$. When $\psi > 0$, during initial stress relief, $d\varepsilon_v^e$ is negative (p' decreases), and $d\varepsilon_v^p$ is positive ($\psi > 0$). Since the state is close to the CSL, there is not enough room to build up the required $d\varepsilon_v^p$ to counteract $d\varepsilon_v^e$, a condition required for a Type I instability, as postulated in Bokkisa et al. (2023) and Vergaray and Macedo (2024). As the stress-relief stage advances, the stress path in the $e - p'$ space eventually crosses the CSL, and $d\varepsilon_v^p$ becomes negative. Consequently, $d\varepsilon_v = 0$ cannot be zero, and a Type II instability occurs. This study describes mixed instability as this instability type on initially loose specimens ($\psi > 0$) where a Type I instability would be expected, but a Type II instability occurs.

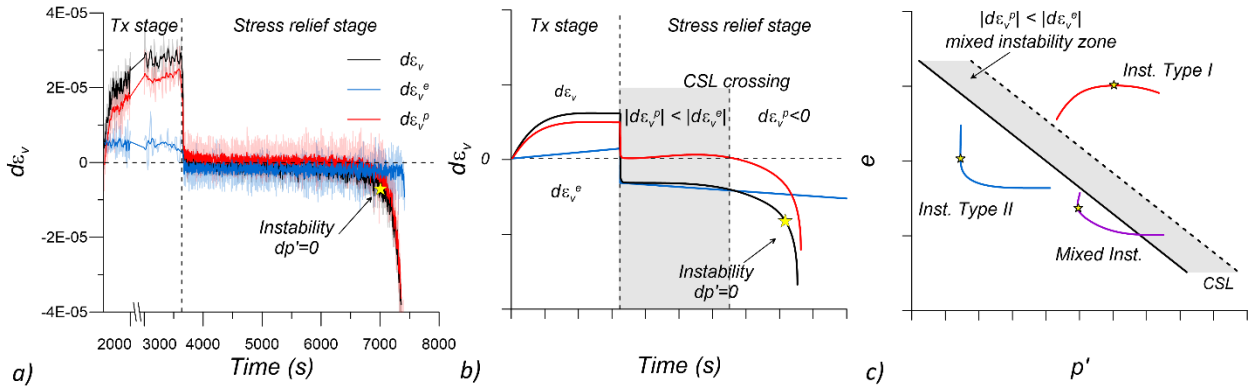

Figure 6: a) Experimental-based and b) schematic variation of ε_v components in a mixed instability. c) Schematic representation of the mixed instability zone in the $e - p'$ space

Figure 6 shows an example of the experimental variation ε_v for the instability just described, considering a test with a positive initial state (ψ~0.01). ε_v components were estimated as in the previous section. Figure 6b shows a schematic generalization. The observations just discussed indicate that there is a region above the CSL within which a mixed instability occurs, i.e., the initial ψ is positive, but instability manifests as Type II. If the state before stress relief is within this region or below the CSL, the response will be similar to that of an initially dense material. If the state is above that region, the response will be

similar to that of an initially loose material. Figure 6c illustrates the described concept schematically. The authors are unaware of previous efforts unraveling the mechanisms behind this instability type as conducted in this study. Previous efforts to assess CSD stress paths in materials with high FC and plasticity are limited and mostly focused on natural soils. For instance, the CSD tests from Anderson and Sitar (1995) on colluvial soils (FC~95%, PI=19), and Xu et al. (2011) on loess (FC=70-85% and PI=19) seem to suggest a mixed instability; however, definitive conclusions cannot be drawn as the CSL assessment is either not fully detailed (Anderson and Sitar, 1995) or not available (Xu et al., 2011).

Finally, it is also instructive to inspect the post-instability responses. Figure 7 shows typical responses after loss of control. In this case, Δu after instability is negative, increasing p', which results in an additional η drop. The $p' - q$ stress path tends to go to the critical state with a tendency to increase q, resembling the hardening behavior observed for this material in the Tx-CU tests. Parallels could be drawn between the response of this fine tailing and the response observed during the Cadia case history failure, where the deposited tailings had a comparable compressibility with relatively large PI (19-24) and λ_e values (~0.05). For instance, after instability and loading control loss in the laboratory, negative excess pore pressure and a tendency to increase q towards the CSL, resembling typical hardening responses in TxC-CU tests, were observed. In the Cadia failure, the runout was controlled (defined by the subsequent forensic study as a slump), which might be associated with the hardening-type response post-instability just discussed.

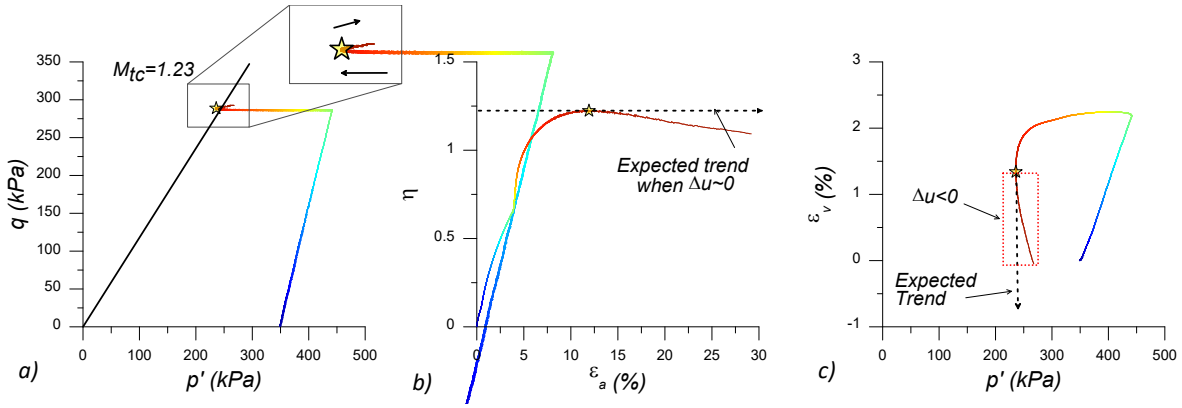

Figure 7: CSD test results in the a) $p' - q$, b) ε_a vs η, and c) p' vs ε_v

Conclusion

As discussed in the introduction, several TSF failures have occurred under prevailing drained conditions, highlighting the importance of drained stress paths. This is particularly important because any pre-failure indicators would be minimal, making it dangerous in terms of static liquefaction. This study assessed the mechanical response of a plastic fine tailing under CSD stress paths. Interestingly, in the examined material only Type II instability was observed, regardless of the initial state (i.e., loose, or dense). This response was described as mixed and attributed to the high compressibility of the fine tailing.

Development of Tailings-specific Correlations for Estimating Fines Content from CPT Data Using Artificial Intelligence Method for the Holden Mine

Mohammad Rashidi, Stantec, USA
Phillip E. Crouse, Stantec, USA
Summer Y. Sun, Stantec, USA

Abstract

Empirical correlations for estimating fines content from cone penetration test (CPT) data have traditionally been derived from various sites such as earth dams, road subgrades, and building foundations, encompassing a range of soil types. However, the applicability of these relationships to tailings facilities is limited due to the distinct mineralogy and behavior of slimes, fines, and coarse tailings compared to naturally deposited sandy, silty, and clayey soils found at typical sites. Consequently, there is a pressing need to develop tailored correlations specifically suited to the unique materials encountered in the tailings industry.

This paper addresses this gap by presenting a correlation developed from field data obtained through co-located CPTs and boreholes at a Holden tailings storage facility in Washington state. Artificial intelligence methods were employed to establish this correlation, utilizing laboratory-measured fines contents and CPT results. Specifically, genetic expression programming (GEP) techniques were employed to develop an equation based on data from 136 tested borehole samples.

The findings from our study underscore that the conventional empirical relationships tend to underestimate fines content, emphasizing the importance of tailoring correlations to the distinct characteristics of tailings dams. Comparison between the artificial intelligence method and traditional empirical relationships demonstrates that GEP yields more accurate estimations of fines content in tailings piles. The newly developed model offers a robust tool for predicting fines content from CPT data, facilitating improved characterization and management of tailings facilities.

Introduction

Traditionally, engineers use empirical correlations for estimating fines content from CPT data derived from various civil projects such as earth dams, road subgrades, and building foundations. These correlations,

which have been proposed by Davies (1999), Robertson and Wride (1998), and Suzuki et al. (1998), are well documented and encompass a wide range of soil types, such as sandy, silty, and clayey soils. However, the applicability of these correlations for tailings is limited due to the distinct mineralogy and behavior of slimes, fines, and coarse tailings, which differ significantly from naturally deposited soils (Russell et al., 2022).

Accurate estimation of fines content is necessary for deriving shear strength and liquefaction potential from standard CPT data, such as corrected equivalent penetration resistance in clean sand. Developing site-specific correlation can be very expensive for a project. It involves drilling numerous boreholes and conducting cone penetration tests (CPTs) in close proximity to establish a reliable relationship between laboratory test results from borehole samples and CPT data, such as cone resistance and friction ratio. This process can incur substantial costs due to the extensive fieldwork and analysis required. This paper presents a method to develop a site-specific correlation between CPT and fines content using genetic expression programming (GEP) techniques that is straightforward, reliable, and easily adapted to other sites. The GEP offers significant advantages over traditional statistical correlation methods. GEP excels at managing complex, high-dimensional data by automatically selecting and combining relevant features, which can uncover intricate, non-linear relationships that traditional methods might lack. This automatic feature selection and creation process simplifies the model-building effort and enhances predictive performance, especially in scenarios where interactions between variables are not straightforward (Koza, 1992).

The GEP technique was applied for a tailings pile characterization program for GISTM compliance at Rio Tinto's Holden legacy mine in Washington state. Artificial intelligence methods were employed to establish this correlation, utilizing laboratory-measured fines contents and CPT results. Specifically, genetic expression programming (GEP) techniques were employed to develop an equation based on data from 136 tested borehole samples. Using a traditional correlation underestimated the fines content in Holden tailings, which could result in unconservative shear strength and liquefaction potential.

The GEP technique provided a reliable site-specific correlation for Holden by leveraging laboratory-measured fines contents and CPT results to create a site-specific relationship between CPT and fines content. This paper provides a step-by-step process for using the GEP technique using data from 136 borehole samples at the Holden Mine site, in conjunction with co-located CPTs, employing Genetic Expression Programming (GEP) methods.

Site background and geotechnical data source

The Holden Mine is in north central Washington near Lake Chelan in the Cascade Mountain Range. The mine was owned and operated by the Howe Sound Company from 1937 until the cessation of mining activities in 1957. Processing of mine ores resulted in the construction of three tailings piles at the site's

TP-1, TP-2, and TP-3. These tailings piles were constructed using the upstream method with starter dams constructed with alluvial material, and are approximately 67, 120, and 84 feet high, respectively. The location of Holden Mine and the three tailings piles are shown in Figure 1.

Figure 1: Holden mine location and site general overview

Over the past 15 years, comprehensive geotechnical site investigations have been conducted on these three tailings piles to facilitate the closure of the tailings storage facilities, and more recently conformance to GISTM, as shown in Figure 2. Geotechnical investigation methods included cone penetration testing (CPT), sonic drilling, and mud rotary boreholes. The purpose of the recent investigations was to update tailings properties since reclamation was completed in 2016. Tailing properties were used for slope stability and deformation using critical state methods. An important component of critical state analyses is the accurate delineation of tailings layers with a narrow range of fine content since the critical state locus is sensitive to small changes in fines content (Jefferies and Been, 2016) for these layers.

The location of a total of 35 co-located CPTs and boreholes from the post-reclamation investigation is provided in Table 1. The average horizontal and vertical distances between these CPTs and boreholes were between 1 to 10 feet, providing data for developing the site-specific fines correlation. The particle size distribution for a total of 136 grab and in-situ samples from the bore holes and the soil behavior type index (Ic) parameter determined by the CPT were used to develop site-specific relationships for fine content estimation for CPT locations without borehole data.

Empirical relationships

Three common empirical relationships for estimating fine content from CPT data developed by Davies (1999), Robertson and Wride (1998), and Suzuki et al. (1998), predict the fines content based on the soil behavior type index (I_C) parameter in CPT, as shown in the equations below:

$$FC(\%) = 42.4179 \times I_C - 54.8574 \text{ (Davies, 1999)} \quad \text{(Equation 1)}$$

$$FC(\%) = 1.75 \times {I_C}^{3.25} - 3.7 \text{ (Robertson and Wride, 1998)} \quad \text{(Equation 2)}$$

$$FC(\%) = 2.8 \times {I_C}^{2.6} \text{ (Suzuki et al., 1998)} \quad \text{(Equation 3)}$$

Soil behavior type index (I_C) in CPT is estimated based on the normalized friction ratio (F_r) and normalized cone resistance (Q_t). To evaluate the applicability of these empirical relationships to tailings materials, we estimated the fine content from CPT data using these empirical relationships and compared them to laboratory data obtained from gradation tests, where the fine content was measured as the percentage passing the #200 sieve.

Figure 3 presents the estimated fine content based on the empirical relationships developed by Davies (1999), Robertson and Wride (1998), and Suzuki et al. (1998). The plots demonstrate that these well-known empirical correlations generally underestimate the fine content for these tailings materials.

Figure 4 shows the estimated fine content versus depth using the Robertson and Wride (1998) relationship. The plot reveals that underestimation of the fine content is more pronounced in the deeper portions of the tailings layers. Due to these discrepancies, it was necessary to develop a tailings-specific relationship based on the co-located CPT and borehole data to provide more accurate estimates for the fine content of the Holden tailings materials.

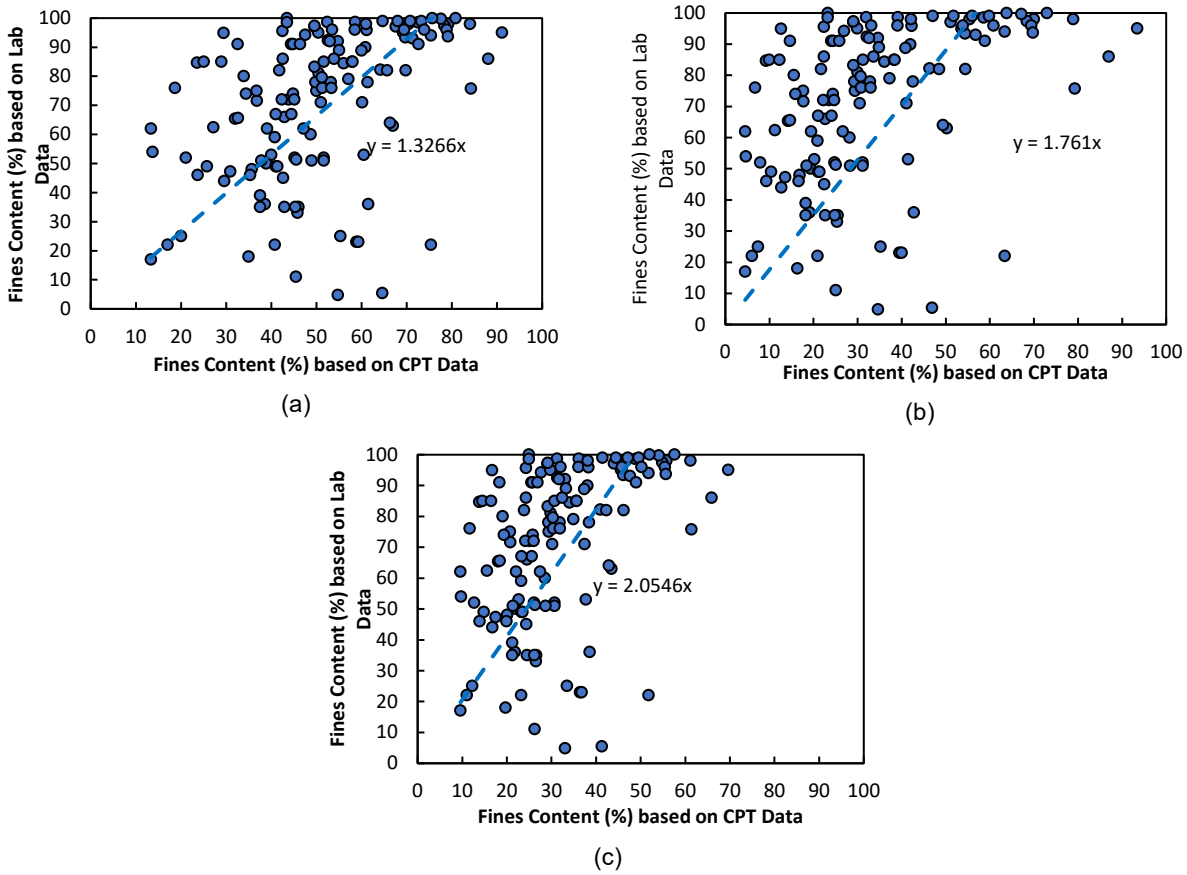

Figure 3: Estimated fines content based on the empirical relationships: (a) Davies (1999), (b) Robertson and Wride 1998, and (c) Suzuki et al. (1998)

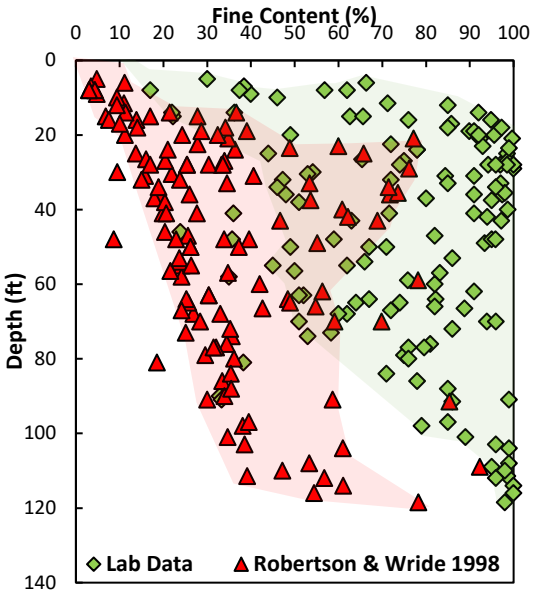

Figure 4: Comparison between laboratory data and estimated fines content from CPT data based on the Robertson and Wride (1998) relationship

Methodology

Genetic expression programming (GEP) techniques were employed to estimate fine content from CPT data based on data from the 136 borehole samples. GEP is a subfield of artificial intelligence that extends the principles of genetic algorithms (GAs) (Goldberg, 1989). GEP begins with an initial population consisting of randomly generated computer programs, represented as syntax trees, composed of functions and terminals suitable for the given problem domain. Functions encompass standard arithmetic operations, programming operations, mathematical functions, logical functions, and domain-specific functions. Terminals, on the other hand, represent constants or variables. Through a supervised trial and error process, the initial functions and terminals undergo adjustments to obtain refined functions and terminals that accurately estimate the desired output.

GEP, much like nature, is inherently a random process and cannot guarantee specific results. However, the stochastic nature of GEP enables it to escape traps that deterministic methods may encounter. This randomness has proven to be a key factor in the success of GEP, as it allows for the evolution of solutions to complex problems in a short amount of time.

In GEP, programs are commonly represented as syntax trees, as opposed to traditional lines of code. For instance, Figure 5 depicts a tree representation of the program "max(x + y, x - 6)," where x and y are independent variables, and 6 is a constant. In GEP, the leaves of the tree, such as variables and constants, are referred to as terminals, while the internal nodes, such as arithmetic operations and functions like "max," are called functions. The collective set of allowed functions and terminals forms the primitive set of a GEP system.

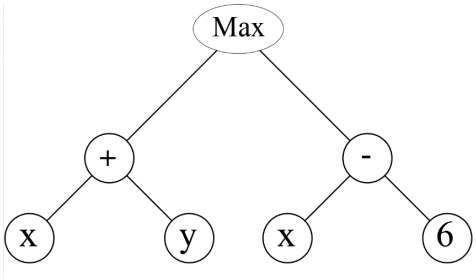

Figure 5: Representation of an expression tree in GEP ("Max" represents the maximum function)

Like other evolutionary algorithms, GEP involves the generation of an initial population of individuals, typically generated randomly. Various approaches exist for generating this initial population, including the full and grow methods, which are simpler and earlier techniques, as well as a widely used combination of the two, known as ramped half and half (Koza, 1992). Genetic operators in GEP, such as crossover and mutation, are applied to individuals who are probabilistically selected based on their fitness, as determined by the objective function.

GEP allows for the exploration of evolving novel solutions, and for addressing complex problems through adaptive and self-improving computational processes.

The advantage of GEP over other soft computing techniques (such as artificial neural networks and adaptive neuro fuzzy inference systems) is that GEP is not a black box and outputs are in the form of semi-complex mathematical solutions, which could be applied to the actual problems. The GEP approach is relatively new in the field of dam engineering, although some studies have been dedicated to their application recently (Rashidi et al, 2022; Yong et al, 2021). In this study the data set was divided into training (80%), and validation (20%) subsets to prevent overfitting. The performance of the testing set is an important step since it validates the accuracy and generalization capability of the model.

For the Holden tailing piles, two statistical evaluation criteria were used to assess the performance of the intelligent methods. These criteria are root mean square error (RMSE) and the determination coefficient (R^2), respectively, given by Equations 4 and 5.

$$RMSE = \sqrt{(\frac{1}{n}) \sum_{i=1}^{n} (a_i - p_i)^2} \quad \text{(Equation 4)}$$

$$R^2 = (\frac{\sum_{i=1}^{n} (p_i - \bar{p})(a_i - \bar{a})}{\sqrt{\sum_{i=1}^{n} (p_i - \bar{p})^2 (a_i - \bar{a})^2}})^2 \quad \text{(Equation 5)}$$

where a is the actual value and p is the predicted value, $\bar{a}$ and $\bar{p}$ are the mean of actual and predicted values, respectively. Evidently, a model with good performance (i.e., RMSE close to 0 or R^2 close to 1) will be the best model among several candidates.

Results and discussion

GEP was utilized to construct a prediction model for estimating the fines content from CPT data for tailings dams. The following equation (Equation 6) was developed using 136 data points based on two parameters of Q_t (normalized cone resistance) and F_r (normalized friction ratio) which are extracted from CPT data. We employed the parameters Q_t and F_r in developing this correlation due to their pivotal role in shaping the soil behavior type index. By incorporating these parameters, we were able to enhance the model's performance significantly for tailings materials, resulting in a robust and highly determinative coefficient of determination.

$$FC(\%) = 37.8 + \frac{2770}{51.5 + Q_t} + 5.62 \times \sin(2980 \times Q_t) + 16.5 \times \cos(0.0402 \times Q_t + \cos(2110 \times Q_t + \sin(F_r))) \quad \text{(Equation 6)}$$

For the estimation of fines content, out of the 136 sets of data, 109 sets of data (80%) were considered for training and the remaining 27 sets of the data (20%) were considered for validation. The training and

validation data sets were selected randomly from the database. Figure 6 shows the relationship between actual fines content and the predictions of GEP for Equation 6.

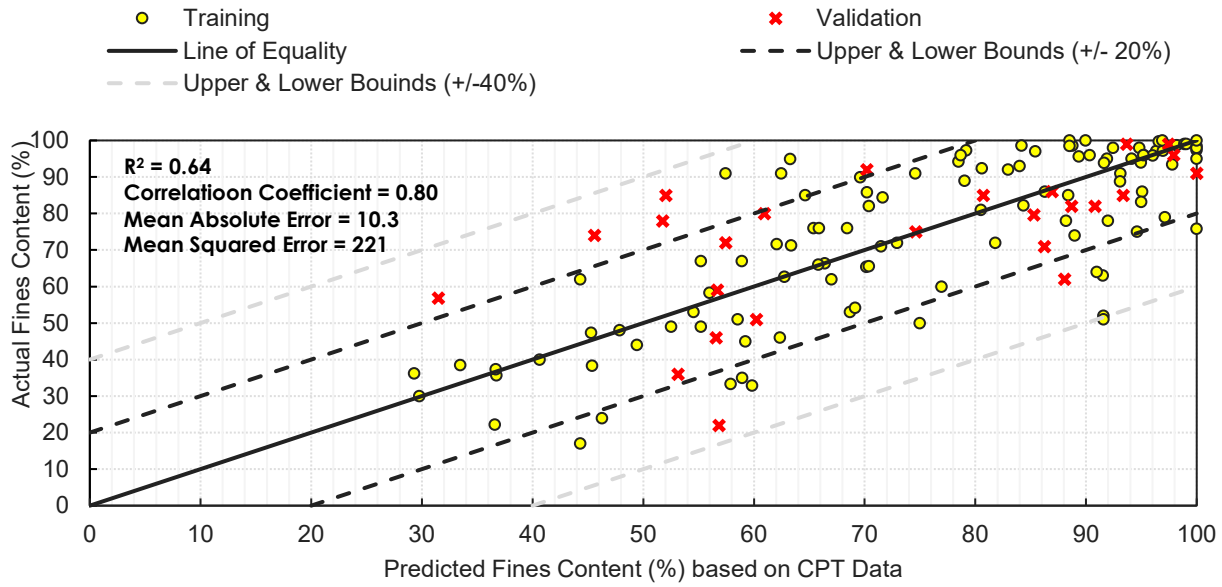

Figure 6: Coefficient of determination between the actual fines content and predictions of GEP model

After developing the GEP prediction model, the results were compared to the well-known empirical relationship noted by Robertson and Wride (1998) to examine the level of accuracy of the newly developed model compared to the traditional equations. Figures 7 and 8 illustrate the statistical results of the newly developed, tailings-specific model in comparison with the empirical relationship. This plot indicates the underestimation of fines content using the existing empirical relationship and its non-applicability for the prediction of fines content in the Holden mine site.

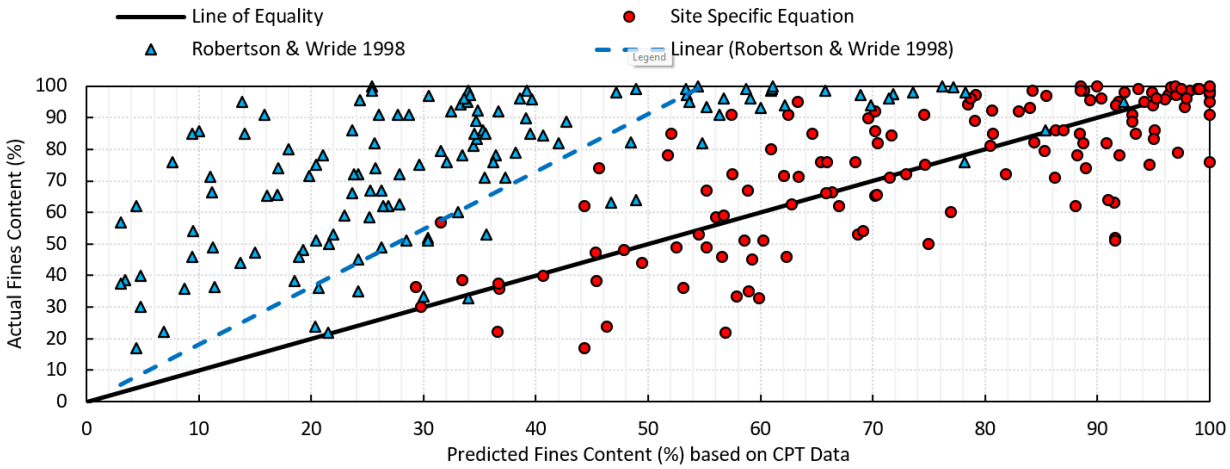

Figure 7: Comparing the actual fines content with tailings-specific model and experimental relationship

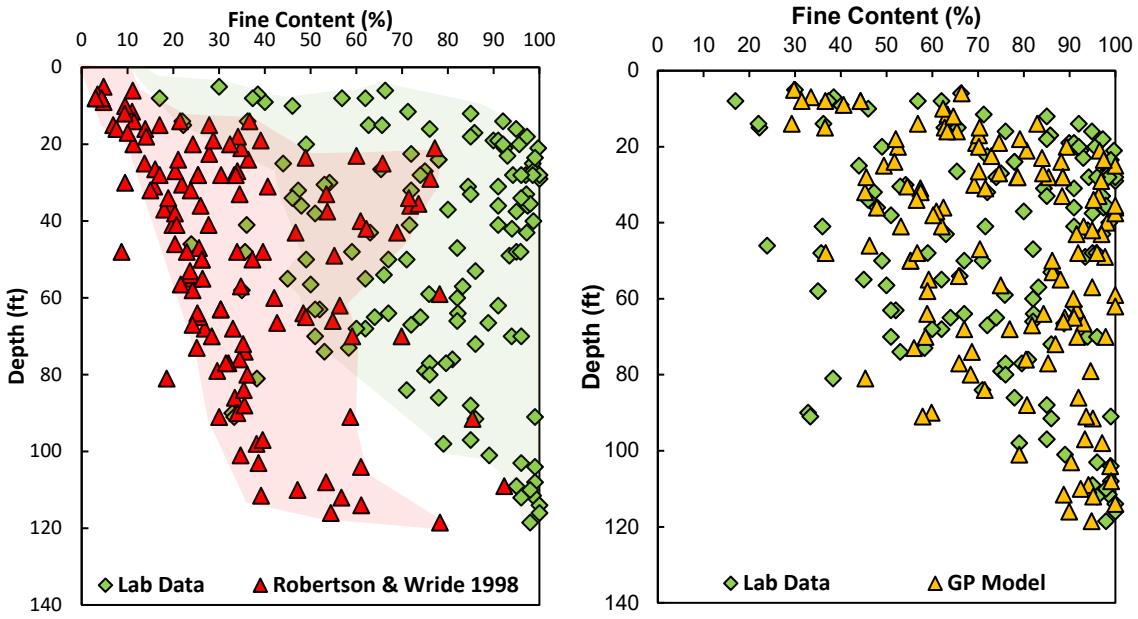

Figure 8: Comparison between laboratory data and estimated fines content from CPT data based on the Robertson and Wride (1998) relationship and the newly developed GEP model

Figure 9 illustrates a comparison of the prediction performance between the GEP models developed in this study and the empirical relationship proposed by Robertson and Wride (1998). The results obtained from comparing the artificial intelligent method and empirical relationships showed that GEP results appears to provide a more reasonable estimation of fines contents of tailings piles at Holden mine site. The newly developed model in this project is ready to be applied as a robust tool for prediction of fines content from CPT data for the Holden tailings piles.

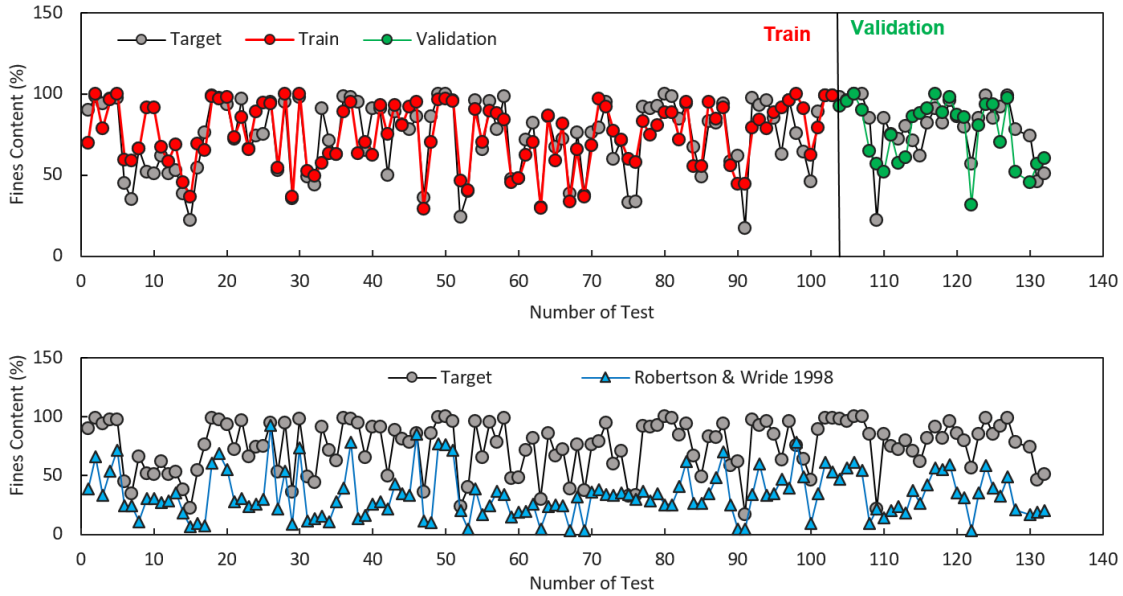

Figure 9: Comparing the actual fines content and predicted intelligent models

Figure 10 presents a cross-sectional view of the Holden tailings piles, illustrating the delineation of tailing layers based on estimated fines content from the GEP model. The plot reveals that tailings with higher fines content are located in the deeper sections of the piles (groups D and E, with fines contents exceeding 75%), whereas coarser tailings are found in the shallower zones (groups A, B, and C, with fine contents less than 75%). This distribution aligns with the historical deposition process at this site: fine tailings, discharged from the cyclone overflow, accumulate in the central parts of the piles, while coarse tailings from the cyclone underflow are deposited along the embankment face.

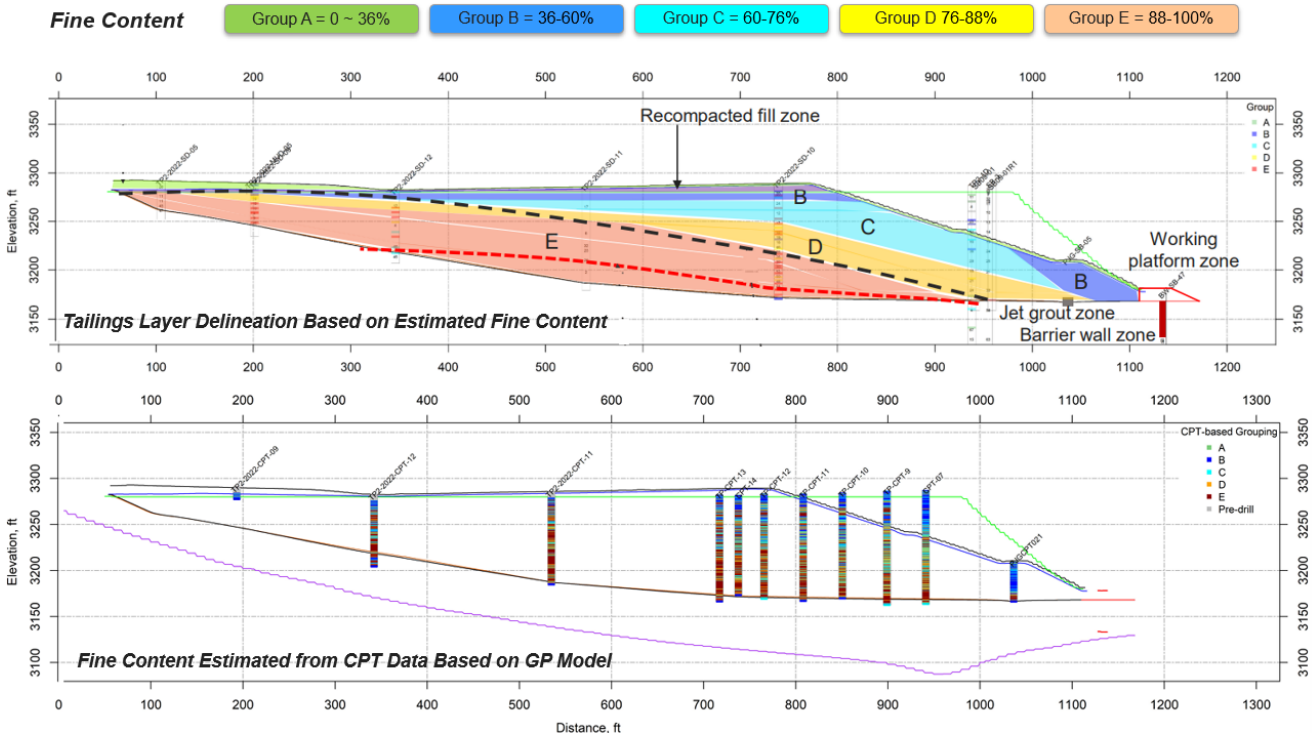

Figure 10: Tailings layer delineation using estimated fine content from GEP model

Conclusion

This study addressed the need for tailings-specific correlations to estimate fines content in tailings materials from CPT data. Conventional empirical correlations, derived from a range of soil types and conditions distinct from those found in tailings facilities, were shown to underestimate fines content at the Holden Mine tailings site. By employing GEP, a form of artificial intelligence, the study developed a robust correlation specifically for the Holden mine tailings. The newly developed model demonstrated superior accuracy in predicting fines content compared to traditional empirical relationships. Statistical evaluations showed the GEP model outperformed traditional methods, with lower RMSE and a higher coefficient of determination, indicating better accuracy and generalization capability.

The successful application of GEP in this context underscores the potential of artificial intelligence methods in geotechnical engineering, particularly for specialized materials like mine tailings. This paper paves the way for more precise and reliable geotechnical assessments, contributing to safer and more efficient tailings management practices and in achieving GISTM Compliance.

Acknowledgements

We extend our sincere gratitude to Rio Tinto for their invaluable support and approval to publish the data presented in this study. Their collaboration and willingness to share information have made a significant contribution to the advancement of knowledge in the mining industry.

Stacked Deposits of Filtered Fluid Fine Tailings Using Geotextile Tubes – Updates on Enhancing Chemical Stability

Fernando Da Silva, WSP Australia Pty Limited, Australia

Abstract

Stacked deposits of thickened and filtered fine tailings using geotextile tubes have the potential to improve tailings management, reducing geotechnical risk and the complexity of closure compared with traditional methods. To this end, previous work has demonstrated that geotextile tubes combined with a novel physicochemical treatment recipe is a feasible alternative approach for filtration and fines capture, accelerated dewatering and consolidation, and reinforcing the shear strength of the fluid fine tailings (FFT) deposits, facilitating reclamation and post-closure long-term safety performance (physical and chemical stability). In this paper, solids and water mass balance and concentration of the major ions (anions and cations) of the analyzed treated FFT within the geotextile tubes show that most ions remain bound in the solid phases, which increases flocculation efficiency. The solids retained inside the geotextile tube are considered captured solids, and the release water is considered process water. This water is used either for the same FFT management or routed into the mining process, since its chemistry, the pH and especially the divalent ion content (i.e., calcium) is kept unchanged, avoiding impacts on bitumen recovery (i.e., oil sands tailings). The outcomes of this study can be used to define the success of the physicochemical treatment recipe as an alternative technology to accelerate dewatering and consolidation, improving the physical and chemical stability of the treated FFT closure land-forms to facilitate reclamation, while opening the potential for further investigating carbon capture, which is linked to solids phase and carbonates precipitation.

Introduction

An important objective of effective tailings management is to protect the environment. Because the main pathway for contaminants is by water, the water balance is a very important element in any tailings management strategy. Mining companies, industry bodies, consulting companies, and regulators have been continuously improving best practice guidelines for the design, construction, and management of tailings facilities and mine-waste.

Dam safety revised practice does not accept the concept of a tolerable failure rate for tailings dams. This resulted in recommending the implementation of the best available tailings technology (BAT) based on principles for physical stability (PS) and chemical stability (CS). Principles for PS consider eliminating surface water from the impoundment; promote unsaturated conditions in the tailings with drainage provisions; and achieve dilatant conditions throughout the tailings deposit by compaction.

A key component for the design of tailings stacks is the degree of water saturation within the tailings profile established over the long-term. For example, tailings profiles with water saturation levels less than 85% are considered resistant to liquefaction. Conversely, tailings profiles with water saturation levels greater than 85% are considered resistant to oxygen diffusion. By including both PS and CS failure mechanisms, likelihood and consequences, one is better able to optimize the trade-offs between PS and CS measures to minimize overall risk.

The objectives of this study are to provide an understanding of the fundamentals of the FFT dispersion and flocculation behaviors, and the enhanced chemical stability of the treated FFT. These objectives will be achieved if the following supporting objectives are completed: (a) investigate how the chemistry and pH of the process water and FFT porewater, inherent properties of the FFT constituents, and zeta potential affect the dispersion and flocculation behaviors of the FFT; (b) investigate why thickening FFT with flocculant only is not enough to provide efficient fines agglomeration and dewatering of the FFT, and determine the gaps to be filled; (c) develop a physicochemical treatment recipe for FFT to assist solids-water separation, fines agglomeration with maximized capture, enhanced dewatering, and accelerated consolidation; (d) develop an inline mixing process of the FFT with the chemical treatment recipe (coagulation and flocculation) for effective flocculation prior to the discharge into the geotextile tube; (e) develop a solids and water mass balance of the treated FFT discharged into the geotextile tube, including concentration and mass of major anions and cations, to understand the solids captured inside the geotextile tube, and release water as process water either for use in the same FFT management or routed into the mining process; and (f) investigate additional benefits of the enhanced chemical stability of the solids captured into the geotextile tube, such as the potential for carbon capture, which is linked to solids phase and carbonates precipitation.

Lessons learned

Oil sands background

Mineable “oil sands” deposits are located relatively close to the surface, typically no more than 50 m deep. Once mined, oil sands are mixed with water to produce a pumpable slurry that can be gravity separated. After bitumen separation from the solids and water, coarse sand tailings (CST) and FFT are formed. The CST are separated from FFT by the hydro-cyclone overflow and settle on deposition to form tailings dikes

and beaches. The hydro-cyclone underflow is much of the water, residual bitumen and approximately 85% of the fines that form FFT (silts and clays). FFT are typically thickened with flocculant only, pumped to storage facilities where process water is recovered, and to form future deposits of mature fine tailings. Therefore, the inherent properties of the oil sands constituents and the oil sands extraction process collectively dictate the characteristics and mechanical properties of the FFT.

Key problems with long-term reclamation performance of the FFT deposits are related to a low rate of shear strength gain and long consolidation timeframes that pose significant challenges in converting FFT into deposits that can facilitate reclamation.

Gaps in assessing the physicochemical properties of the FFT still exist, including their dispersion and flocculation behaviors with regards to mineralogy, pore water chemistry, pH, and the mine extraction processes impacting the characteristics and mechanical properties of the FFT. This study will explain the potential causes of the significant amounts of trapped water when thickening FFT with flocculation only and will provide a rationale for the physicochemical treatment recipe to increase fines agglomeration and dewatering of the FFT.

Previous studies have shown that geotextile tubes are an innovative solution in engineering projects because of their ability to modify mechanical and hydraulic properties in a controlled manner. Additionally, the geotextile tube deposits with treated FFT will act more as a filter pressure system, with most of the water recovery happening while the geotextile tubes are being filled.

Key testing, materials, and methods

The identification and quantification of FFT mineralogy is considered “critical” for the successful manipulation of clay and non-clay mineral behaviors, along with porewater chemistry and pH. Bulk X-Ray Diffraction (XRD) analysis, elemental analysis by X-Ray Energy Dispersive Spectrometry (EDS) and Scanning Electron Microscopy (SEM) were performed to characterize the mineralogy of the FFT used in this study. Quantitative elemental analysis was performed by an Oxford INCA microanalysis system attached to a JEOL JSM-6610 scanning electron microscope.

All particles in suspension exhibit a zeta potential, or surface charge. The measurement and knowledge of the zeta potential is critical for optimizing processes, predicting particle stability and interactions, and as a simple method of flocculation quality control. The zeta potential is crucial in determining the stability of a colloidal suspension. When all particles have a large negative or large positive charge, they will repel each other, and the suspension will be stable. The higher the value (positive or negative), the more stable the colloid dispersion is. If the zeta potential is low, the tendency for flocculation is higher. Another important consideration when discussing zeta potential is pH; in fact, quoting a zeta potential without considering pH is nearly meaningless. For suspensions of most materials, a plot of zeta

potential versus pH exhibits an isoelectric point, which is the pH where the net charge on the particles is zero. At this point, the suspension is highly unstable, and flocculation is most likely to occur.

The FFT slurry density, specific gravity, water content, and bulk and dry densities were determined to characterize the tailings and evaluate coagulant and flocculant dosages and concentrations.

Particle Size Distribution (PSD) was obtained by sieve and hydrometer method (SH), as per ASTM D422-63. The SH was carried out with the variant of "dirty" hydrometer dispersed (bitumen as-is).

Dilution was applied to control variations of the feed densities if the initial slurry density by mass was higher than 20%. FFT at initial slurry density by mass of 20% provided enhanced mixing and maximized flocculant adsorption at relatively low dosages.

Coagulation was applied prior to flocculation to efficiently neutralize the electrostatic charges of particles (mainly quartz and kaolinite) and reduce repulsion between them. The coagulant solution was prepared using Alum and process water. Flocculant solution was prepared using anionic polyacrylamide (PAM) flocculant and process water.

FFT was coagulated with Alum at concentration 0.1% and dosage 0.65% (by mass) of dry solids, prior to flocculation with 30% charge high molecular weight (HMW) anionic PAM flocculant at concentration 0.1% and dosage 0.1% (by mass) of dry solids.

Settling tests were carried out to evaluate the initial dewatering performance of the physicochemical treatment recipe applied to FFT inline prior to the discharge into the geotextile tube.

This study summarizes results of a parametric analysis of the FFT dispersion and flocculation behaviors, Da Silva (2022), to investigate the causes and manners of why significant amounts of trapped water remain in the flocculated FFT. The findings and recommendations, supported by facts observed in the laboratory are also included. A pure kaolinite powder (≤ 2 μm size) and pure quartz flour (≤75 μm size) were used for laboratory bench scale observations of their individual and combined behaviors. This observational method focused on the dispersion and flocculation behaviors of quartz and kaolinite suspensions as a function of pH, hydrolyzed salts (calcium and aluminum), and anionic PAM flocculant.

The chemical analyses performed in this study focused on the interaction between the mineral composition (i.e., FFT mineralogy) and pore water chemistry (i.e., pore solution electrolytes, ion concentrations, and pH) with the aim of understanding their significant influence on FFT dispersion and flocculation behaviors. Routine chemical analyses were necessary for characterization of the ion concentrations and pH of the FFT pore water, plant process water, and release water from the treated FFT that can be used as recycle water (FFT management and mining process). In addition to pH, the key component of the FFT pore water chemistry is the calcium content due to its significant impact on the flocculation behavior of the FFT.

Inherent properties, soil characterization, pore water chemistry and zeta potential

Mineralogy is the primary factor that controls the size, shape, and properties of soil particles. These same factors determine the possible ranges of physical and chemical properties of any given soil. A prior knowledge of what minerals are in a soil provides intuitive insight as to its behavior (Mitchell, 2005).

The XRD analysis of the original FFT shows the crystalline components of the sample consist of kaolinite, 52.35; quartz, 40.1%; illite, 4.6%; microcline, 1.3%; albite, 0.7%; siderite, 0.8%; and rutile; 0.2%.

Quartz is a non-clay mineral within the fine particle size fraction of the FFT in this study. At pH > 2, quartz particles possess negatively charged surface, show dispersive behavior and are more hydrophilic (van Lierde, 1980), (Hunter, 1981), (Hussain et al., 1996), and (Gan and Liu, 2008). The reason for this behavior is that the particle surface reacts with water, forming silicic acid, which in turn dissociates to form a silicic anion at the surface and a hydrogen (H^+) ion that diffuses off into the solution. This chain of events negatively charges the particle surface as the diffusing H^+ carries away a positive charge and leaves a negative charge behind.

Kaolinite is a clay mineral and has negatively charged surface at pH >2 (Goldberg et al., 1991). The illite is a non-swelling clay mineral in nature and has a lower cation exchange capacity than kaolinite.

The elemental analysis by EDS of the original FFT of this study shows Oxygen (O) and silicon (Si) dominate the elemental spectrograph, respectively forming approximately 54.92 wt.% and 23.05 wt.% of the sample. Aluminum (Al) is common, forming approximately 9.42 wt.%. Carbon (C) as non-crystalline oxygen-bearing compound was measured at 6.96 wt.%, as shown in Table 1 and Figure 1.

Table 1: Elemental composition by EDS of the original FFT of this study

Sample ID	H	C	N	O	Na	Mg	Al	Si	S	Cl	K	Ca	Ti	Mn	Fe	Cu
Original FFT	–	6.96	–	54.92	0.21	0.21	9.42	23.05	0.27	0.04	1.84	0.31	0.41	0.03	2.01	0.27

H – Hydrogen	Mg – Magnesium	K – Potassium	Cu – Copper
C – Carbon	Al – Aluminum	Ca – Calcium	
N – Nitrogen	Si – Silicon	Ti – Titanium	
O – Oxygen	S – Sulphur	Mn – Manganese	
Na – Sodium	Cl – Chlorine	Fe – Iron	

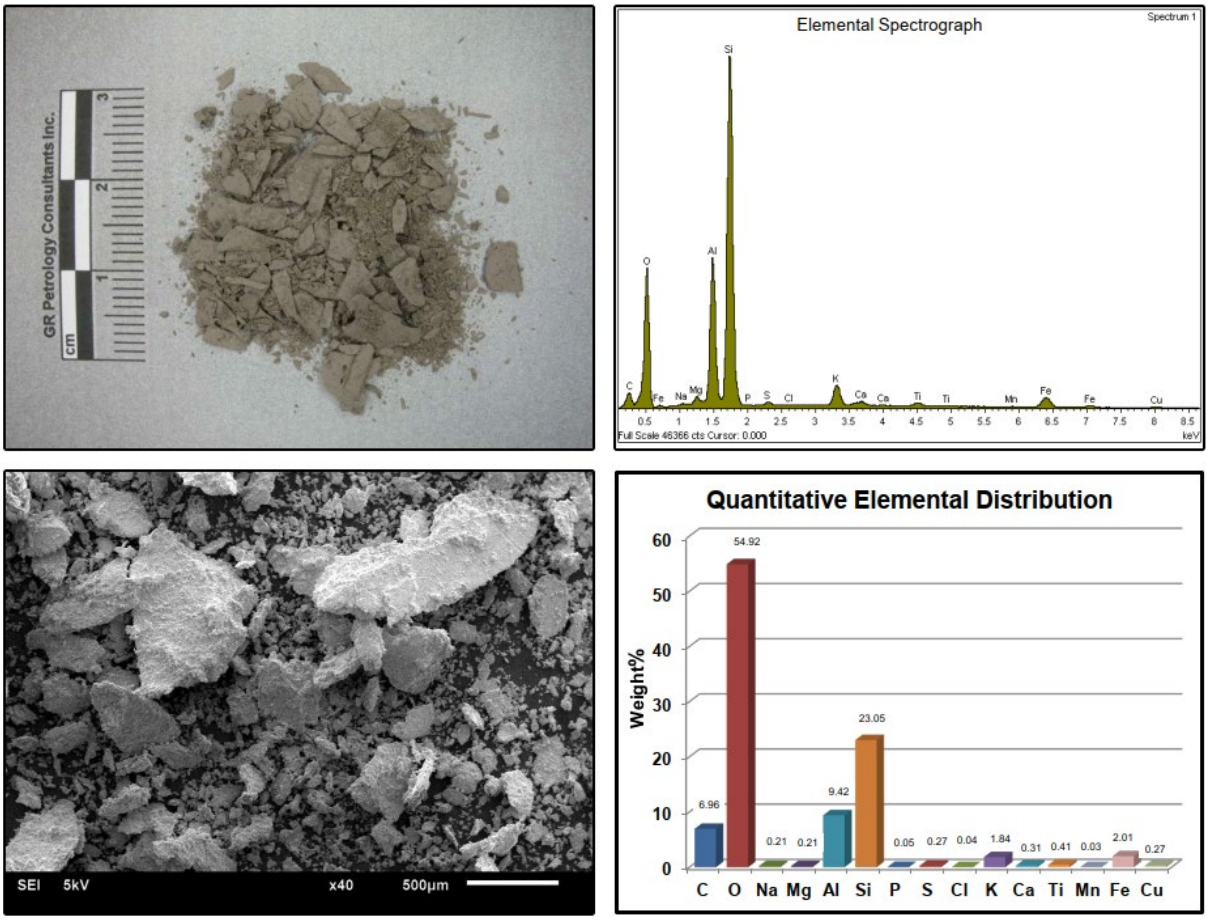

Figure 1: Quantitative elemental distribution, spectrograph and scanning electron microscopy analyses of the original FFT of this study

The PSD results of the analyzed original FFT is consistent with the results from the mineralogy analysis of this study. It should also be noted that the measured solids specific gravity is 2.5 and solids content by mass vary between 15 and 39%. The original FFT porewater chemistry contains 47 ppm calcium ions and process reclaim water contains 86 ppm calcium ions (high calcium concentration). The original FFT has a measured zeta potential -47 mV at porewater pH 8.

The XRD analysis of the treated FFT shows the crystalline components of the sample consist of kaolinite, 30.8%; quartz, 41.2%; illite, 9.6%; microcline, 2.1%; albite, 1.3%; siderite, 3.9%; greigite, 3.1%; pyrite, 1.2%; anatase, 1.7; rutile 0.8%; halite, 1.6%; tenorite, 1.2%; dolomite, 0.8%; and calcite, 0.7%.

The EDS results of the treated FFT show Oxygen (O) and silicon (Si) dominate the elemental spectrograph, respectively forming approximately 51.75 wt.% and 18.93 wt.% of the sample. Aluminum (Al) is common, forming approximately 10.61 wt.% of the sample. Carbon (C) as non-crystalline carbon oxygen-bearing compounds is approximately 12.60 wt.% which compared to the original FFT sample

suggests that 80% of the carbon oxygen-bearing compounds were transferred to the solid phase of the treated FFT, as shown in Figure 2 and Table 2.

These findings are very encouraging and suggest the potential for carbon capture, which is linked to solids phase and carbonates precipitation. Transition metal carbonate and bicarbonate complexes are coordination compounds containing carbonate (CO_3^{2-}) and bicarbonate (HCO_3^-) as ligands.

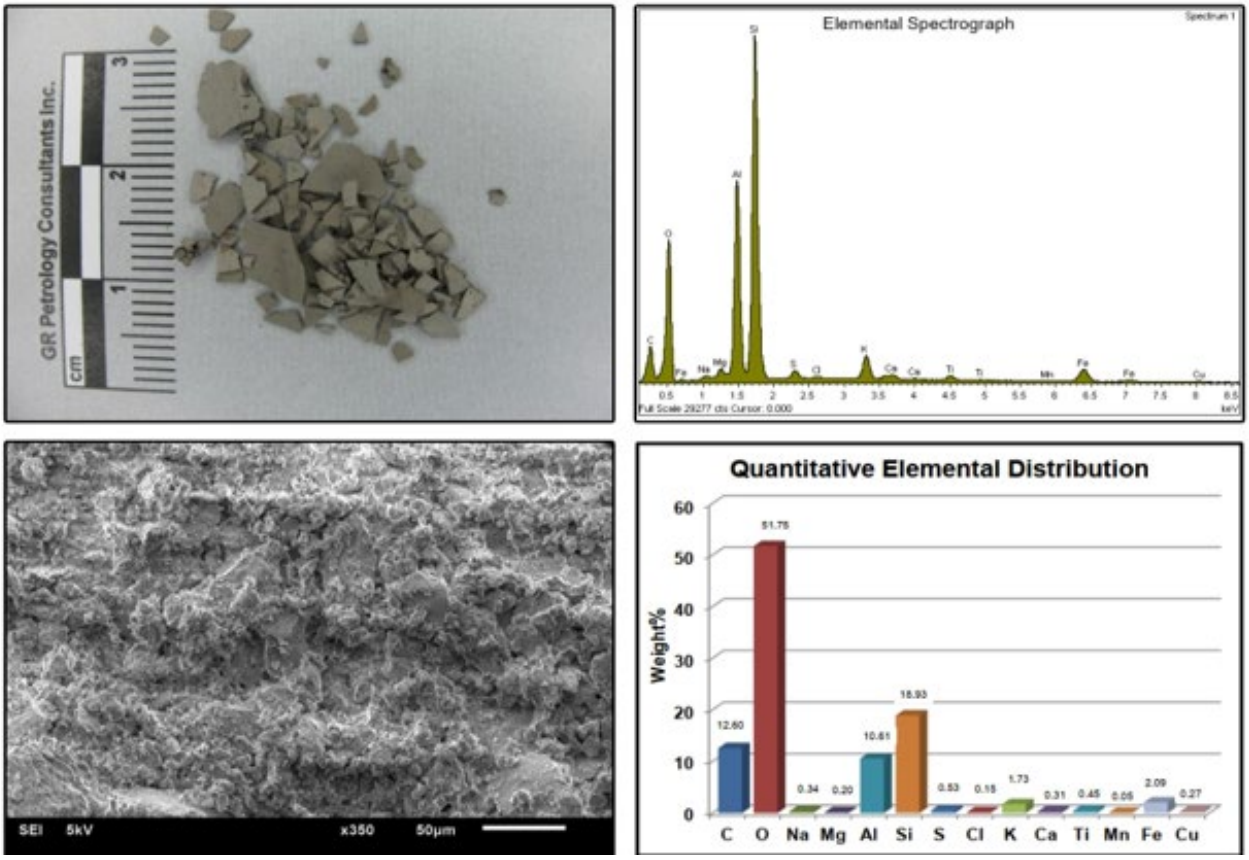

Figure 2: Quantitative elemental distribution, spectrograph and scanning electron microscopy analyses of the treated FFT of this study

The PSD of the analyzed treated FFT is consistent with the results from the mineralogy analysis of this study.

The treated FFT released water contains 86 ppm calcium ions which means the same concentration of the reclaimed water used for the process, showing no increase in calcium ions. The treated FFT measured zeta potential is -17 mV at porewater pH 8.

Coagulation and flocculation behaviors of the FFT

The objective of the physicochemical treatment recipe is to maximize fines capture, enhance dewatering, accelerate consolidation, increase shear strength, and maintain the integrity of the aggregate to ensure that fines segregation does not occur.

Maintaining the initial slurry density of the original FFT at 20 wt.% solids was part of the methodology to control variations of the feed densities while maintaining unaltered coagulant and flocculant dosages.

The measured average properties of the original FFT of this study were solids specific gravity, 2.50; water content (geotechnical), 360.0%; solids content, 20 wt.% solids; total bulk density, 1.15 t/m^3; dry density, 0.25 t/m^3; and void ratio of 9. These initial properties are fundamental for the design of the physicochemical treatment recipe, including flocculant and coagulant dosages and concentrations and release water volumes.

The results of the treated FFT obtained immediately after the geotextile tubes were completed (filled up to the specified maximum height by the manufacturer), were solids specific gravity, 2.48; water content, 86.9%; solids content, 53.6 wt.% solids; total bulk density, 1.47 t/m^3; dry density, 0.79 t/m^3; and void ratio, 2.16. The laboratory and field test results indicated that the treated FFT was dewatered in the geotextile tubes during filling, providing significantly enhanced fines capture as indicated by its dry density and void ratio. Unified Soil Classification System (USCS) classification was CH, the liquid limit was 76.8%, the plastic limit was 29.0%, and the liquid index was 47.8%.

A rigorous control of the original FFT slurry density intake was part of the inline mixing process of the physicochemical treatment recipe to provide the required amount of dilution water (reclaim process water) for adjustment of the initial slurry density to 20 wt.% solids if it was higher than 20 wt.% solids.

Quartz particles at pH > 2 are dispersed by action of electrostatic repulsive forces. These forces are affected by the ionic strength of the soil-water-ionized system, which depends on the pore solution electrolyte concentration and ion types (Verwey and Overbeek, 1948). In the presence of high valence cations, such as aluminum, the repulsive forces of quartz particles are reduced, resulting in the coagulation of particles. The mechanism of coagulation effectively lowers the electrostatic repulsive forces between

particles causing charge neutralization and the formation of stable micro-flocs (slow-settling flocs). Charge neutralization is equivalent to compressing the diffuse double ionic layer energy barrier (i.e., reducing the double ionic layer charge to near zero). It was observed in this study that at pH 8, quartz particles showed poor flocculation performance in the presence of calcium at concentrations of 40 and 72 ppm and anionic PAM flocculant. This observation confirms that as Ca^{2+} ions are predominant they influence the behavior of the anionic PAM flocculant. Calcium ions can be adsorbed onto the COO− functional groups of the anionic PAM flocculant to form $(–COO)_2Ca$. $CaOH^+$ may also be adsorbed onto $–COO^-$ functional groups to form (–COO)Ca(OH). As the concentration of calcium increases, more Ca^{2+} ions are available to adsorb onto the anionic PAM flocculant; however, when in excess, these Ca^{2+} ions are partially attracted as counter-ions in the double layer of the adsorbed anionic flocculant chains, causing steric stabilization at the particle surface. Steric stabilization results from covering the particles with the anionic flocculant, preventing the particles from getting close to the range of attractive forces and thereby allowing quartz particles to be dispersed. It was also observed in this study that the impact of excess calcium at pH 8 on the flocculation of quartz can be reversed with the addition of metal salts of a higher valence than calcium, such as aluminum ions.

While kaolinite surfaces are negatively charged in media such as water, they exhibit positive surface charge characteristics at pH < 3 in the solution of calcium ions, and at pH 9.2 in the solution of aluminum ions, as shown in Figure 3 (Peng and Di., 1994). However, in solution of aluminum ions, the zeta potential decreases from +30 to -7 mV as the pH increases from 3 to 10 with a point-of-zero charge at pH 9.2. In contrast, kaolinite maintains close to a constant value of zeta potential -15 mV at pH 4 or higher in the presence of calcium ions; as pH decreases below 4, zeta potential increases passing by a point-of-zero-charge (PZC) at pH 3, approximately, as showing in Figure 3. Calcium alone has a small effect on kaolinite coagulation (Atesok et al., 1988).

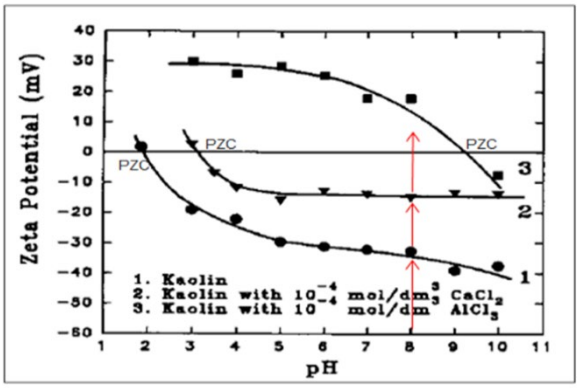

Figure3: Zeta potential of kaolinite particles vs. pH adopted from Peng and Di (1994)

An excess of hydrolyzed metal ions (i.e., aluminum) used to coagulate negative charged particles of kaolinite might cause the reversal of double layer charge and lead to a stable suspension with positive

double layer charge which could suppress the kaolinite flocculation process (Matijevic et al., 1966), as also showing in Figure 3. Increasing pH causes the hydroxyl ion to react with the kaolinite surface, which will make the zeta potential more negative. Sulfate and bicarbonate ions can also adsorb on the kaolinite surface and make zeta potential more negative. The suggested adsorption mechanism of anionic PAM flocculant on kaolinite is by hydrogen bonding. However, it is possible for anionic PAM flocculant to be attracted to the positively charged sites of kaolinite by electrostatic attraction (Peng and Di, 1994). Precipitation of calcium hydroxyl on the kaolinite surface covers up the active function groups, which prevent the formation of hydrogen bonding between kaolinite and anionic PAM flocculant.

Supported by facts observed in the laboratory a parametric analysis on of the coagulation and flocculation behaviors of the FFT was performed by Da Silva (2022). A pure kaolinite powder (≤ 2 µm size) and pure quartz flour (≤ 75 µm size) were used to observe the dispersion and flocculation behaviors of kaolinite and quartz suspensions as a function of pH, hydrolyzed salts (i.e., calcium and aluminum hydrolyzed metal ions), and anionic PAM flocculant.

The parametric analysis has shown that both quartz and kaolinite particles have similar issues regarding the adsorption of anionic PAM flocculant due to pH, and that the presence of an excess of Ca^{2+} ions could cause their poor flocculation at pH 8 with flocculant only. In addition, the parametric analysis has shown that the impact on the flocculation of quartz and kaolinite, caused by an excess of Ca^{2+} ions at pH 8, can be reversed by addition of metal salts of higher valence than calcium, such as aluminum ions.

Photograph 1 shows an efficient flocculation of the treated FFT (quartz and kaolinite) at initial slurry density 20 wt.% solids, coagulated with 0.1% aluminum ions concentration at a 0.65% dosage (by mass of dry solids), prior to flocculation with medium charge density HMW anionic PAM flocculant at concentration of 0.1% and dosage of 0.1% (by mass of dry solids).

Solids, water and chemical mass balance calculations for dewatering the treated FFT within geotextile tubes

The simplified process flow diagram of an actual field trial, shown in Figure 4, refers to the original FFT treated inline by coagulation and flocculation prior to the discharge into geotextile tubes.

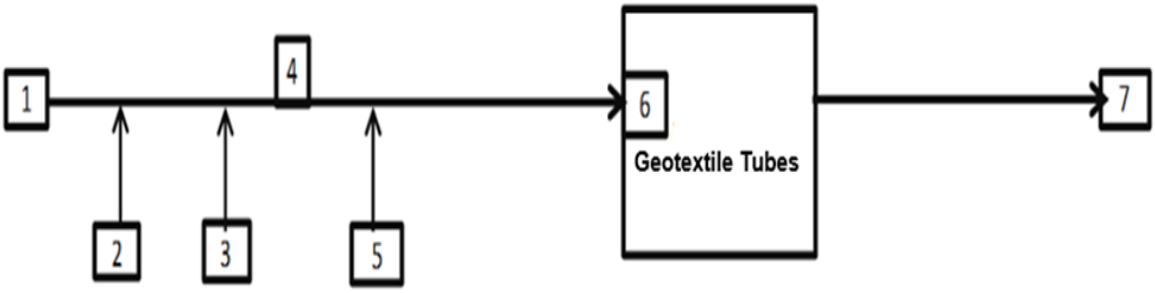

Figure 4: Simplified process flow diagram of the treated FFT inline, sampling, discharged into geotextile tubes and monitoring of the released water

Definitions of the streams and sampling points

- Stream #1 is the original FFT Stream.
- Stream #2 is the process water used to dilute FFT to 20 wt.% solids (as the original FFT is > 20 wt.% solids).
- Stream #3 is the coagulant addition using Alum to coagulate the diluted FFT inline.
- Node #4 is a sampling point where samples are taken periodically to measure the wt.% solids and to analyze the chemical components of the aqueous phase (including major cations and anions).
- Stream #5 is the flocculant addition using anionic PAM flocculant to flocculate the coagulated FFT inline.
- Node #6 is the sampling point right at the discharge of the treated FFT inline into geotextile tubes where samples are collected to measure the wt.% solids and to analyze the chemical components of the aqueous phase (including major cations and anions).
- Stream #7 is the release water from the geotextile tubes where samples are collected to analyze the chemical components of the release water (including major cations and anions).

Between Node #6 and Stream #7, solid core samples are retrieved from the geotextile tubes and analyzed for wt.% solids, pore water chemistry, and in-situ and laboratory shear strength of the deposit. The analyzed volume of each stream is presented in Table 3.

Table 3: Volume of each stream used in the field trial

Stream/ Node #	Stream/Node description	Slurry volume (m^3)	Wt.% solids
1	Original FFT Stream	12.0	28.0
2	Dilution water stream (process water)	5.0	0.00
3	Coagulant stream (Alum solution)	27.0	0.00
4	Coagulated FFT sampling (node # 4)	44.0	8.70
5	Flocculant stream (anionic PAM solution)	4.4	0.00
6	Flocculated FFT (stream/node = Treated FFT discharge into geotextile tubes and sampling)	48.0	8.00

Solid and water mass balance calculations

In this field trial, the easily measured parameter was to record the volume of each stream used to fill the geotextile tube and take grab samples at predefined points such as Node #4 (before flocculation addition) and Stream/Node #6 (at the discharge into geotextile tube). The first basic step in a mass balance is to calculate the volume of solids and fluids in the slurry following the process flow diagram of the Figure 4, and then convert these volumes into mass using the specific gravity of the solids and liquid in the streams.

- Solid mass fraction conversion.

Stream #1 was analyzed for wt.% solids, slurry bulk density, and solids specific gravity. The rest of the streams were measured for wt.% solids and water during the trial period. The average values of the measured parameters of the Stream #1 were:

- Bulk density = 1.2 t/m^3
- Solids content = 28 wt.% solids
- Specific gravity of solids = 2.5

To conduct a mass balance on the water and solids contents in the slurry in each stream, the first approach was to convert all the solids in the streams to a volumetric basis so that the volume of water (refer to as fluid phase volume) in the FFT slurry can be accurately calculated. The following correlation was used:

$$\emptyset_{sl,v} = \frac{1}{1 + SG_s\left(\frac{1}{\emptyset_{sl,m}} - 1\right)} \ldots\ldots (1)$$

where:

$ø_{s,l,v}$ = solids content of the FFT slurry on a volumetric basis

$ø_{sl,m}$ = solids content of the FFT slurry on a mass basis = 28 wt.% solids (for Stream #1)

SGs = specific gravity of solids of the FFT slurry = 2.5 (for solids in Stream #1)

From the correlation (1) the solids content of the FFT slurry on volumetric basis were 13.5%. This means 28 wt.% solids represent 13.5% of the slurry volume in the FFT slurry. Therefore, in 12 m^3 of FFT slurry, the solids volume based on the above correlation will be (13.5% × 12 m^3) = 1.62 m^3. Other input streams do not have solids; therefore, their volumetric representation will remain unchanged. Specific gravity of other streams (fluid phase) is considered as that of water. The mass of any phase (solid or fluid/water) in a stream is the product of specific gravity and volume of that phase. Percent mass representation of any phase (solid or fluid/water) in any stream is fraction of a phase in the total stream mass multiplied by 100. The fundamental principle in mass balance is conservation of mass if something is not measured or known.

Inline flocculation mass balance on solids

Table 4 represents a complete mass balance for solids when the original FFT was added inline and then discharged into the geotextile tube after the inline treatment with coagulation and flocculation. Once the flocculated FFT is released into geotextile tube, the mass in the tube will change with time through the release of the water; because of this change, a separate mass balance is presented in the following section.

Errors in the field-measured data can be back-checked with the calculated mass balance as shown in Table 4; for example, the sum of all the masses from Streams #1 to #3 must be equal to the mass measured at Node #4. In addition, the subtotal mass Node #4 + Stream #5 must be equal to the mass measured at Node #6. If this is not true, then there are errors in the field measurements or in the calculations. The mass balance results in Table 4 do not have any errors with respect to the field measurement at Nodes #4 and #6.

Table 4: Solid and water mass balance (inline)

Stream/ Node #	Stream/node description	Volume (m^3)			Specific gravity		Mass (T)		Wt.% Solid	Wt.% Fluid
		Slurry	Fluid	Solid	Solids	Fluid	Solids	Fluid		
1	Original FFT	12.0	10.38	1.62	2.5	1.0	4.04	10.38	28.0	72.0
2	Dilution with process water	5.0	5.00	0.00		1.0	0.00	5.00	20.8	79.2
3	Alum solution	27.0	27.00	0.00		1.0	0.00	27.00	8.7	91.3
Subtotal	**(1 +2 + 3)**	**44.0**	**42.38**	**1.62**			**4.04**	**42.38**	**8.7**	**91.3**
4	Coagulated FFT	44.0	42.38	1.62	2.5	1.0	4.04	42.38	8.7	91.3
5	Flocculant	4.0	4.0	0.00		1.0	0.00	4.00	8.0	92.0
Subtotal	**4 + 5**	**48.0**	**46.38**	**1.62**			**4.04**	**46.38**	**8.0**	**92.0**
6	Flocculated FFT	48.0	46.38	1.62	2.5	1.0	4.04	46.38	8.0	92.0
		Errors in mass balance					**0.00**	**0.00**	**–**	**–**

By carefully reviewing the mass balance, it can be concluded that at the start of this process, the solids fraction of the original FFT Stream #1 was 28 wt.% solids, which was diluted down to 8 wt.% solids at the stage of flocculant addition. This changes the volume of the fluid from 10.38 m^3 to 46.38 m^3, representing 4.5 times additional water that needs to be handled at the front and back-end of the process, in addition to the water in the original FFT.

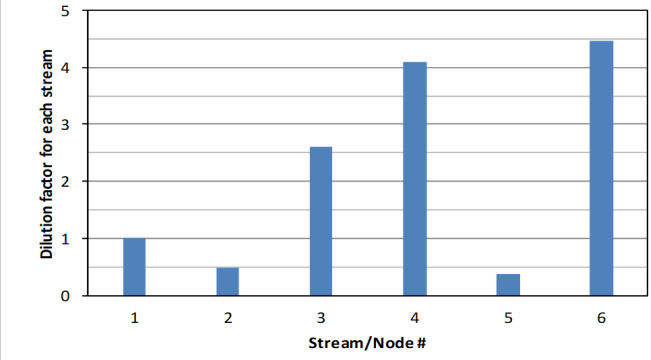

Figure 5: Relative water volume after every stream addition to the process

Figure 5 shows the cumulative water added during the process with respect to unit water volume in original FFT Stream #1. Stream #2, dilution of the original FFT with additional water, is only required if the original FFT solids content is higher than 20 wt.% solids. Streams 3 and 5 are waters from the coagulation and flocculant solutions. Nodes #4 and #6 are measurements (monitoring) points. This analysis is important because the proposed treatment in this study will be utilizing existing tailings lines and therefore, it is necessary to evaluate if there will be any issues with infrastructure regarding sizing of the water management systems.

Balance after deposition in the geotextile tubes

Once the treated FFT was poured into the geotextile tube, instantaneous dewatering was observed. However, it will be extremely difficult, although not impossible, to measure the exact volume of water released by collecting in a sump to avoid seepage losses. In this trial, the volume of the water released from the geotextile tube was not measured. During the pour, the water split into two parts: the volume of water retained inside the geotextile tube and water released from the geotextile tube. This split of water reported in Table 5 is an indirect measurement (back calculated).

In the trial program, core samples were collected from the geotextile tubes for solids and water analysis. Porewater chemistry was also analyzed from the core samples. Grab samples were collected from the release water and analyzed for chemistry. Four key data points were selected to evaluate the dewatering and solids consolidation into the geotextile tubes. The mass of release water was calculated using the difference between the starting mass of water and the residual from the core sample. Since the density of

water is unity, the mass for water reported can be interpreted as volume (m^3) of water. Table 5 shows the solid/water mass balance of the core samples collected from the geotextile tube at different time intervals.

Calculations in Table 5 reveal most of the dewatering from the geotextile tubes occurs during the first five hours after deposition, which may be attributed to the release of the dilution waters added to the original FFT feed. The solids content after the first five hours of deposition is approximately 27 wt.% solids, which is close to that of the original FFT used in the trial. Next, core samples were collected from the geotextile tube after 7 and 30 days, which had 50 wt.% and 55 wt.% solids, respectively. A comparison of the results from the end-of-pipe and after five hours with the 7-day samples shows that there is a significant initial increase in dewatering from 8 wt.% to 50 wt.% solids.

Table 5: Solid and water mass balance on the core samples from the geotextile tube

Stream/ Node #	Stream Node description	Mass (T)				% Mass in tubes		Cum. wt.% water release	Drying time (days)
		Solid	Water in /tube	Cum. Water release	Total	Solid	Water		
6	Flocculated FFT	4.04	46.38	0.00	50.42	8.0	92.0	0.00	0.0
Inside Tube	5 hours after tube filled	4.04	10.88	35.50	50.42	27.0	73.0	76.54	0.2
	7 days after tube filled	4.04	4.08	42.30	50.42	50.0	50.0	91.20	7.0
	30 days after tube filled	4.04	3.3	43.08	50.42	55.0	45.0	92.88	30.0

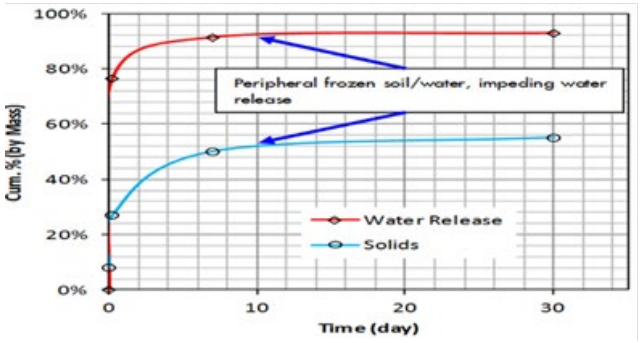

Figure 6: Variation in wt.% solids content and mass of water released within 30 days after deposition (Nov. 3rd = time zero)

Figure 6 shows a summary of the dewatering of the treated FFT poured into the geotextile tube as a function of time. After 30 days, the sample does not show a change in dewatering kinetics because of the physical limitation to dewatering caused by the peripheral frozen soil/pore water that impedes water release during wintertime (freeze condition).

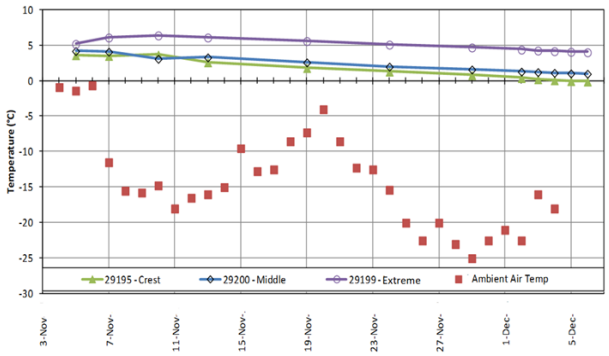

Figure 7: Temperature measurements inside the geotextile tube and outside (ambient)

Figure 7 shows the temperature measurements inside and outside (ambient temperature) the geotextile tube from November 3rd (the day when the geotextile tube was completed) to December 5th (± 30 days after the tube was filled completely with treated FFT). Additional water release will likely occur during the "thaw" cycle of the freeze-thaw process during the spring season as freeze/thaw is a well-known dewatering process for shallow fine tailings deposits.

Chemistry balance calculations

The original FFT consist of approximately 70% by mass water which is a major constituent. To ensure that the recovered water is suitable for reuse in the process as a process water, it is important to analyze the chemistry of the recovered water. It becomes more crucial when chemical treatment (coagulation and flocculation) is used to separate the solids and water in the FFT. Chemicals used in coagulation and flocculation may poses reactivity with the solid surface where different anions and cations are released from the solid minerals in the FFT. The best way to understand the chemistry of the released water is to perform an anions and cations balance analysis where sum of all cations mass should be equal to the sum of all anions mass to maintain a charge neutrality in the aqueous phase. This makes the entire chemistry balance analysis more complex. However, for indicative purposes concentration analysis and mass balance of major cations and anions will provide predictions on the reactive behaviors in the FFT when chemically treated and suitability of the released water as a process water.

The chemical analyses of the mixed inline streams and the release water from the geotextile tube show changes in the chemistry throughout the treatment process. Process water containing high concentrations of dissolved divalent cations (Ca^{2+} ions), was used to investigate their impacts on the flocculation of quartz and kaolinite at pH 8.

The mass balance and concentration analyses of the major ions in the water phases show that majority of the ions remained in the solid phase after deposition. The concentration of Ca^{2+} in the release water was the same as in the process water used for the field trial. The major source of Al^{3+} in the process is from

Alum (coagulant stream), which has a negligible concentration of 0.015 mg/L in the release water. Therefore, there is no indication of any excess divalent or multivalent cations in the release water. Generally, the concentration of anions and cations show encouraging results for the release water chemistry.

Based on the process flow diagram shown in Figure 4, all the process streams and samples collected at Nodes #4 and #6 were analyzed for major anions and cations to understand the chemistry of the release water. Table 6 shows the concentration (anions and cations) of individual process streams, Node #4, and Node #6.

Table 6: Concentration of major anions and cations in the process streams

Stream/ Node #	Stream node description	Concentration of major ions (mg/L)							
		HCO_3^-	SO_4^{2-}	Cl^-	Ca^{2+}	Mg^{2+}	Na^+	K^+	Al^{3+}
1	Original FFT	420	190	150	47	22	260	22	0.12
2	Dilution with process water	440	180	59	86	26	110	16	0.0091
3	Alum solution	40	550	72	92	28	160	10	110
		Subtotal (1 + 2 + 3)							
4	Coagulated FFT	310	430	74	97	35	170	59	0.012
5	Flocculant solution	540	190	180	43	13	140	51	0.037
6	Flocculated FFT	330	460	110	99	36	220	19	0.011
7		**Release/Retained of anions/cations**							
	Tube Run-off water	**280**	**470**	**99**	**86**	**31**	**180**	**15**	**0.015**

To calculate the mass balance of the anions and cations, the fluid phase volumes from Table 4 for the Streams #1, #2, #3, #5 and Nodes #4 and #6 were used.

Table 7 shows the results of the mass balance conducted on the process flow diagram shown in Figure 4. Carefully reviewing the results in Table 7, the cumulative mass for Streams #1, #2, and #3 should be equal to the mass at Node #4, which is calculated from the chemical analysis results of Node #4 (sampling point) collected during the deposition of materials in the process. If there is a difference in the masses, this suggests some sort of chemical reaction.

When the mass of Node #4 is subtracted from the sum of Streams #1, #2 and #3 and results in a negative number, this indicates that the mass has increased in the liquid phase by means of some reaction(s) in the original FFT. Conversely, a positive result means those cations or anions have been transferred from the liquid phase onto the solids, which is commonly referred to as cation exchange reactions taking place at the soil particle surfaces.

Comparing the coagulated FFT (Node #4) with the collective mass of the input streams #1 to #3, it can be concluded from the sign conventions for HCO_3^- , SO_4^{2-}, Ca^{2+}, Mg^{2+}, and K^+ that they are released

into the fluid (aqueous) phase of the coagulated FFT where Cl^-, Na^+ and Al^{3+} are retained into the solid phase. This change in chemical composition suggests that cation exchange reactions are happening on the solid surfaces.

Similarly, subtracting the chemistry of the flocculated stream (Node #6) from the subtotal upstream sites (Node #4 + Stream #5) a major shift in the overall chemistry is seen. In the flocculated FFT, only K^+ is released into the fluid (aqueous) phase while other major cations and anions are retained in the solid phase.

The difference in the ion mass of flocculated FFT (Node #6) and the release water (Stream #7) indicates that all the anions and cations have positive values. This means the anions and cations are retained into solid phase, including bicarbonate (HCO_3^-) after treatment (coagulation + flocculation) with the physicochemical recipe. This can provide miss guidance if not interpreted correctly. Therefore, the stream(s) mass needs to be compared on individual basis to see the impact of the input stream(s) on the product stream.

Table 7: Mass of major anions and cations in the process streams

Stream/ Node #	Stream/node description	Fluid vol.	Mass of major ions (kg)								Unit load T/m³
		(m³)	HCO_3^-	SO_4^{2-}	Cl^-	Ca^{2+}	Mg^{2+}	Na^+	K^+	Al^{3+}	
1	Original FFT	10.38	4.36	1.97	1.56	0.49	0.23	2.70	0.23	0.00	1.11
2	Dilution with process water	5.00	2.20	0.90	0.30	0.43	0.13	0.55	0.08	0.00	0.92
3	Alum solution	27.00	1.08	14.85	1.94	2.48	0.76	4.32	0.27	2.97	1.06
	Subtotal (1 + 2 + 3)	42.38	7.64	17.72	3.80	3.40	1.11	7.57	0.58	2.97	1.06
4	Coagulated FFT	42.38	13.10	18.23	3.14	4.11	1.48	7.21	2.50	0.001	1.18
	Release/Retained in coagulated FFT in the pipeline (1 + 2 + 3) – (4)	–	-5.5	-0.5	0.7	-0.7	-0.4	0.4	-1.9	3.0	
5	Flocculant solution	4.00	2.2	0.8	0.7	0.2	0.1	0.6	0.0	0.00	1.15
	Subtotal (Node 4 + 5)	46.38	15.3	19.0	3.9	4.3	1.5	7.8	2.5	0.00	1.17
6	Flocculated FFT	46.38	15.3	21.3	5.1	4.6	1.7	10.2	0.9	0.00	1.27
	Release/Retained in the flocculated FFT in the geotextile tube Node 6 – (4 + 5)	–	0.00	2.27	1.26	0.30	0.12	2.40	-1.6	0.00	
7	Tube Run-off water	45.00	12.6	21.2	4.5	3.9	1.4	8.1	0.7	0.00	1.16
Chemistry difference between 6 and 7			2.7	0.1	0.6	0.7	0.3	2.1	0.2	0.00	0.11
Chemistry difference between 1 and 7			-8.2	-19.2	-2.9	-3.4	-1.2	-5.4	-0.4	0.00	

Comparing Stream #1 to Stream #7, there is an increase in the mass of all the cations and anions in the aqueous phase. This is indicative that the other process streams added between Stream #1 and #7 contributed to this increase of anions and cations mass in the aqueous phase in addition to the surface reaction. Example, if we replace the Stream #2 (dilution water) with an alternative stream having no or low concentration of anions and cations the overall mass in Stream #7 will be lower.

Comparing all the streams individually for mass loading of cations and anions, the most complex is the coagulant Stream #3. The unit loading of anions and cations masses for all streams is approximately 1 kg/m^3, suggesting that all the stock solutions (coagulant Stream #3 and flocculant Stream #5) were prepared in similar type of water (the water used from Stream #2).

Comparing the volumes of fluid added into the process from different streams, the volume of the Alum solution Stream #3 is about three times that of the original FFT Stream #1 plus the dilution Stream #2 volume. See Figure 5 to understand the rationale behind the change in unit volume of water from the Alum solution Stream #3. This suggests that this stream alone is a major contributor to the change in the downstream process chemistry.

The geotextile tube run-off or release water Stream #7 was sampled at different intervals of time. The same concentrations of ions in the release water were reported each time the sample was collected. The concentrations of the anions and cations are presented in Table 6 (Stream #7). The 45 m^3 run-off volume shown in Table 7 from the geotextile tube is considered an approximation for complete drying when all water is released.

Table 8 shows the mass of major cations and anions in the release water from the geotextile tubes.

Table 8: Mass of major anions and cations in the released water from the geotextile tubes

Stream/ Node #	Stream/node description	Fluid volume	Mass of major ions (kg)								Unit load T/m^3
		(m^3)	HCO_3^-	SO_4^{2-}	Cl^-	Ca^{2+}	Mg^{2+}	Na^+	K^+	Al^{3+}	
6	Flocculated FFT	46.4	15.3	21.3	5.1	4.6	1.7	10.2	0.9	0.0	1.27
7	5 hours after tube filled	35.5	9.9	16.7	3.5	3.0	1.1	6.4	0.5	0.0	1.16
	7 days after tube filled	6.8	1.9	3.2	0.7	0.6	0.2	1.2	0.1	0.0	1.16
	30 days after tube filled	0.78	0.2	0.1	0.0	0.0	0.0	0.0	0.0	0.0	0.38

As mentioned above, the concentration of the major ions remains the same, but the mass loading varies depending on the volume of water released, and subsequently the unit mass loading is also reduced. In a nonreactive environment (solid surface), the sum of the individual species masses should be equal to the corresponding species in the treated (flocculated = flocculation of the coagulated FFT) FFT Stream (#6),

and the unit loading should continue decreasing. If this is not true, then the solid surface is reactive and cations are released during the dewatering process in the geotextile tube, causing the ion concentrations and overall mass to change.

Conclusion

This study has confirmed that the poor flocculation of quartz and kaolinite particles observed in the range of pH 8 is due to the adsorption of Ca^{2+} ions on anionic PAM flocculant, causing steric stabilization at the particles surface. Steric stabilization results from covering the particles with the anionic flocculant, preventing the particles from getting close to the range of attractive forces and thereby allowing the particles to be dispersed.

The physicochemical treatment recipe of the FFT is designed to achieve efficient flocculation performance by maximizing the agglomeration of fines to form large flocs while maximizing water release. To achieve this design criterion, the coagulated FFT slurry density at the flocculation step should be approximately 8 wt.% solids and, therefore, the dilution of the original FFT should be set for this condition while maintaining the concentration and dosage of the coagulant and flocculant constant.

The initial change in the solids content by mass of the flocculated FFT from 8% (end-of-pipe) to 27% in the geotextile tube after five hours of pour shows release of dilution water used in the process and an effective coagulation and flocculation in the pipeline prior to the discharge into the geotextile tube. Comparing the results at end-of-pipe and after five hours with the data after seven days of the completion of the geotextile tube filling, there is a significant initial increase in dewatering from 8 wt.% to 50 wt.% solids.

The concentration of Ca^{2+} ions in the release water is the same as the process water used for the trial (86 ppm). The Al^{3+} loading is mainly contributed from the coagulant (Alum) stream, which is transferred to the solid phase and remains in very low concentration in the release water. The results show that the physicochemical treatment recipe for FFT with coagulation and flocculation does not generate any excess divalent or multi-valent cations in the release water in the scenario of high divalent ion-content dilution water.

As a result, this study through the solid, ions and water mass balance analyses has identified that the negative impact of an excess of calcium ions on flocculation of the FFT can be reduced or even eliminated by aluminum ions in the range of pH 8.

The mineralogy identification and quantification by elemental distribution, spectrograph, and scanning electron microscopy analyses of this study show that 45% – 80% of carbon oxygen-bearing compounds, approximately, were transferred to the solid phase of the treated FFT with Da Silva's recipe. The mass balance and concentration of major anions and cations analyses performed in this study have

confirmed that about 2% – 33% of the major ions except Al (100%), including 22% bicarbonate (HCO_3^-), were transferred and remained in the solid phases of the treated FFT after deposition in the geotextile tube. These findings are very encouraging and suggest further investigation of the potential for carbon capture (more work is still needed to quantify accurately how much carbon can be sequestrated into the treated FFT from organic carbon and inorganic carbon dioxide from the atmosphere), which is linked to solids phase and carbonate compounds precipitation. However minuscule the amount may be, this bit of CO_2 pulled from the air, mineralized, and turned into part of the solid phase of the reclaimed geotextile tube tailings deposits is no longer heating up our planet.

Carbon sequestration by carbonation through FFT treatment is promising and has potential to benefit the environment, especially for oil sand tailings, where the residual organic carbon from extraction of oil and bicarbonate originating from the atmosphere are both mineralized into carbonate. Formation of carbonate can enhance the consolidation of the treated FFT and directly trap some metals into the crystal of carbonate. Because of coagulation and flocculation, almost all cations and anions in solution, dissolved or suspended, are trapped into solids, and therefore this process would allow an assessment of all contaminants trapped in the solids (up to 50 elements) using inductively coupled plasma mass spectrometry (ICP-MS).

Spatial Variability Assessment of Mine Tailings

Luis Vergaray-Astupina, Georgia Institute of Technology, USA
Jorge Macedo, Georgia Institute of Technology, USA

Abstract

The Global Industry Standard on Tailings Management (GISTM) promotes performance-based approaches in geotechnical assessments. Hence, characterizing the spatial variability of deposited tailings is expected to be a key input for some tailings storage facilities (TSFs); however, it has seldom been investigated. In this study, we assess the spatial variability of thickened and conventional tailings that have been deposited into the same TSF, providing a unique opportunity to investigate two tailings technologies. A dense array of 15 cone penetration tests (CPTus) has been conducted to collect data. The results were processed using traditional and machine learning-based methods for data detrending when deriving random fields. In terms of correlation lengths, we find similar ranges for the thickened and conventional tailings and similar distributions, likely influenced by the depositional processes. In contrast, the variance in the conventional tailings is higher, which we attribute to its segregating nature.

Introduction

Previous efforts on characterizing the spatial variability of soil deposits have been mainly focused on natural soils, often using the random field theory (RFT). In terms of man-made waste materials, the Bagińska et al. (2016) study characterized the vertical spatial variability of a mine waste dump in a coal mine using CPTu. However, they focused only on the vertical variability due to the large spacing between the CPTus. Regarding mine tailings, to the best of the author's knowledge, there have been no previous efforts to characterize the extent of their spatial variability at a local scale considering vertical and horizontal directions, which is one of the key contributions of our study.

Advancing the spatial variability characterization of mine tailings is a step forward to enable better treatment of uncertainties in performance-based assessments, a framework recommended in the Global Industry Standard on Tailings Management (Global Tailings Review, 2020). In addition, gaining insights into the spatial variability of mine tailings provides valuable information to improve the planning of site investigation programs for TSFs. The spatial variability assessments of this study rely on data collected on conventional and thickened tailings using a dense array of CPTus. In addition to the traditional use of

polynomial functions in the detrending process to assess the extent of spatial variability, we highlight the significant potential of modern machine learning-based procedures for trend removal, which is a major contribution from our study. Unlike traditional polynomial functions with limited flexibility due to their fixed forms, machine learning-based methods offer greater flexibility in capturing trends in CPTu data.

CPTu characterization

The investigated tailings were deposited using conventional deposition starting in the 1990s until 2010, when the deposition method was changed to high-density thickened tailings, providing a unique opportunity to investigate both conventional and thickened tailings in the same TSF. The solids contents for the conventional and high-density thickened tailings are about 50% and 62 to 70% (the variation is due to seasonal change), respectively. The field characterization was planned to collect data on both tailings and included 15 CPTus. The CPTu array was oriented parallel to the discharge points in the dam, as illustrated by Figure 1a. The CPTus were conducted at a standard penetration rate of 2 cm/s and were spaced at a distance of 1.5 m, as shown in Figure 1b. The separation was selected following the recommendations of Cary (2021) to minimize any potential disturbance between nearby CPTus. The dissipation tests confirmed a phreatic surface approximately 6.1 m below the surface. The CPTus were pushed to a depth of 16 m.

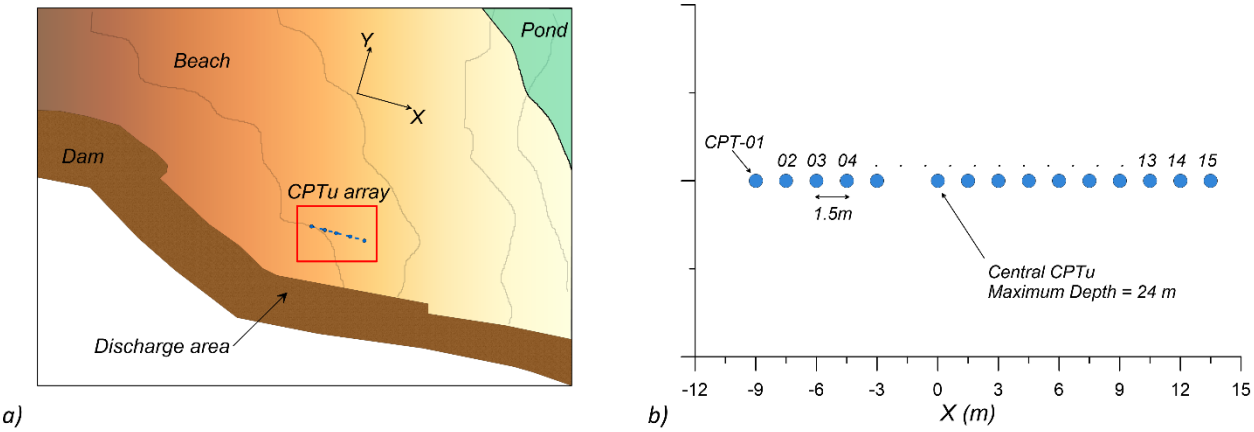

Figure 1: a) CPTu array location relative to the discharge area b) CPTu array zoom-in and labels

Figure 2a and 2b show q_t and f_s profiles, soil layering, and the phreatic surface inferred from the CPTu tests. The inferred soil profile can be divided into three layers. The layer from the surface to 2 m is a pad access built to access the site, which is not considered in the interpretations. The second layer, extending from 2.0 to about 8.5 m, corresponds to the thickened tailings showing relatively uniform q_t, f_s, and a linear trend in u_2. The conventional tailings underlay the thickened tailings and extend to the bottom of the profile, showing a more erratic variation of q_t, f_s and u_2 values. The separation of the conventional and thickened tailings at about 8.5 m is consistent with the tailing's deposition history.

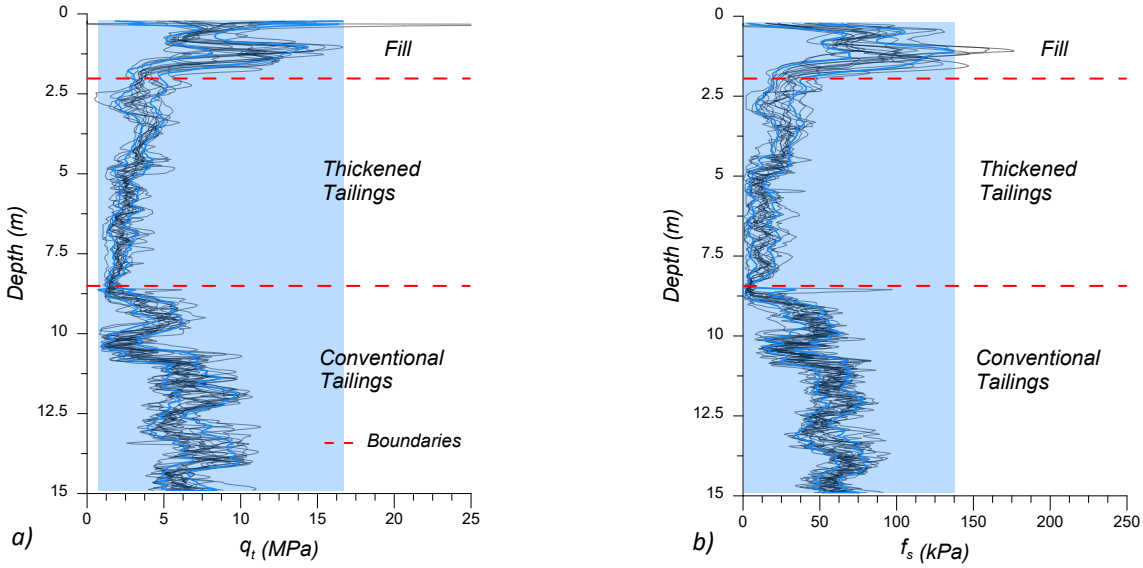

Figure 2: a) q_t, and b) f_s, profiles

Spatial variability assessment

The inherent spatial variability of soils can be modeled with the random field theory (RFT), which has been used in several previous studies mainly focused on natural soils. In the following, we provide a brief overview of the RFT framework and its use in assessing spatial soil variability. Interested readers can refer to Jaksa et al. (1999) and Bong and Stuedlein (2017) for additional details. Under the RFT framework, a measurement of some spatially varying soil property of interest $g(z)$ at a given depth z can be expressed as the sum of a deterministic trend $[t(z)]$ and a fluctuating component $[w(z)]$ as expressed by Equation 1. The spatially varying parameter of interest is then characterized by the correlation length (δ), and the coefficient of variation (COV) of $w(z)$. δ is a measure of the distance within which a particular measurement is correlated, and COV is the standard deviation (σ) of $w(z)$ normalized by the mean of $t(z)$.

$$g(z) = t(z) + w(z) \tag{1}$$

The δ can be calculated by different geostatistical procedures (e.g., Jaksa, 1995; Vanmarcke, 1977; DeGroot and Baecher, 1993). In particular, the use of autocorrelation models to fit the autocorrelation in the observed data is common in geotechnical applications. In this procedure, the sample autocorrelation function $\rho(\tau_j)$ – i.e., based on the observed data, which defines the spatial correlation for a given lag distance (τ_j) on the measurement of interest – is evaluated according to Equation 2.

$$\rho(\tau_j) = \frac{\sum_{i=1}^{n_d-j} w_i \times w_{i+j}}{\sum_{i=1}^{n_d-j} w_i^2} \tag{2}$$

As suggested by Box and Jenkins (1970), different lag distances τ_j can be considered by varying the sampling space (Δz) for $j = 1,2,3 \ldots n_d/4$, where n_d is the sample size. Once $\rho(\tau_j)$ is assessed, δ can be estimated by fitting different autocorrelation models (ACMs – Table 1) to $\rho(\tau_j)$. In using the RFT framework, it is highly beneficial to have stationarity in w, i.e., the covariance structure only depends on the distance between observations (τ). Thus, a key step in assessing spatial soil variability is detrending the data (i.e., removing $t(z)$), ideally leading to a stationary $w(z)$ random field.

This study used traditional polynomial and three non-parametric machine learning (ML) methods, namely, Random Forest (Breiman, 2001), Gradient Boosting Decision Tree (GBDT – Friedman, 2001), and the K-Nearest Neighbor (KNN – Peterson, 2009) for conducting the CPTu data detrending. The autocorrelation models were fitted to $\rho(\tau_j)$ above the Bartlett's limit $r_B = 1.96/\sqrt{n_d}$, where n_d is the number of samples, . The fitting is considered acceptable when the coefficient of determination R^2 is above 0.9 (Phoon et al., 2003).

The stationarity conditions of the detrended data were assessed using the stationarity score (S), which is based on the Bartlett's statistic test. S is a normalized scalar quantity (bounded from −1 to 1), where negative values indicate nonstationary and positive values indicate stationary. S combines the contributions from both R^2 and Bartlett's statistic and can be used as a single metric to evaluate the performance of different trend functions. Further details are provided in Macedo et al. (2024).

Table 1: Autocorrelation models and corresponding correlation length (Uzielli and Vanucchi, 2005)

Autocorrelation model	Functional form	Correlation length
Single exponential (SNX)	$\rho(\tau) = e^{-k\|\tau\|}$	$\delta = 2/k$
Cosine exponential (CSX)	$\rho(\tau) = e^{-k\|\tau\|}\cos k\tau$	$\delta = 1/k$
Second-order Markov (SMK)	$\rho(\tau) = (1 + k\|\tau\|)e^{-k\|\tau\|}$	$\delta = 4/k$
Square exponential (SQX)	$\rho(\tau) = e^{-(kt)^2}$	$\delta = \sqrt{\pi}/k$

Vertical correlation length

The vertical autocorrelation length (δ_{wv}) was calculated by fitting four different autocorrelation models (Table 1) to the sample autocorrelation functions. Figure 3 illustrates the process by showing the results obtained for the q_t profile of CPT-14 for the conventional tailings using the CSX autocorrelation model with polynomial and random forest detrending methods. The hyperparameters that produce the highest S for each method are noted in the figure titles. In this case, a polynomial function of order two was selected because it gives the highest S. However, S is negative, implying nonstationarity. In contrast, all ML-based

methods produce stationarity (Figure 3, right column). Hence, the CSX model would be discarded if only traditional polynomials were considered.

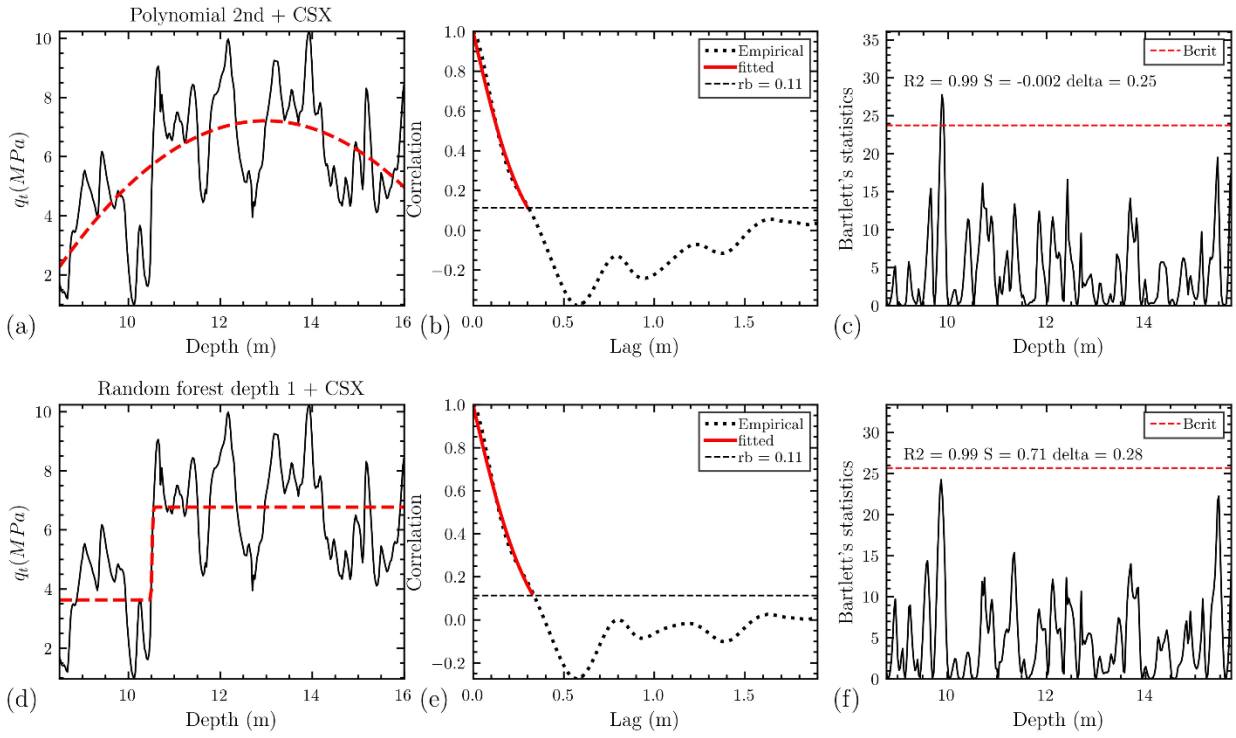

Figure 3: Results using polynomial and ML-based trend functions for a representative q_t profile, considering the conventional tailings

Figure 4 presents the cumulative distribution functions (CDFs) of δ_{wv} and COV_{wv} for q_t (Figure 4a and 4b) and f_s (Figure 4c and 4d), respectively. Interestingly, the estimated δ_{wv} and COV_{wv} values are in a relatively narrow range. In the case of the thickened tailings, the mean δ_{wv} estimated from q_t is 0.33 m, which is smaller, but still comparable with the δ_{wv} of 0.49 m based on f_s. In the conventional tailings, the mean δ_{wv} estimated from q_t is 0.35 m, quite close to the mean δ_{wv} of 0.31 m considering f_s. The q_t-based δ_{wv} CDFs for both tailings are also consistent. The f_s-based δ_{wv} CDFs for the thickened tailings are shifted to the right with respect to the CDFs for conventional tailings, but the δ_{wv} are still comparable.

The similar δ_{wv} values can be attributed to the combination of two aspects i) the deposition scheme for the conventional and thickened tailings; and ii) averaging effects in CPTu measurements. In terms of the deposition process, similar phenomena are involved in both the deposition of the conventional and thickened tailings. These phenomena include pauses in the tailings discharge (the deposition is conducted on layers), drying-wetting cycles, induced consolidation when new layers are deposited, and induced flow gradients. Moreover, even though the thickened tailings have a less segregating nature, it is still reasonable to expect some segregation under field conditions during the deposition process. In terms of the averaging

during CPTu penetration, it is well known that q_t is influenced by the response of the units that are at a distance of 1 to 3 cone diameters for soft soils and 20 to 30 cone diameters for stiffer soils (Lunne et al., 1997; Ahmadi and Robertson, 2005). Similarly, f_s also represents an averaged measurement. Thus, the relatively increased heterogeneity on the conventional tailings may have also been averaged out to some extent by the nature of the CPTu process.

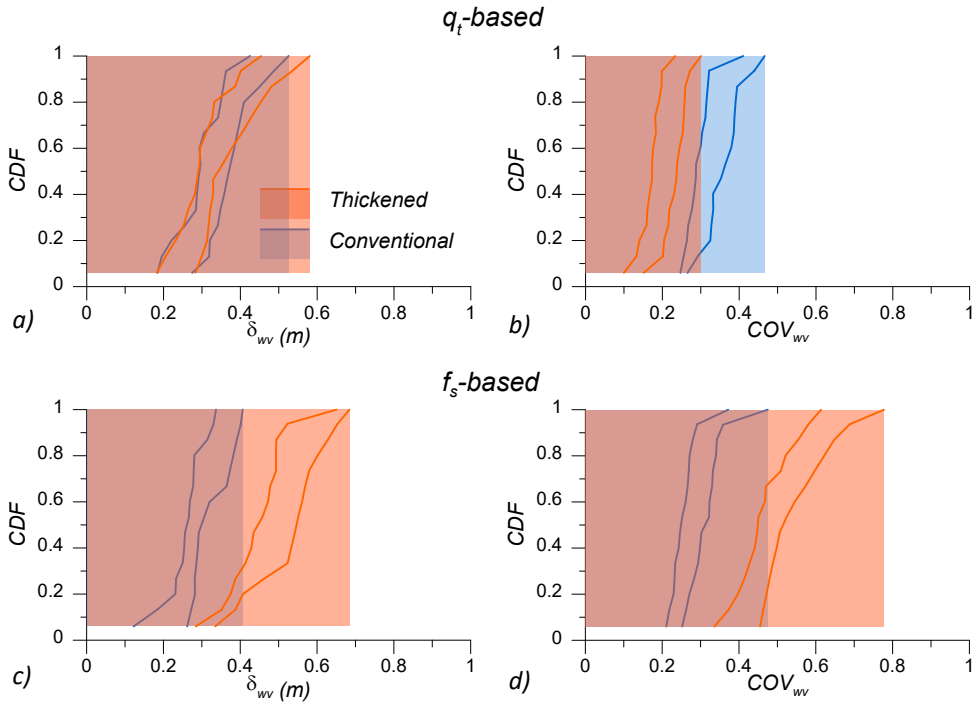

Figure 4: Ranges of a) δ_{wv} and b) COV_{wv} CDFs estimated from q_t data. Ranges of c) δ_{wv} and d) COV_{wv} CDFs estimated from f_s data

In terms of the COV_{wv} CDFs, it is important to put in context that COV_{wv} is a measurement of the fluctuation (i.e., σ) of $w(z)$ with respect to its order of magnitude (i.e., $t(z)$). The relatively larger COV_{wv} for q_t in the conventional tailings reflects the more significant fluctuation of q_t, potentially influenced by the more segregating nature of the conventional tailings. In contrast, the larger COV_{wv} for f_s in the thickened tailings reflects the significantly lower f_s in the thickened tailings compared to the conventional tailings (i.e., a factor of about 3), which counteracts the σ contribution.

Horizontal correlation length

Due to the relatively large sampling interval in the horizontal direction compared to the vertical, deriving on significantly fewer points at a given depth, the horizontal correlation length (δ_{wh}) is estimated following the expeditive method, which was originally proposed by Vanmarcke (1977) and has been used in previous studies for natural soils (e.g., Stuedlein et al., 2012; Bong and Stuedlein, 2017; Cary, 2021). The expeditive

method estimates δ_{wh} as $\sqrt{2/\pi}\,\bar{d}$, where $\bar{d}$ is the average length of the segments obtained at the crossings of $g(z)$ and its linear trend function $t(z)$, where $g(z)$ is the metric of interest (i.e., q_t or f_s). Following the recommendations of Stuedlein et al. (2012) and Bong and Stuedlein (2017), in applying the expeditive method, we considered a minimum of five crossings to get stable COV_{wh} and δ_{wh} estimates. Figure 5a illustrates the q_t-based δ_{wh} estimation in the thickened and conventional tailings at depths of 4 and 12 m, and Figure 5b illustrates the f_s-based δ_{wh} estimation at the same depths.

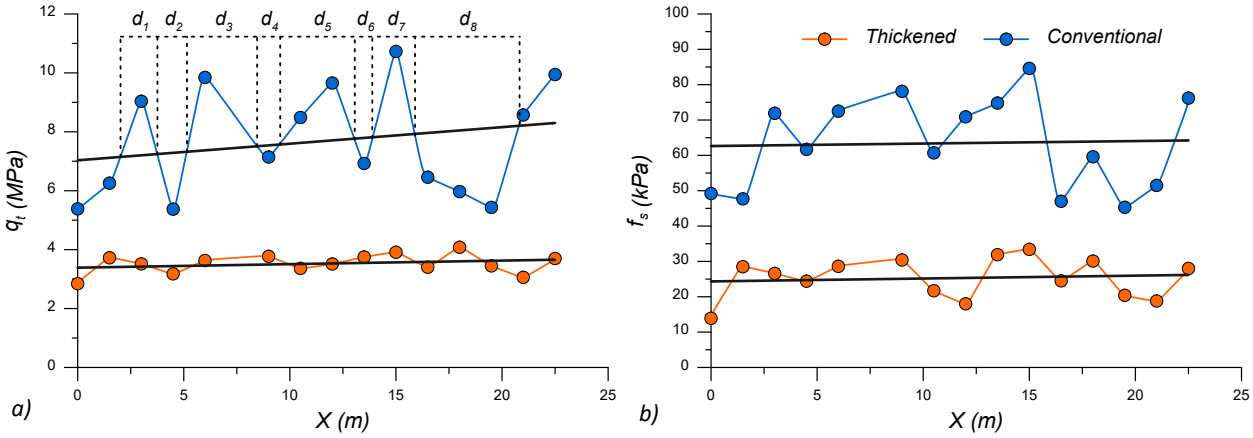

Figure 5: Application of Vanmarcke's expeditive method for estimating the horizontal autocorrelation l based on a) q_t and b) f_s, considering the thickened and conventional tailings at selected depths (4 m for the thickened tailings and 12 m for the conventional tailings)

Figure 6a shows the estimated δ_{wh} considering q_t and f_s for the entire deposit, and Figure 6b presents the associated horizontal coefficient of variations (COV_{wh}). It can be observed that the thickened and conventional tailings exhibit a similar δ_{wh}. For instance, the 16 – 84 percentiles for the q_t-based δ_{wh} is in the range of 2 to 3.5 m for the thickened tailings and in the range of 1.8 to 3.0 m for the conventional tailings. In the case of the f_s-based estimations, the 16 – 84 percentiles δ_h is in the range of 1.7 to 3.2 m for the thickened tailings and 1.9 to 2.9 m for the conventional tailings. The similar δ_{wh} in both tailings can be attributed to the deposition process and associated phenomena (e.g., pauses in the discharge, flow gradient, drying-wetting cycles, freezing, and consolidation) as discussed before for the δ_{wv}.

Moreover, it is reasonable to expect segregation to have less effect in the horizontal direction compared to the vertical, which is reflected in a similar δ_{wh}. The q_t-based COV_{wh}values tend to be slightly larger for the conventional tailings as the existing variance controls them, whereas the f_s-based COV_{wh} values are larger for the thickened tailings as they are controlled by the lower f_s values in the thickened tailings.

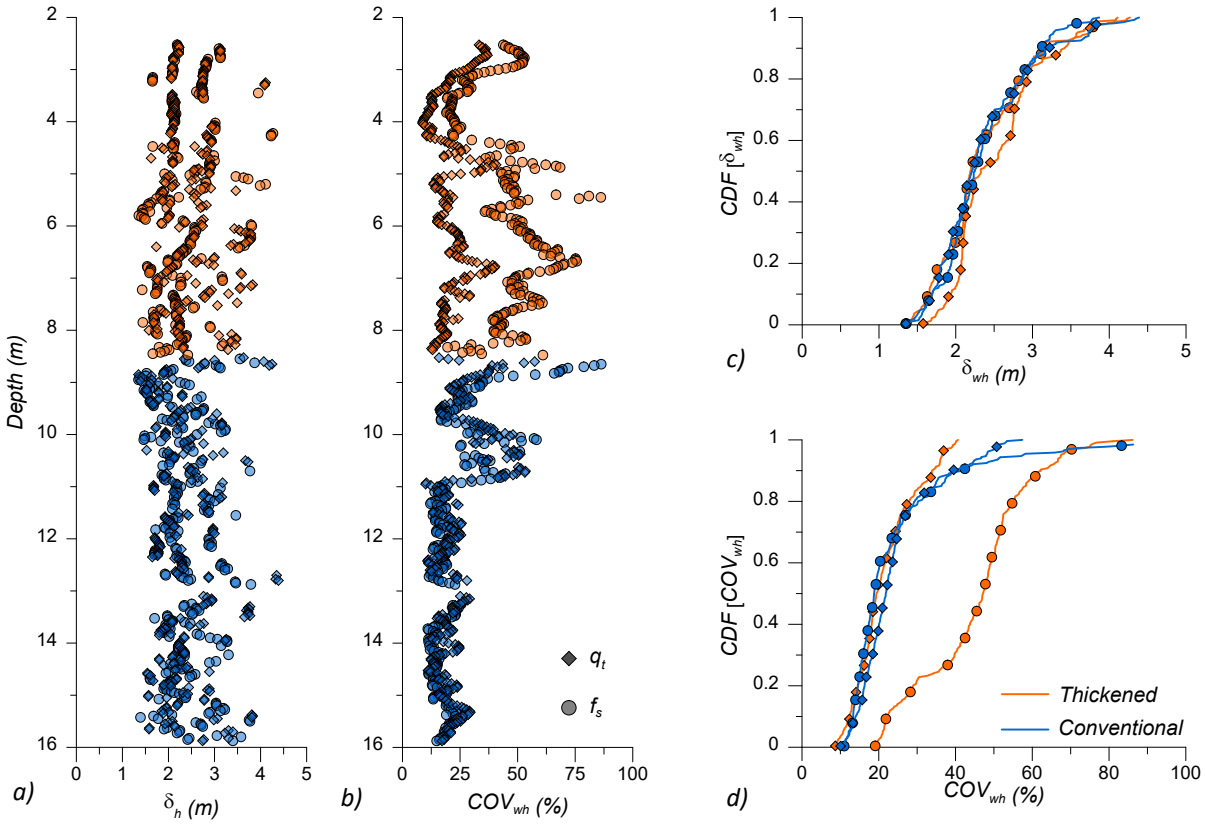

Figure 6: a) δ_{wh} and b) COV_{wh} profiles based on q_t and f_s, considering the thickened and conventional tailings. CDFs of q_t and f_s based c) δ_{wh} and d) COV_{wh} in the thickened and conventional tailings.

Figure 6c and 6d present q_t- and f_s-based CDFs for δ_{wh} and COV_{wh}; it can be observed that the δ_{wh} CDFs for q_t and f_s are consistent for both the thickened and conventional tailings. In addition, similar q_t-based COV_{wh} CDFs for the thickened and conventional tailings are also observed, being also consistent with the f_s-based COV_{wh} for the conventional tailings, whereas the f_s-based COV_{wh} CDF for the thickened tailings is shifted to the right, showing larger values for reasons already discussed.

Discussion

The generation of random fields depends on δ and COV (or variance, σ^2); hence, having similar δ, which is the case for the thickened and conventional tailings, does not necessarily imply similar random fields. This can be illustrated by generating random fields with the parameters evaluated for the thickened and conventional tailings using the GSTools package (Muller and Schüler, 2021). Figure 7a shows one of these realizations considering the SNX autocorrelation model and parameters estimated using the GBDT model for detrending. In this case, the q_t-based estimated parameters for the thickened tailings are $\sigma^2 = 0.3$ MPa, $\delta_{wv} = 0.37$ m, and $\delta_{wh} = 2.45$ m, whereas the parameters for the conventional tailings are $\sigma^2 = 2.6$ MPa,

$\delta_{wv} = 0.41$ m, and $\delta_{wh} = 2.29$ m. As can be inferred from these parameters, the main difference is in σ^2. It is interesting to note that the extent and shape of zones with similar $w(z)$ values are comparable for the two types of tailings due to the similar δ. However, the random field for the thickened tailings is significantly more stable (i.e., it presents less variability) due to the lower σ^2. Thus, despite the similar δ for both tailings, the simulated random field for the thickened tailings shows a more homogeneous structure than conventional tailings.

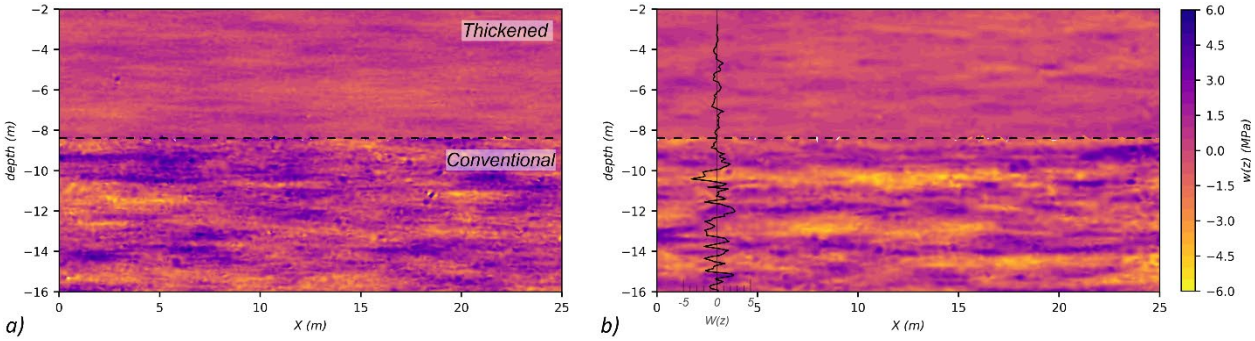

Figure 7: a) Unconditioned and b) conditioned q_t -based $w(z)$ random field realizations for the thickened and conventional tailings

Figure 7b presents a $w(z)$ random field realization conditioned at various depths across the 15 CPTu locations. This conditional random field (CRF) offers a more realistic representation of spatial variability by incorporating site-specific data. Consequently, CRF realizations enhance the understanding of the distribution of tailings properties and improve the stability analysis and modeling of TSFs, which often rely on simplified assumptions, such as uniform layers, isotropic and homogeneous properties, and deterministic characteristics. By enabling probabilistic assessments, CRFs provide a more accurate and comprehensive approach to evaluating TSF stability.

Conclusion

As the application of performance-based approaches to tailings management advances (Morgenstern, 2018), the quantification of variabilities (spatial and aleatory) is expected to become crucial, particularly for TSFs where the geotechnical characterization of mine tailings is key in assessing the overall response (e.g., the overall physical stability in upstream TSFs). In this context, we have collected data using a dense CPTu array to assess the spatial variability of two different types of tailings deposited in the same TSF. We also evaluated the potential of modern machine-learning methods for informing the estimation of random field parameters. The examined methods provided advantages, which we attribute to the interpolation nature of CPTu detrending (machine learning can act as a black box for extrapolation problems). This study's findings may prove valuable in geotechnical analyses that require adopting δ values to account for spatial

variability in mine tailings similar to those examined in this study, specifically thickened and conventional tailings produced from gold ore. Given the lack of spatial correlation information on mine tailings, we expect that it would also be helpful as a benchmark for future efforts. Of note, case studies exist documenting the importance of spatial variability parameters for water dams (Sanchez-Lizarraga and Lai, 2014; Boulanger and Montgomery, 2016; Guo et al., 2019). Thus, it is reasonable to expect similar spatial variability studies focused on TSFs to translate into engineering practice in the future.

Tailings Characterization for Flow Liquefaction Evaluation at a Large Tailings Storage Facility by Advanced Laboratory Testing

Juan Carlos Ayes-Zamudio, WSP, USA
Akhter Hossain, WSP, USA
Tony Freiman, WSP, USA

Abstract

This paper presents the material characterization results of a large tailings storage facility (TSF) with an upstream-constructed tailings dam, currently exceeding 230 m in height. The tailings deposits beneath the outer coarse (sand) shell forming the dam generally consist of non-plastic to low-plasticity, mostly contractive, sandy silt and silty sand-type materials. The results of an advanced laboratory testing program designed to characterize these contractive tailings for flow liquefaction evaluation are presented. The program comprised 17 isotropically consolidated undrained (CIU) and 17 isotropically consolidated drained (CID) triaxial compression tests conducted on saturated reconstituted tailings specimens with 21 to 61% fines under effective confining pressures ranging from approximately 97 to 3,040 kPa. Critical state loci for the tailings, based on the results of the CIU and CID triaxial tests, are presented. The strength loss and brittleness behavior of the tailings, derived from the CIU tests, indicate the presence of highly brittle materials within the TSF. The program also included nine constant-volume cyclic direct simple shear (CDSS) tests with post-cyclic monotonic shear and reversals of loading to complete five shear loops. Liquefied (residual) undrained shear strengths of the tailings, obtained from the CIU triaxial tests and post-cyclic DSS prior to reversal, as well as the final shear loop, are plotted against normalized effective vertical stresses. The triaxial test-based results indicate an increasing trend consistent with other published laboratory test results. The post-cyclic DSS prior-to-reversal residual strength values appear to provide a more reasonable estimate for the tailings within the studied TSF.

Introduction

The studied TSF is currently active with regular tailings deposition. It is the largest active upstream-constructed tailings dam in North America, with a current height exceeding 230 m from crest to toe and a maximum tailings thickness of 175 m. Periodic geotechnical investigations, involving extensive field and

laboratory testing, have been conducted at the TSF to characterize the tailings deposits. These investigations have revealed that beneath the coarse (sand) shell forming the dam are deposits of generally non-plastic to low-plasticity, mostly contractive, sandy silt and silty sand-type tailings. This paper presents the results of a recent advanced laboratory testing program aimed at characterizing these contractive tailings for a flow (static) liquefaction evaluation.

Index property testing

All laboratory test results presented in this paper were performed at a specialized WSP geotechnical laboratory in Lakewood, Colorado. Index property testing, including particle size distribution, Atterberg limits, and specific gravity (G_s) tests, was conducted on three sonic drill core samples collected from depths of 15.5 to 28.5 m below ground surface and a bulk sample from a test pit excavated within the tailings impoundment. The core samples were tested in May 2020, and the bulk sample was tested in April 2023. Table 1 summarizes the index test results, showing that the tailings are non-plastic silty sand (SM) and sandy silt (ML) with fines content (*FC*) varying from 21 to 61% and G_s ranging from 2.66 to 2.72.

Table 1: Summary of index properties of tailings

Sample type and number	Sample depth below ground surface (m)	*FC* (%)	USCS group name [group symbol]	*LL*	*PL*	G_s	Tailings type as characterized in this study
Sonic Drill Core Sample 1	21.6 – 22.9	21	Silty sand [SM]	NP	NP	2.72	Coarse Tailings (CT)
Sonic Drill Core Sample 2	15.5 – 16.6	43	Silty sand [SM]	NP	NP	2.69	Intermediate Tailings (IT)
Sonic Drill Core Sample 3	28 – 28.5	61	Sandy silt [ML]	NP	NP	2.7	Fine Tailings (FT)
Test Pit Bulk Sample	< 1	49	Silty sand [SM]	NP	NP	2.66	Intermediate Tailings (IT)

Note: *FC* = fines content; USCS = unified soil classification system; *LL* = liquid limit; *PL* = plastic limit; G_s = specific gravity; NP = non-plastic

The particle size distribution (PSD) curves for the tailings samples are plotted alongside the indicative gradation curves by ICOLD (2022) in Figure 1. For the purpose of this study, tailings are characterized as coarse tailings (CT), intermediate tailings (IT), and fine tailings (FT) based on their *FC*: less than 30%, between 30 and 55%, and more than 55%, respectively. It is noteworthy that the PSD curves for both CT and IT samples tested in this study plot within the zone of CT as defined by ICOLD, whereas the PSD curve for the FT sample tested in this study plots within the zone defined by ICOLD as hard rock tailings (HRT).

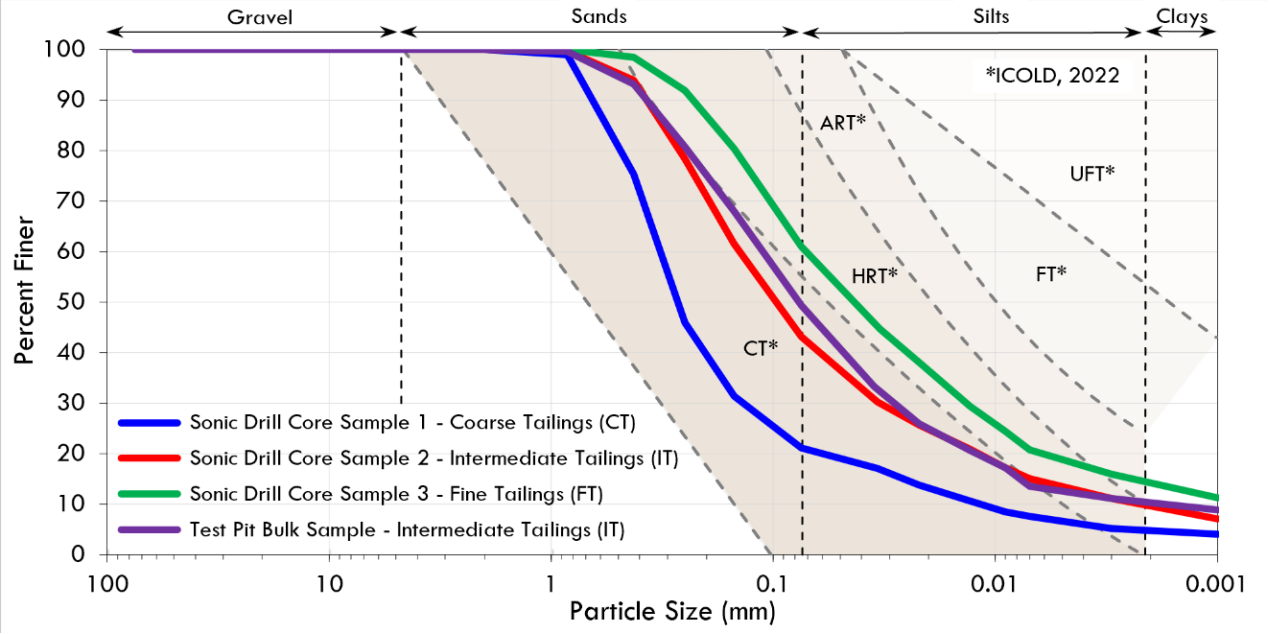

Figure 1: Tailings particle size distributions compared to ICOLD (2022) indicative gradation curves (HRT = hard rock tailings, ART = altered rock tailings, UFT = ultra fine tailings)

CIU and CID triaxial compression testing

A total of 17 isotropically consolidated undrained (CIU) and 17 isotropically consolidated drained (CID) triaxial compression tests were conducted between February 2021 and March 2023. These tests were performed in general accordance with the American Society for Testing and Materials (ASTM) Standard Specifications D4767 (ASTM, 2020a) for CIU tests and D7181 (ASTM, 2020b) for CID tests, incorporating the recommended modifications by Jefferies and Been (2016) on standard equipment. Summaries of the CIU and CID triaxial tests are presented in Tables 2 and 3, respectively. For the CIU tests, 6 were performed on CT samples, 3 on IT samples, and 8 on FT samples. Similarly, for the CID tests, 6 were conducted on CT samples, 5 on IT samples, and 6 on FT samples.

The tests were conducted on a combination of initially loose and dense tailings samples with a diameter of 71 mm and a height of 142 mm. Sample preparation was carried out using the water pluviation method, employing oversized lubricated end platens at the base of the specimens.

Values of e ranged from 0.66 to 0.99 prior to consolidation, and the confining pressures varied from 96.5 to 3,039.9 kPa (1 to 30 atm) in the CIU triaxial tests, as shown in Table 2. Consolidation resulted in a 4 to 50% reduction in e across the specimens. All specimens achieved 100% saturation at the end of the consolidation phase. Subsequently, undrained triaxial compression was applied in a strain-controlled manner at an axial strain (ε_a) rate of 0.083% per minute.

Table 2: Summary of CIU triaxial compression testing

Test ID	*FC* (%)	G_s	Confining pressure (kPa [atm])	e in consolidation stage		Y_d in consolidation stage (kN/m³)		s_r (kPa)	s_r ratio	Ψ

For the CID tests, as presented in Table 3, values of *e* ranged from 0.51 to 0.9 before consolidation, with confining pressures varying from 81.4 to 500.6 kPa (0.8 to 4.9 atm). Consolidation led to a 10 to 46% reduction in *e* across the specimens, and all test specimens achieved 100% saturation at the end of this phase. Following consolidation, drained triaxial compression was applied in a strain-controlled manner with rates of ε_a ranging from 0.004 to 0.017% per minute.

Table 3: Summary of CID triaxial compression testing

Critical state locus

Figures 2(a, c, and e) present the effective stress paths plotted in mean effective stress (p')-deviator stress (q) space for the CIU tests on the CT, FT, and IT samples, respectively. These figures also display the critical state friction ratio from triaxial compression (M_{tc}) for each tailings type.

The state (e-log p') plots for the triaxial tests on the CT, FT, and IT samples are presented in Figures 2(b, d, and f), respectively. These figures also show the straight-line critical state locus (CSL) fitted for each tailings type and the associated tailings properties (i.e., altitude of CSL at reference stress [p_{ref}] of 100 kPa, Γ, and slope of CSL, λ_{10}). Furthermore, the curved CSLs represented by power law equations (critical state void ratio (e_c)-p'/p_{ref} relationships) fitted for each tailings type are shown.

The CIU tests were primarily used to determine the CSL parameters, as they tend to reach critical state more reliably, while the CID tests provided additional data points to validate and refine the CSL definition. As evident from Figure 2, at higher stress levels, the CT samples exhibit significant divergence between the straight-line and curved CSLs, whereas for the IT and FT samples, the two CSLs essentially coincide.

Figure 2 shows that the λ_{10} values increase as the grain size decreases, following the order: CT < IT < FT. This trend indicates increasing compressibility with decreasing grain size. Values of M_{tc} generally exhibits an increasing trend with grain size from FT to CT. However, the IT samples deviate from this trend, showing anomalous behavior. Conversely, the Γ values decreases with increasing grain size from FT to CT. Again, the IT samples demonstrate behavior that deviates from this general trend.

The estimated values of state parameter (Ψ) with respect to the curved CSLs, presented in Figure 2(b, d, and f), are included in Table 2 and 3. As shown in Table 2, all CIU tests yield Ψ values greater than

-0.05, the commonly accepted contractive/dilative boundary. However, the CID test samples yield a combination of Ψ values both greater and less than -0.05.

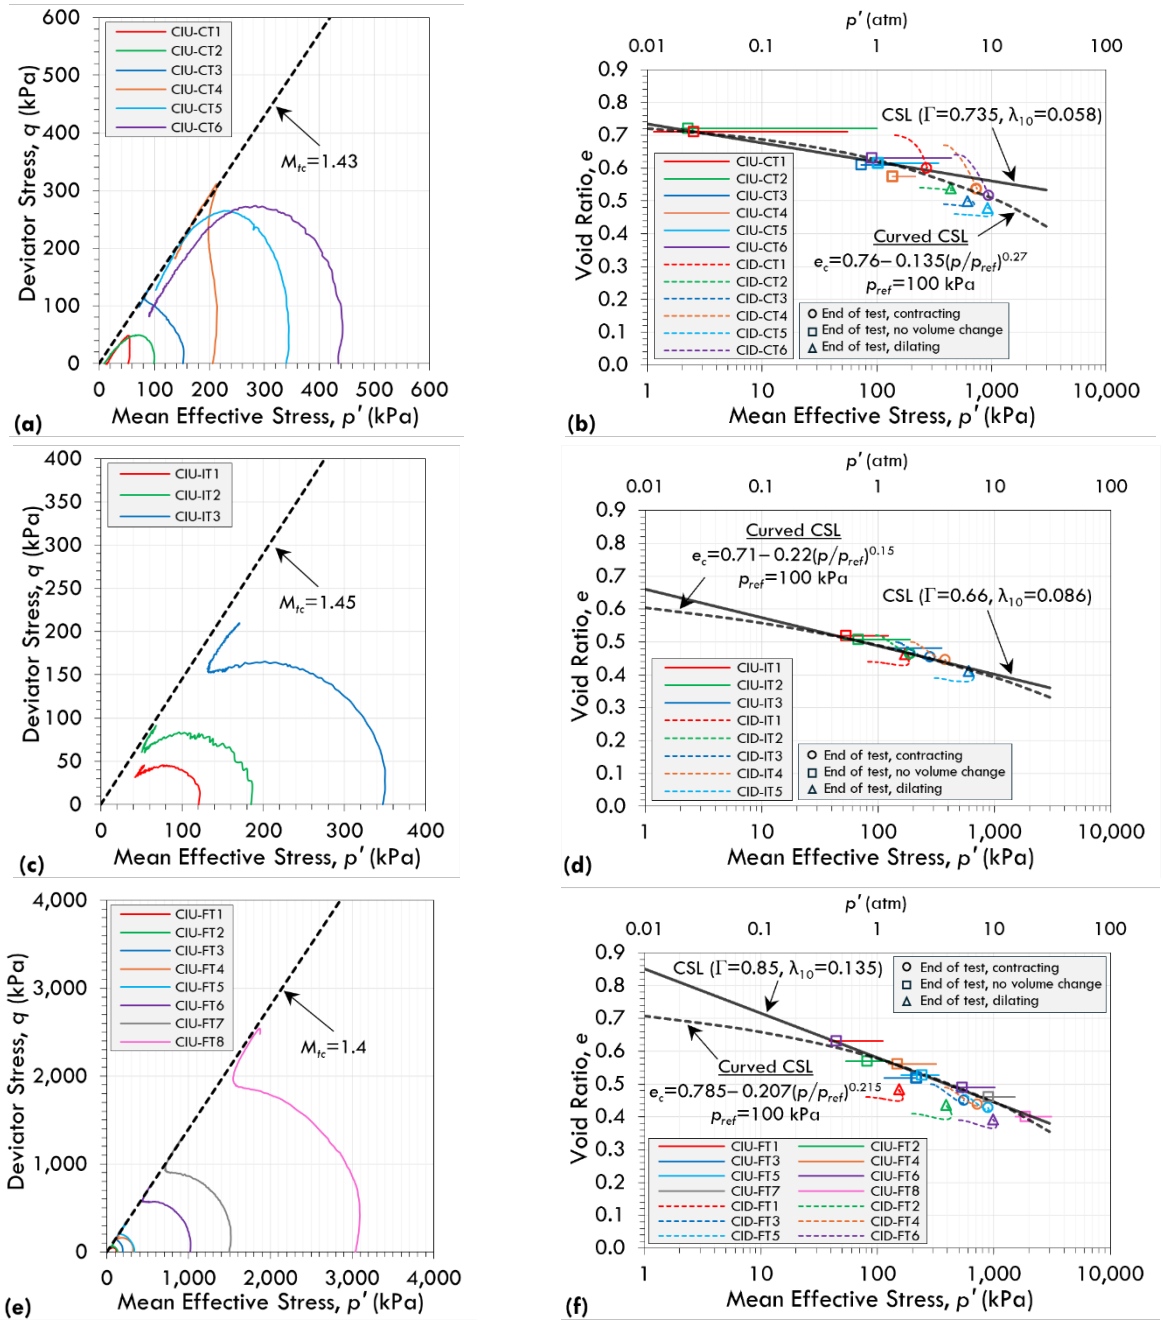

Figure 2: Effective stress paths and critical state loci for (a and b) coarse tailings, (c and d) intermediate tailings, and (e and f) fine tailings

The effective stress path for each CIU test, as presented in Figure 2, demonstrates that most samples did not reach liquefaction. Instead, they exhibited the typical S-shaped curve, characterized by initial contraction followed by dilation. Values of residual undrained shear strength (s_r) and s_r *ratio* (ratio of s_r to

effective vertical stress, σ'_{v0}) were determined based on either the points of phase transformation (from contractive to dilative behavior) or the points of minimum strength. These s_r and s_r *ratio* values are included in Table 2.

Strength loss and brittleness behavior

Results of the CIU tests were utilized to evaluate the potential ductile/brittle stress-strain behavior and to identify possible "highly brittle" tailings using the indicative criteria outlined by ICOLD (2022). Figure 3(a) presents the stress-strain curves (q versus ε_a) for the 17 CIU tests. All CT and IT samples exhibit strain-softening behavior, while five of the FT samples (CIU-FT3, CIU-FT5, CIU-FT6, CIU-FT7, and CIU-FT8) demonstrate strain-hardening behavior.

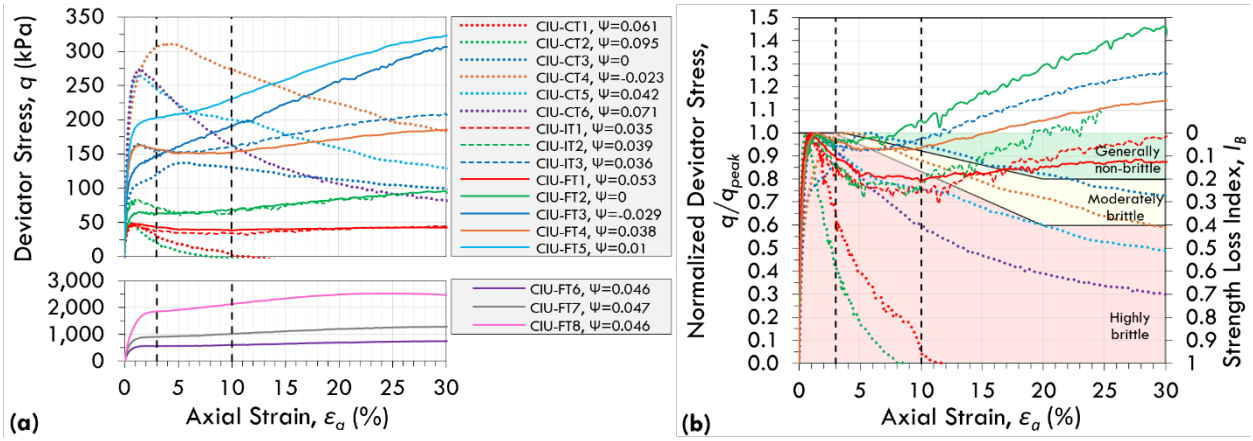

Figure 3: Strength loss behavior and brittleness assessment in CIU triaxial compression tests: (a) deviator stress vs. axial strain curves and (b) normalized deviator stress vs. axial strain curves on ICOLD (2022) brittleness chart

The majority of samples exhibiting strain-softening reach an initial peak value of q (q_{peak}) at a ε_a of 3% or less. Figure 3(b) presents the q/q_{peak} versus ε_a curves for these samples plotted on the brittleness assessment chart as defined by ICOLD. They lose more than 20% of their initial peak strength (i.e., strength loss index, $I_B > 0.2$) prior to reaching 10% strain and can therefore be characterized as "highly brittle" tailings according to the ICOLD criteria. However, it is noteworthy that six of these samples exhibit strain-hardening behavior at ε_a higher than 10%.

Cyclic and post-cyclic monotonic DSS testing

A total of nine constant-volume CDSS tests with post-cyclic monotonic shear were conducted between January 2021 and May 2024 in general accordance with the ASTM Standard Specification D8296 (ASTM, 2019). These tests were performed using a Norwegian Geotechnical Institute (NGI)-type simple shear

device. Table 4 summarizes the CDSS tests, indicating that 3 tests were performed on CT samples, 1 on IT samples, and 5 on FT samples.

Samples were prepared using the slurry deposition method, with solids content ranging from 72 to 73% and moisture content (w) between 36 and 37%. The specimens were formed in a shear ring measuring 71 mm in diameter and 30 mm in height.

Following the initial seating load, vertical stresses were applied at a load increment ratio of two until the target vertical stress was reached, which ranged from 24.5 to 497.5 kPa (0.24 to 4.9 atm) in the tests. Cyclic horizontal shear loads corresponding to cyclic stress ratio (CSR) values of 0.077 to 0.125 were applied at a frequency of 0.1 Hz until the samples reached a single-amplitude shear strain (γ) of 3.75%.

Strain-controlled monotonic shear loads were applied at the end of cyclic loading at a rate of 5% per hour until γ reached 20%. As shown in Table 4, three of the nine tests were completed at this point. For the other six tests, direction of the monotonic shear was reversed until a total of five shear loops were completed.

Table 4: Summary of CDSS testing with post-cyclic shear

Test ID	*FC* (%)	G_s	γ_d (kN/m³)	Vertical stress (kPa [atm])	*CSR*	No. of post-cyclic shear loop	s_r *ratio* from post-cyclic shear before reversal	s_r *ratio* from final shear loop	ψ
CDSS-CT1			12.8	99.8 [1]	0.083	5	0.1	0.02	0.012
CDSS-CT2	21	2.72	13.2	100 [1]	0.101	5	0.11	0.02	0.017
CDSS-CT3			13.3	100.1[1]	0.077	5	0.12	0.02	0.002
CDSS-IT1	49	2.66	13	497.5 [4.9]	0.11	5	0.07	0.02	0.061
CDSS-FT1			12.8	24.5 [0.24]	0.11	0 (no reversal)	0.23	NA	0.091
CDSS-FT2			13.1	49.5 [0.5]	0.1	0 (no reversal)	0.18	NA	0.059
CDSS-FT3	61	2.7	11.6	99.7 [1]	0.09	5	0.13	0.06	NA
CDSS-FT4			12.8	99.2 [1]	0.1	0 (no reversal)	0.16	NA	0.055
CDSS-FT5			12.6	100.3 [1]	0.125	5	0.13	0.05	0.06

Note: *FC* = fines content; G_s = specific gravity; *CSR* = cyclic stress ratio; s_r = residual undrained shear strength; Ψ = state parameter; NA = not available.

Since the stress state in a CDSS test is not fully defined, approximate values of Ψ were estimated and included in Table 4. The results of one post-cyclic DSS test per tailings type (CDSS-CT2, CDSS-IT1, and CDSS-FT5) are presented in Figure 4. Figure 4(a) presents the shear stress ratio (defined as the ratio of shear stress, τ, to σ'_{v0}) versus γ curves, while Figure 4(b) shows the excess pore pressure ratio (defined as the ratio of change in pore pressure, Δu, to σ'_{v0}) plotted against γ.

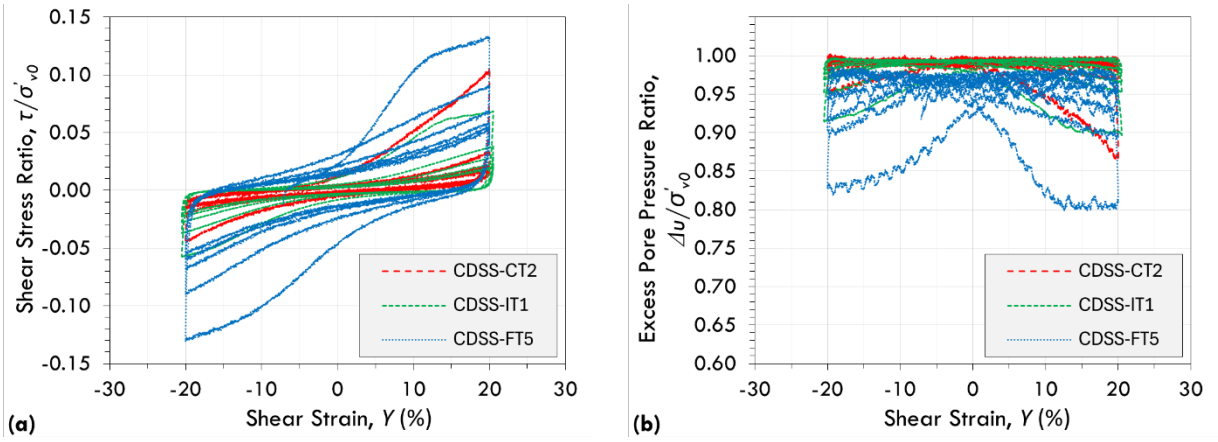

Figure 4: Post-cyclic shear response of tailings – (a) shear stress ratio vs. shear strain and (b) excess pore pressure ratio vs. shear strain

Figures 5(a and b) present the variation of s_r *ratio* and $\Delta u/\sigma'_{v0}$ with number of post-cyclic shear loops for all nine tests. As evident from Figure 5(a), s_r *ratio* values decrease rapidly, with approximately 30 to 70% reduction occurring during the first loop. The rate of decrease then slows during the second and third loops, ultimately stabilizing after the third loop. Conversely, the $\Delta u/\sigma'_{v0}$ values increase rapidly during the first loop and stabilizes after the third loop, as shown in Figure 5(b). Samples with lower $\Delta u/\sigma'_{v0}$ values throughout the tests yield higher values of s_r *ratio*.

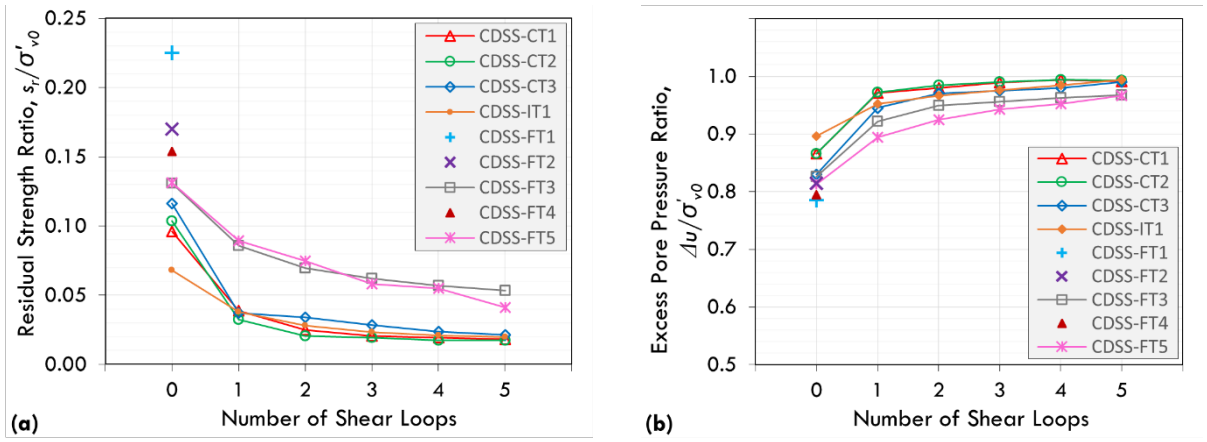

Figure 5: (a) Residual undrained shear strength vs. number of post-cyclic shear loop and (b) excess pore pressure ratio vs. number of post-cyclic shear loop

Residual strength ratio and effective vertical stress

Values of s_r *ratio* estimated from the CIU and post-cyclic DSS tests, as presented in Tables 2 and 4 respectively, are plotted against the normalized σ'_{v0} (σ'_{v0}/p_a, where p_a is the atmospheric pressure) in Figure 6. Published s_r *ratio* curves for other tailings by several researchers (Robertson et al., 2023; Schnaid et al., 2013; Jefferies and Been, 2016) are also included in Figure 6 for comparison. Generally, the s_r *ratio* values

increase with the *FC* of the tailings.

Figure 6 demonstrates that the triaxial tests yield higher s_r *ratio* values (represented by triangular markers) compared to the post-cyclic DSS tests for all tailings types, which is consistent with other published data. Although significant scatter in data exists, there is an observable increasing trend in the s_r *ratio* values, ranging from 0.1 to 0.46 as σ'_{v0}/p_a varied from 1 to 30. Note that the three data points with very high s_r *ratio* values at σ'_{v0}/p_a of 1.5 to 2 correspond to CIU tests in which the initial *e* values were very close to the CSLs, rather than being entirely in the contractive zone.

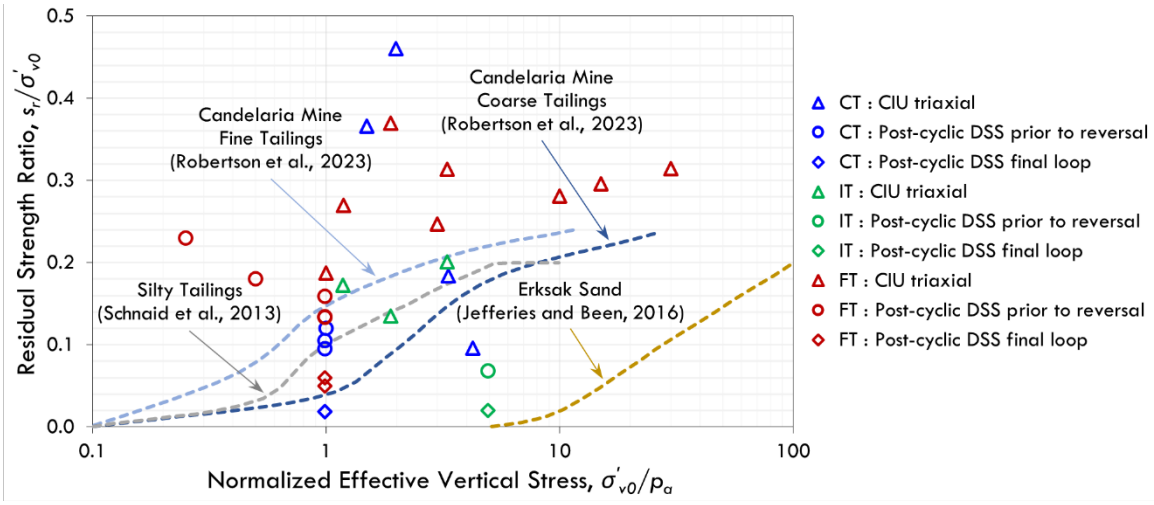

Figure 6: Variation of residual strength ratio of tailings with normalized effective vertical stress

The s_r *ratio* values from the post-cyclic DSS tests presented in Figure 6 include estimates based on the post-cyclic monotonic shear prior to load reversal for all nine tests. It also includes the post-cyclic final (fifth) shear loop results for the six tests where reversal loading was applied. The s_r *ratio* values from shear prior to reversal (represented by circular markers) range between 0.07 and 0.17, with σ'_{v0}/p_a varying from 1 to 5 for the three tailings types. The s_r *ratio* values from the post-cyclic final shear loop (represented by diamond markers) are significantly lower, ranging from 0.02 to 0.05. Due to the limited range of σ'_{v0} tested, no conclusive observations can be made in this study regarding the trend of s_r *ratio* with respect to σ'_{v0}/p_a from the post-cyclic DSS test data. A wider range of σ'_{v0} would be necessary to establish a definitive relationship.

Presented in Table 5 is a summary of four previous studies involving the estimation of s_r *ratio* values for various tailings from post-cyclic DSS testing. The reported s_r *ratio* values exhibit significant variation across these studies. The estimated s_r *ratio* values of the studied TSF tailings fall at the lower end of the published range, both in terms of prior-to-reversal and final loop results. However, the prior-to-reversal s_r *ratio* values (ranging from 0.07 to 0.17) appear to provide a more reasonable estimate. The authors intend

to compare these laboratory-estimated s_r *ratio* values of the studied TSF tailings with those derived using cone penetration test-based empirical correlations and the state parameter approach in a forthcoming paper.

Table 5: Summary of four previous studies involving post-cyclic DSS testing

Study	Tailings type	Sample type	No. of tests	*FC* (%)	*PI*	G_s	Vertical stress (kPa)	s_r *ratio* from post-cyclic DSS	s_r *ratio* from post-cyclic final shear loop
Wijewickreme et al., 2005	Laterite	U	9	93-100	12	4.1	100-200	0.41 to 0.6	No loop
	Copper-gold	U	4	97-99.6	NP	2.78	100	0.42 to 0.64	No loop
	Copper-gold-zinc	U	18	81.1-94.1	2	3.36-4.42	144-461	0.13 to 0.53	No loop
		R	3	97.6	1	3.67	100-250	0.27 to 0.33	No loop
Al-Tarhouni, 2008	Gold	R	23	> 70	2-3	2.89	100-400	0.1 to 0.36	No loop
James et al., 2011	Gold	R	5	55-80	NP	3.62-3.9	102-401	0.08 to 0.12	No loop

		R	4			NA	100	0.14 to 0.37	0.04 to 0.06
	Copper-zinc	U	4	80-100	0-3	NA	100	0.48 to 0.75	0.16-0.23
		U	4			NA	100	0.25 to 0.36	0.09-0.13

Note: *FC* = fines content; *PL* = plasticity index; G_s = specific gravity; s_r = residual undrained shear strength; U = undisturbed; R= reconstituted; NP = non-plastic; NA = not available.

Conclusion

The results of an advanced laboratory testing program designed to characterize the tailings within a large TSF for flow liquefaction evaluation were presented. A series of tests were performed on reconstituted tailings samples, including CIU and CID triaxial compression tests, as well as constant-volume CDSS tests with post-cyclic monotonic shear and reversals of shear loading to complete five loops. These samples had fines content ranging from 21 to 61%, representing the full range of contractive tailings present within the TSF. Critical state loci were formulated, and the associated tailings properties were derived for the various tailings types. The strength loss and brittleness behavior were evaluated, indicating the presence of highly brittle materials within the TSF. Residual strengths of the tailings were estimated from the CIU and post-cyclic DSS tests. The CIU tests generally yielded higher residual strengths compared to post-cyclic shear. Residual strengths from post-cyclic shear prior to reversal were significantly higher than those from the post-cyclic final shear loop. The prior-to-reversal residual strength ratio values (ranging from 0.07 to 0.17) appeared to provide a more reasonable estimate. The impact of vertical stress on residual strength was examined, revealing a noticeable increasing trend in triaxial test-based estimates. However, due to limited post-cyclic DSS test data across a broad range of vertical stresses, definitive conclusions regarding this relationship could not be established.

Acknowledgements

The authors would like to express their sincere gratitude to the mine personnel involved in the TSF management for granting permission to publish the data.

TAILINGS AND MINE WASTE 2024

Improving Tailings Deposition: A Drone and Satellite Survey Validation Framework for Enhanced Facility Management

Abstract

To enable continued deposition at the Aitik Tailings Management Facility (TMF) during a period of remediation works since 2022, it was necessary to reconfigure the tailings deposition plan to divert the deposited tailings and surface water to a different area of the facility. The Aitik TMF, owned by Boliden AB, is a sidehill impoundment formed by a contiguous sequence of dams. An unusual feature of this facility is that all the perimeter dams are constructed at different elevations, such that the dams at the bottom of the original valley are at a lower elevation than those at the top of the original valley.

Historically this simplified tailings operations, but it added complexity when it was necessary to reconfigure the deposition arrangement for this period of remediation works. A temporary exclusion zone for deposition near the downstream dams had to be demarcated on the surface of the tailings impoundment via the construction of rockfill "piers" to redirect annual deposition of tailings (43 Mtpa) and water towards a newly constructed spillway located south of the previous spillway.

Deposition modeling was performed using Muk3D Tailings+ Software by MineBridge to simulate short- and long-term deposition with the construction of rockfill piers to assess the effect on shaping the TMF tailings surface and water contours towards a new sedimentation pond and spillway. Due to the complexity of the deposition modeling and sequencing of the deposition with construction of additional piers, the deposition modeling has been updated on an ongoing basis and calibrated against field monitoring data.

To assess the validity of the models, regular as-built drone (weekly) and satellite (monthly) surveys (including high resolution photographs) were recorded and compared with models processed by Muk3D Tailings+ simulations monthly. The implementation of a validation framework for tailings deposition operations through the integration of drone and satellite survey data has allowed Boliden to continue normal deposition operations despite a temporarily exclusion of its Downstream Dams until April 2025.

Introduction

The Aitik Mine is an open-pit copper mine located approximately 15 km southeast of Gällivare in the Arctic region of northern Sweden. Waste tailings generated from mineral ore processing at the mine are deposited hydraulically within the Aitik tailings management facility (TMF) for storage, with approximately 1,000 Mt of tailings deposited to date. The current TMF footprint covers an area of ≈15 km^2, impounded by 10 km of continuous perimeter embankments around the eastern, northern, and western extents, and partially by natural ground and Dam V2 in the south (see Figure 1).

Figure 1: Satellite imagery/overview of the Aitik TMF, dated May 31, 2024

All the perimeter dams are constructed at different elevations that reflect the grade of the natural topography, such that the dams at the bottom of the original (i.e., pre-construction) valley are at a lower elevation than those at the top of the original valley. This has the benefit of allowing deposition to occur primarily from the dams at a higher elevation (referred to as the *Upstream Dams* and Dam H-S), denoted as Dams H-S, H-S2, A-B2, A-B, C-D and C-D2, using gravity to form an average beach slope of 0.4% towards the dams at lower elevation (referred to as the *Downstream Dams*). The original cross-valley or sidehill impoundment dams are up to approximately 70 m high, following periodic expansion to increase storage capacity. The existing tailings impoundment dams are currently being raised using the upstream construction method.

Boliden has committed to complying with the Global Industry Standard on Tailings Management (GISTM, 2020). Under GISTM, the TMF has a consequence classification of *"Very High,"* and a design flood with a 5,000-year return period is recommended. Under the Swedish Mining industry's (SVEmin)

dam safety guideline (GruvRIDAS, 2021), the TMF has a consequence classification of *"Klass B,"* and the Class 1 Flood is recommended. The Guidelines for Design Flood Determination for Dams states that the Class 1 Flood has an annual probability lower than 1:10,000, implying that the Class 1 Flood, calculated according to the Guidelines, is a more significant event either in volume, peak inflow, or both, than the GISTM recommendation.

Following geotechnical investigations, an extensive remediation program was put in place to improve the stability of the Downstream Dams (Boliden, 2023), denoted as Dam E-F/E-F2 and Dam G-H/G-H2 (refer Figure 1). As part of the remediation measures (Girard and Quinn, 2024), a temporary exclusion zone was demarcated in June 2022 from Dam G-H2 through Dam E-F2. The design objective of the exclusion zone was to redirect water and tailings towards the new *"U3 spillway,"* located south of the existing *"U2 spillway."* The aim was mitigating tailings and water from accumulating near the Downstream Dams (while the remediation measures were implemented).

To achieve this aim, a series of rockfill piers (Piers 1-2, 3-4 and 5-6) was designed and constructed on the tailings surface to retain tailings and re-shape the TMF surface contours towards the U3 spillway (see Figure 1). The typical pier design comprises a 20 m wide crest with a maximum height of 5 m from the tailings surface, with 2H:1V side slopes and the inclusion of a 25 m wide × 2 m high support buttress constructed immediately downstream (see Figure 2). All piers are constructed from non-frozen granular mine waste rockfill. Where required, Combigrid 40/40 GRK4 geogrid was laid directly on top of the tailings surface to improve the bearing capacity for plant/machinery during construction and to reduce settlement of the rockfill into the underlying tailings.

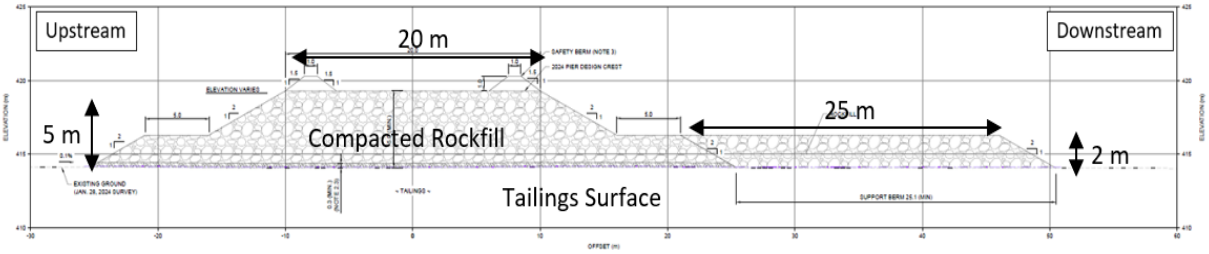

Figure 2: Typical cross-section of a TMF rockfill pier

Although water (including fine tailings) was expected to permeate through the piers, an interceptor drainage ditch was constructed downstream of the lowest pier (Pier 1 – see Figure 1) to redirect water southwards and away from the Downstream Dam exclusion zone. If a significant accumulation of fine tailings developed in the sedimentation pond downstream of Pier 2, this was removed using either mechanical excavation, dredging, or a combination of both.

The piers were constructed over time as a function of tailings deposition to maintain a maximum tailings longitudinal slope less than 2% between piers. The pier design, with a maximum height of 5 m and spaced 300 m apart upstream in the TMF (centerline to centerline), was intended to limit the potential for a runout failure into the Downstream Dams region, should failure of a pier occur. This is to maintain an overall slope that is flatter than the lower-bound post failure ground slope angle of liquefaction case histories (Martin et al., 2019).

A trapezoidal broad-crested weir was designed at Piers 2, 4 and 6 to safely pass the Class 1 Flood and allow it to flow to either the U2 or U3 spillway. The weir freeboard (weir invert to pier crest level) is set to 1 m, which allows for at least 4 m of operational tailings capacity retained for each set of piers.

Methodology

To forecast whether the constructed pier configuration would be successful in re-shaping the contours of the TMF surface until the restart of operations at Dam E-F/E-F2 and Dam G-H/G-H2, planned for April 2025, deposition simulations were initially performed in MUK3D Tailings+ by Minebridge (MUK3D). Once finalized, weekly and monthly drone and satellite surveys of deposition operation were subsequently undertaken to validate and regularly re-calibrate the short- and long-term MUK3D simulations (1 month to 3 years), respectively. Additionally, simulations were used to forecast the stage-capacity for each constructed pier to plan the construction of the subsequent set of piers.

This section initially describes the survey files referenced and the input parameters used in MUK3D prior to running deposition simulations. Subsequently, the methodology regarding the deposition analyses is outlined, with a description of how these were validated on site using drone and satellite technology.

Drone and satellite surveys

Weekly drone and monthly satellite (1 m) surveys, including high-resolution (50 cm) orthophotographs, were delivered to Klohn Crippen Berger (KCB) by Team EXACT (surveyors) and PhotoSat Survey Services, respectively. The Coordinate Reference System (CRS) used is *"Aitik Local,"* which is a local site-specific CRS based on SWEREF99 2015 – EPSG:3016. The height datum referenced is *"RH00,"* which involves a correction of 0.79 m from *"RH2000"* based on the Swedish national height system from 1900.

Satellite surveys (including high-resolution orthophotographs) were used as the primary ground reference tool, given the wide coverage of surface area available in a single record. The weekly drone surveys were used as a backup reference tool when inclement weather or winter conditions meant a clear satellite record was not possible (usually because of excess cloud cover). The disadvantage with using drone surveys was that only a quarter of the full extent of the deposition area could be covered weekly, meaning

that 4No. weekly surveys would be "stitched" together with Quantum Geographic Information System (QGIS) software to represent a monthly survey.

MUK3D parameters

The input parameters that were used when running simulations in MUK3D are as follows:

- **Tailings production** – Storage of a maximum of 43 Million tonnes per annum (Mtpa) of tailings upstream of the pier configuration based on Boliden plant requirements, equating to 3.58 Mt per month.
- **Tailings pipeline discharge locations –**Tailings pipeline discharge at the Aitik TMF occurs solely from the Upstream Dams (see Figure 1) during this period while the exclusion zone is in place. The Boliden deposition plan operates 3No. and 4No. pipelines during the summer (June to September) and winter (October to May) months, respectively. The total tailings production was divided by the number of pipelines depending on the seasonal requirements; e.g., 25% per pipeline for summer and 33% per pipeline for winter conditions. The multi-stream deposition function was applied in MUK3D to represent the above.
- **Dam raising** – Dam raising at the Aitik TMF is performed using the upstream dam methodology, which involves sourcing tailings from the deposited beach as construction material for the subsequent dam raise. Operations at the Downstream Dams were paused, hence no dam raising was modeled at Dam E-F/E-F2 and Dam G-H/G-H2. The Upstream Dams comprise a +3 m raise in dam crest per year, typically constructed during the summer months to the beginning of the winter months, depending on annual plans (typically June to October).
- **Pipeline discharge parameters –** Each pipeline comprises spigot discharge points spaced 40 m apart along its length, with a primary outlet at the end of the pipeline. Modeling assumptions considered that 70% of the total pipeline discharge would be spread across the number of individual spigots points, while 30% would report to the end of the pipeline. This was based on KCB estimations of pipeline flow rates based on relative accumulation depths observed on site.
- **Tailings density** – Tailings slurry dry density equal to 1.4 tonnes/m^3 based on material testing records received from Boliden.
- **Tailings beach slope (%)** – Overall TSF average longitudinal beach slope (equal to ≈ 0.4%) and compound beach slope parameters based on LIDAR surveys of the facility conducted prior to the construction of the piers (pre-2022). The input of compound slope parameters shapes the characteristic TMF beach over a defined incremental distance (see Table 1), while maintaining an average slope specified (0.4%) over the full length of the beach.

- **Water management (pond)** – Deposition simulations in MUK3D did not include the modeling of a water pond, as the pier system constructed from granular waste rock material was assumed to be free-draining towards the U3 Spillway.

Table 1: MUK3D Compound slope parameters

Incremental distance (m)	Beach slope (%)
191	1.73%
154	0.74%
901	0.49%
2,113	0.31%
824	0.26%

Analyses and validation

Monthly cumulative MUK3D deposition analyses were performed to forecast and simulate deposition operations up to April 2025 (from June 2022), with the most recent satellite surveys used as the topographical reference in the model. Because of the uncertainty in calibration of the modeling to actual operations, a validation framework was progressively introduced. Calibration of the MUK3D analyses was performed by comparing monthly MUK3D models with as-built surveys every month.

An example of a typical monthly deposition plan for input into MUK3D is shown in Figure 3. Figure 3 illustrates the December 2024 deposition plan, whereby 3No. pipelines, denoted as SL5, SL3 and SL4, are depositing from Dam A-B and C-D. SL1 and SL2 located on Dam H-S and near H-S2 are shown as inactive for this month, given previous months of deposition in this region.

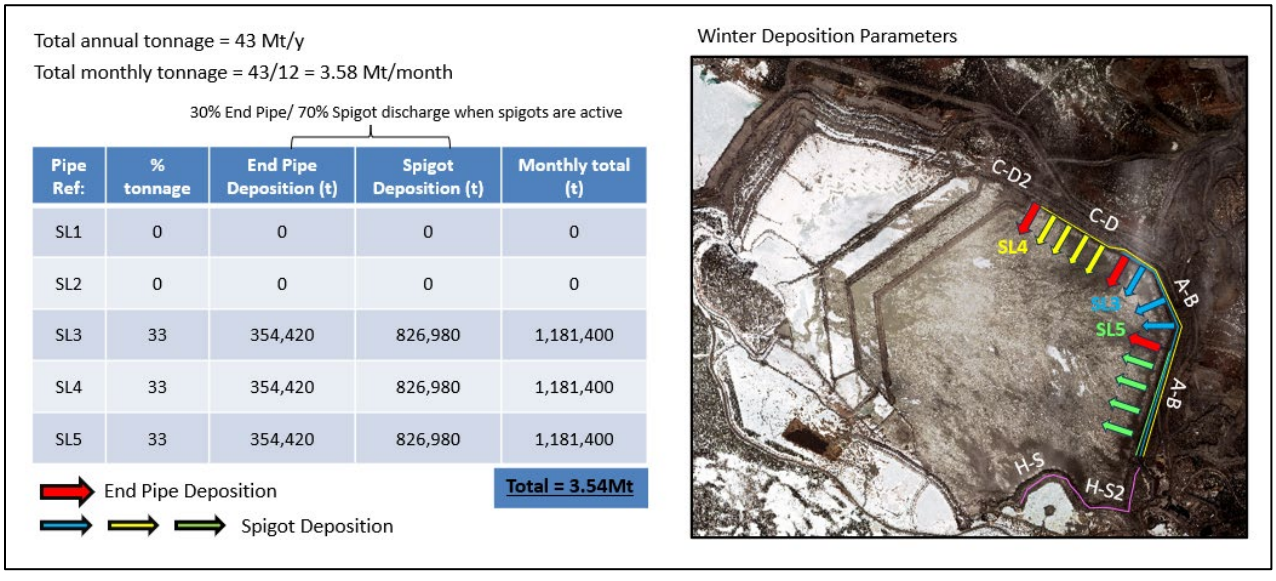

Figure 3: Example of monthly deposition plan – December, 2024

Short-term validation and iterative calibration are essential because they provide the mine with confidence that the long-term plan can be achieved. The dynamic nature associated with deposition means that a plan is subject to regular updates. For deposition modeling and validation to be successful, the following were performed on a regular basis:

- Comparing as-built tailings beach slope (%) and monthly Rate of Rise (RoR) data with the MUK3D models across the TMF deposition area (upstream of the piers).
- Assessing hourly tailings production and deposition data received from the Boliden Mine plant for each pipeline.
- Tracking the position and operational status of end pipes and spigots on the TMF via site inspections by KCB and Boliden personnel.
- Assessing the overall TMF contour surface shape to assess whether the deposition plan adopted is redirecting water towards the U3 Spillway as planned.
- Evaluating upstream beach capacity to inform pipeline deposition planning and construction of subsequent dam raises.
- Re-calibrating long-term deposition assumptions based on recent as-built survey data updates.
- Bi-weekly meetings with the Boliden operations team for scheduling of construction and deposition activities, with an emphasis on regular client-consultant communication.

Observed changes to MUK3D forecasts would necessitate iterative re-calibration of short and long-term deposition simulations, whether this be refining initial MUK3D parameters to suit, accommodating unexpected changes in pipeline production, or adjustments in planning for potential delays in construction activities (e.g., dam raising). While all the above items are good practice for regular deposition planning, there was a heightened focus on achieving reliable forecasts for the current scenario because of the need to avoid deposition in the exclusion zone and the need to sequence construction of subsequent piers at the right time.

Additionally, as the project progressed, previous surveys provided a site-specific historical database for identification of deposition trends within the TMF, which improved the accuracy of deposition projections. This also benefits early detection of potential deviations, which becomes a tool for proactive management of deposition operations on the TMF, whether that is sequencing construction for the next set of piers or planning annual Upstream Dam raises.

Results and discussion

This section outlines the results from the MUK3D simulations, including the validation undertaken to date. Deposition planning/MUK3D iterations indicated that preferential deposition along Dam C-D and the northern part of Dam A-B would assist in shaping TMF contours towards the U3 Spillway (see Figure 3).

The MUK3D models and as-built records both indicated that the RoR of the tailings surface adjacent to the pier would range between 0.3 m and 0.4 m per month (on average). By measuring the clear height between the pier crest and the abutting tailings surface, it was possible to forecast the remaining tailings capacity upstream for each set of piers.

Figure 4 illustrates the long-term cumulative deposition model, which indicates that Piers 5-6 would likely reach full capacity by April 2025. This is indicated by the Δ0.1m elevation difference between the tailings surface and the nearby invert level of the weir located on pier 6. Colors represent relative elevation with red-yellow shades being higher elevations, and green shades being lower elevations.

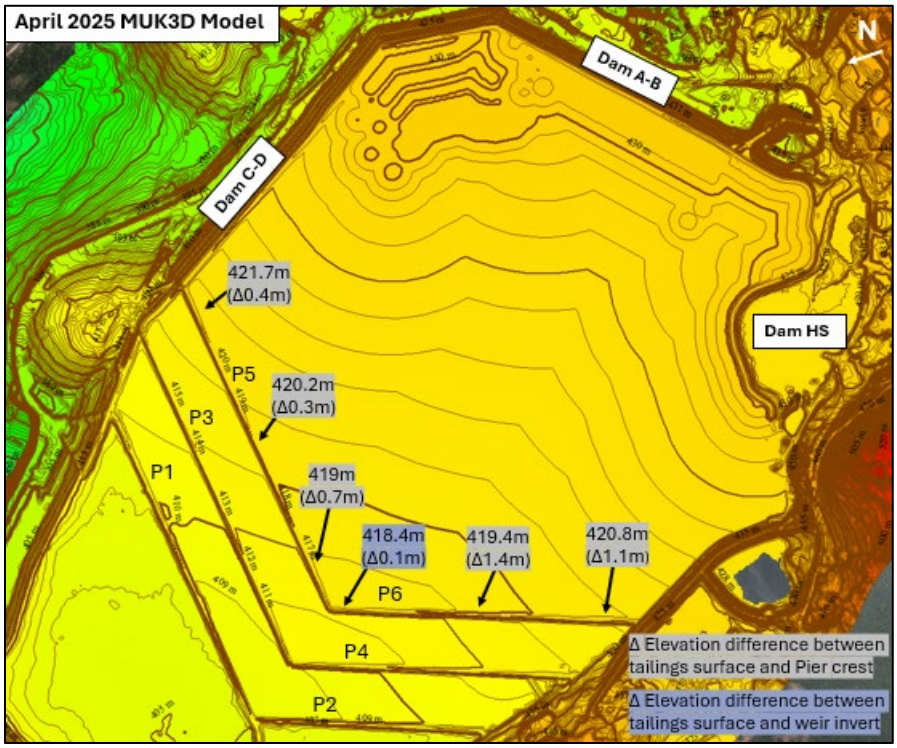

Figure 4: Cumulative MUK3D model projection for April 2025

Challenges encountered

Operational constraints meant that between September and December 2023 deposition of tailings was not possible from the northern Dams C-D and A-B. By January 2024, three months of central deposition from Dam A-B resulted in an altered TMF tailings surface contour shape that sloped predominantly towards the Downstream Dams – see Figure 5 (left). As a result, an increase of water flow conveyed to the U2 Spillway was reported on site.

A modified short-term deposition plan to re-shape the TMF tailings contour surface towards the U3 Spillway was required. The plan focused on placing pipelines and depositing primarily from the northern part of Dams C-D and A-B for an extended period (3 to 4 months) until May 2024. The execution can be

seen from satellite imagery recorded during the winter months, dated March 10, 2024 (see Figure 6). By May 2024, the survey record in Figure 5 (right) showed that the short-term objectives had been achieved.

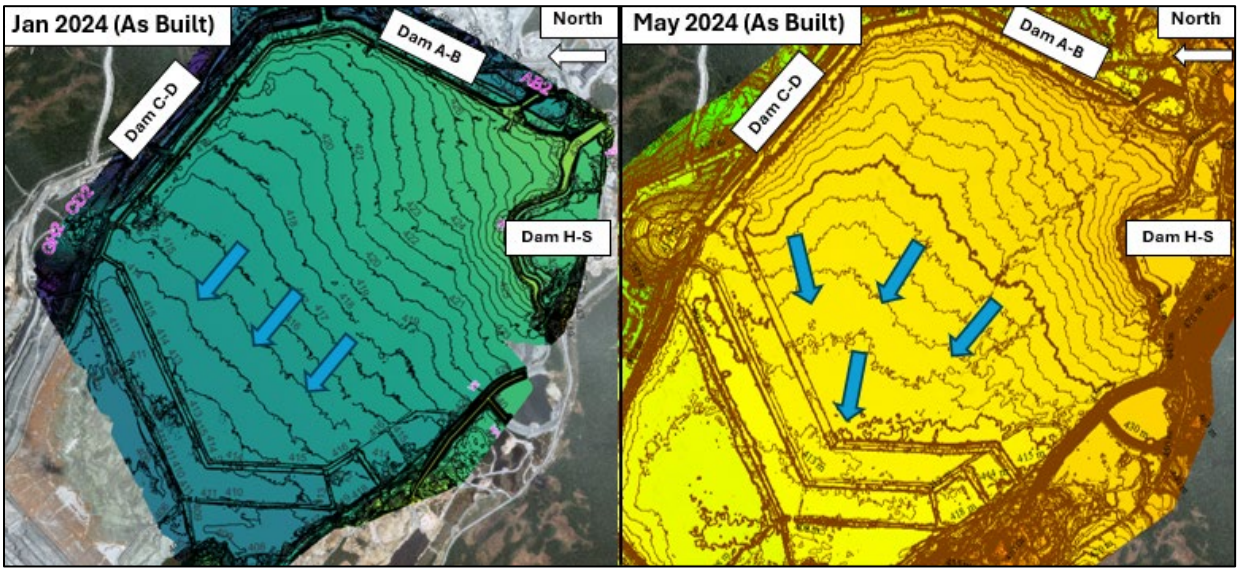

Figure 5: As-built comparison records between January 2024 (left) and May 2024 (right)

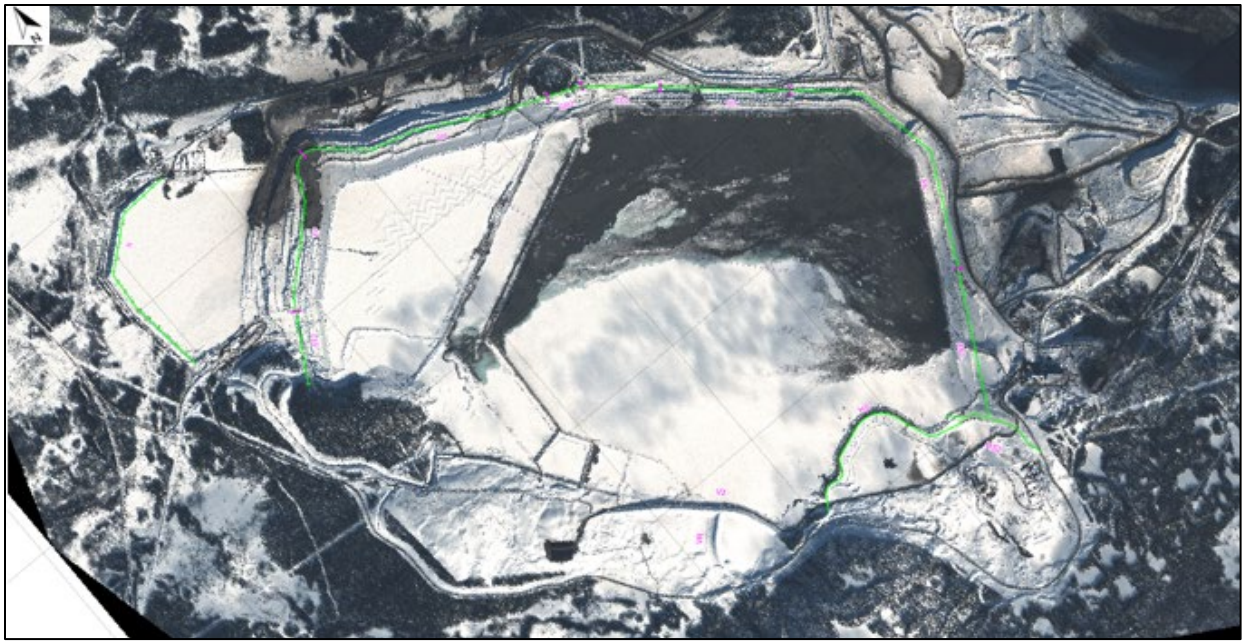

Figure 6: Satellite imagery of the Aitik TMF dated March 10, 2024

A comparison of the tailings surface in the section immediately upstream of Piers 3-4 in Figure 7 shows that approximately 2 to 3 m of tailings was placed in the northern portion of the TMF between January 6 and May 5, 2024. To maintain the longer-term deposition plan, it is essential that the shape of the

tailings surface remains parallel to the MUK3D long-term target for that month (demonstrated by the black dashed line in Figure 7).

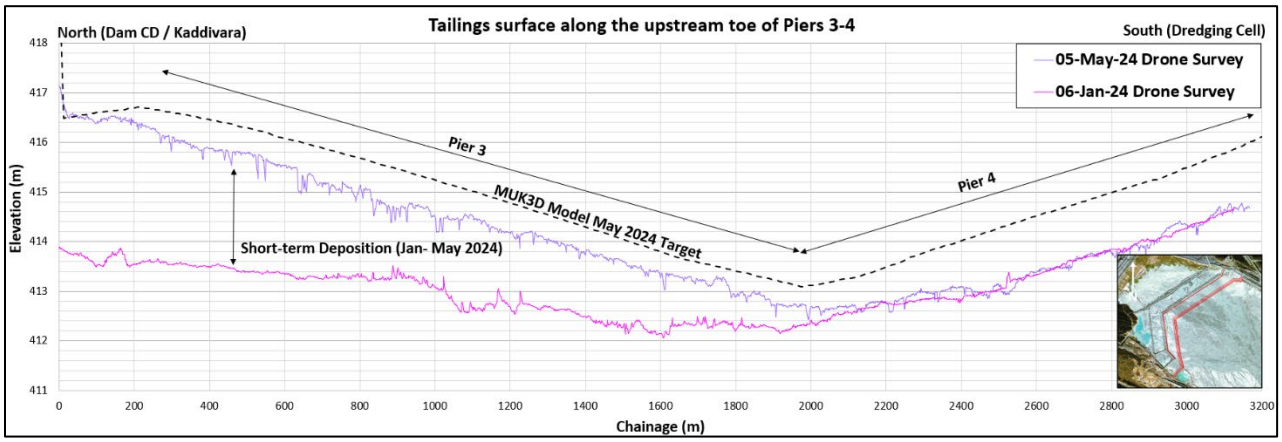

Figure 7: Elevation of the tailings surface along the upstream toe of Piers 3 and 4

Figure 7 shows that in January 2024, it was identified that the tailings surface was too flat. However, by May 2024, the TMF tailings surface was successfully re-shaped relative to the long-term target as expected. Although the shape of the May 2024 survey is parallel to the May 2024 MUK3D target, it is observed below expected targets – this indicates that less tailings were placed into the TMF by May 2024 than initially expected. Upon further investigation of plant production data, it was noted that the tailings deposition rate had temporarily decreased from 43 to 41 Mtpa during this time. Upon discussion with Boliden, this was not considered as an input parameter change in the future and did not necessitate a full re-calibration of the long-term model to April 2025 (Figure 4).

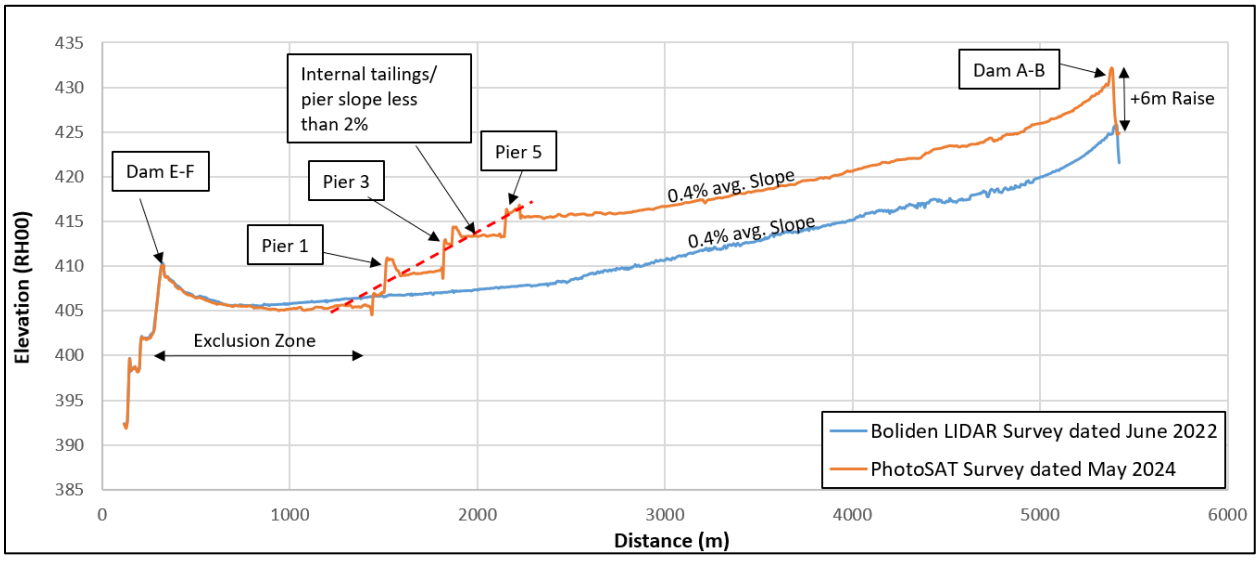

Figure 8: Longitudinal TMF survey comparison

To conclude for operations to date, a comparison of TMF surface surveys between June 2022 and May 2024 (see Figure 8) shows that the pier system has allowed Boliden to continue normal deposition operations as planned to date; thereby facilitating continued operations at the TMF during this period while the exclusion zone is in place at the Downstream Dams.

Figure 8 shows that the pier system has maintained a slope of less than 2%, while the exclusion zone has not accumulated additional tailings since June 2022. Conversely, observations in the exclusion zone show that the tailings surface has decreased in height by up to one meter, likely due to consolidation of the tailings mass beneath.

Conclusion

As demonstrated in this paper, three sets of piers (Piers 1-2, 3-4, and 5-6) were constructed on the TMF surface by May 2024, each providing tailings capacity for a maximum of one year of operations (as initially forecasted in MUK3D). With Piers 5-6 recently constructed in April 2024, it was expected that a total of approximately 122 Mt of tailings would be deposited in the Aitik TMF from June 2022 to April 2025 whilst preventing additional loading and pore pressure at Dams E-F and G-H.

The implementation of a validation framework for tailings deposition operations through the integration of drone and satellite survey data has allowed Boliden to continue normal deposition operations despite a temporarily exclusion of its Downstream Dams until April 2025.

The dynamic nature associated with deposition means a plan is subject to regular updates. As demonstrated, deposition forecasting is only as reliable as the accuracy of the input parameters, which must be maintained regularly. When unexpected operational scenarios occur, MUK3D modeling in combination with the established validation framework can reliably forecast alternative options to mitigate the effect of operational deviations through effective client-consultant communication.

Risk Management for Access to Dams at Emergency Level Control: Control Levels (OMS Manual) and Safety Plan

Abstract

Following recent accidents at tailings dams, countless efforts have been made to implement and improve governance models capable of effectively managing the risks involved. The main governance model is the Global Industry Standard for Tailings Management (GISTM), comprising 15 Principles that integrate various disciplines to prioritize the management and safety of tailings structure facilities. Among these, Principle 6 emphasizes the importance of implementing Operation, Maintenance, and Surveillance (OMS) Manuals, which serve to provide critical controls for safe operations. While the implementation of these principles does not guarantee dam stability, they can form crucial barriers for efficient risk management.

A project was therefore developed to enable conventional access for workers to tailings dams with restricted access due to an emergency condition having been established. The objective of the "Emergency Level Dam's Access Plan" is to establish monitoring measures, their corresponding control levels, and criteria for activating TARPs – Trigger Action Response Plans, to be adopted during the execution of essential activities aimed at enhancing the structural integrity that may be compromised during periods of restricted access to the dams. This information was integrated into the OMS Manual to ensure safe operations and facilitate communication and evacuation plans during maintenance, inspection, and monitoring activities, especially in the event of any change indicating a potential rupture.

The implementation of integrated controls and communication flows has enabled the safe execution of necessary monitoring, inspection, and maintenance activities, through conventional access by workers to the structures' Self-Rescue Zone. The efficacy of implementing the Access Plan is validated by the considerable improvement in the dams' state of conservation, including the removal of emergency level

from one of the structures covered, as well as by a notable reduction in the number of outstanding anomalies in these tailings storage facilities.

Introduction

Dam safety management is of paramount importance to prevent disasters and environmental damage and protect lives. Dam failures can cause devastating impacts and correct management requires a multidisciplinary approach, combined with current legislation and best engineering practices.

In 2010, the National Dam Safety Policy (PNSB) was established in Brazil through Law 12.334, and since then, several national and state regulations have been published focusing on dam safety. In 2020, Law 14.066 amended the PNSB with respect to various safety aspects, mainly focusing on dams raised upstream. This included the prohibition of this methodology for building new dams, further reinforcing the need to eliminate existing upstream dams in the country.

In addition to federal laws, two other regulations are worth highlighting: Law No. 23.291, which establishes the State Dam Safety Policy that defines safety aspects, self-rescue zones, emergency response plans, and environmental issues, and Resolution No. 95/2022 of the National Mining Agency (ANM), which details various aspects of mining dam safety management. Regarding compliance with legislation, mining companies must register their dams in the official government system, keep the information up to date and submit, among other documents, declarations of stability conditions (semi-annually), as well as provide details of any anomalies and changes to the dams that have been detected with regular and special inspections.

These regulations also define matters related to the potential damage associated with the structure and its risk category, both related to possible failures. Depending on the risks mapped in the classification matrices, a dam is associated with a certain emergency level, indicating that it failed to meet the criteria of current legislation and/or safety factors for normal stability conditions.

It is important to highlight that any dam project, in the design, operation and closure phases, must prioritize the integrity of the geotechnical structure and, above all, guarantee the safety of workers involved in all stages of the dam's useful life.

This project called the "Emergency Level Dam's Access Plan" fits into this context of dam management with a focus on prior planning of activities, worker safety, and an efficient solution for dealing with anomalies, pursuing continuous improvement of the structure. This methodology has been applied for almost two years in six Brazilian dams, including three raised upstream, at different emergency levels in accordance with current Brazilian legislation, one raised by center line and one dam built in a single stage. The results obtained are positive and made it possible to reduce risks, improve the state of conservation of structures, and improve safety controls for the workers involved.

Methodology

The premise of the Access Plan is to guarantee the safety of workers when carrying out essential monitoring, inspection, and maintenance-related activities of dam structures, without increasing the geotechnical risk to the structure.

This Plan is a document prepared and then revised by the company's technical team (Geotechnics and Occupational Safety) whenever improvement points are identified, coordinated by the dam's Technical Specialist in Tailings Management (RTFE) and validated by the Engineer of Record (EoR). It consists of a safety protocol made up of three main documents:

1. Safety Plan: a document that defines the basic occupational health and safety guidelines for the workers, establishing responsibilities, procedures, training, and actions that must be adopted to carry out previously approved essential activities.
2. Activity Planning: a document that clearly and objectively summarizes the survey of all necessary maintenance and repairs in compliance with current regulations.
3. Geotechnical Monitoring Plan: a document that establishes the set of existing monitoring instruments, their respective levels of control, and the associated Trigger Action Response Plans (TARPs) to be considered during the execution of essential activities to maintain the conservation condition of the structures, these being defined within the OMS Manual for each dam.

These three documents form a safety protocol that details what must be done, how it must be carried out, the deadline for each activity, the number of people involved, specific training, the monitoring systems that must be working, and the TARPs.

The basis of the Access Plan are the TARPs, as they reflect the dam's performance based on the control levels of the different monitoring instruments (such as piezometers, radars, ETR and microseismic), indicating whether these are within the pre-defined limits considered safe, which can allow people to access them in a conventional way. Therefore, if any instrument considered critical for granting access is not functioning properly, activities are suspended until it returns to operation.

The control levels of the instruments and their respective TARPs are defined in the Operation, Maintenance and Surveillance Manuals (OMS Manuals) and are specific to each dam, based on its individual technical characteristics. Based on the control levels defined for each instrument (attention, alert and emergency), four TARPs were associated that indicate variations in monitoring data or anomalous conditions observed in field inspections, identifying the need to start the action protocols in response to deviations.

The TARPs defined are:

- TARP 1 – Green TARP or normal operating condition;
- TARP 2 – Yellow TARP or low risk alert condition;
- TARP 3 – Orange TARP or moderate risk condition;
- TARP 4 – Red TARP or high-risk condition.

Brazilian legislation defines the emergency levels of dams through the association with safety factors obtained through flow and stability analyses considering drained and undrained conditions of the structures. Commonly, the definition of instrumentation control levels (attention, alert, and emergency) is also linked to the safety factors obtained in stability analyses, as shown in Table 1.

Table 1: Levels of controls, TARPS and associated safety factors

MANAGEMENT LEVEL	TARP/ Color	Peak Undrained Safety Factor		Correspondence with the Emergency Levels provided for in ANM Resolution No. 95 (2022) for Peak Undrained Safety Factor. (Art. 41) [1]
Normal	TARP 1	1. 0		–
Warning	TARP 2	1. 0	1. 0	Emergency Level 1
Alert	A P	1.00	1. 0	Emergency Level 2
Emergency	TARP 4	1.00		e en e el

[1] The correspondence between TARPS and the Emergency Levels provided for in ANM Resolution No. 95 (2022) is strictly related to safety factors. Other aspects that can classify the structure according to the Emergency Levels provided for in this legislation are not included in the Table.

An example control level for instruments that measure interferometry, such as ground-based radars or Robotic Total Stations (ETRs), is shown in Figure 1.

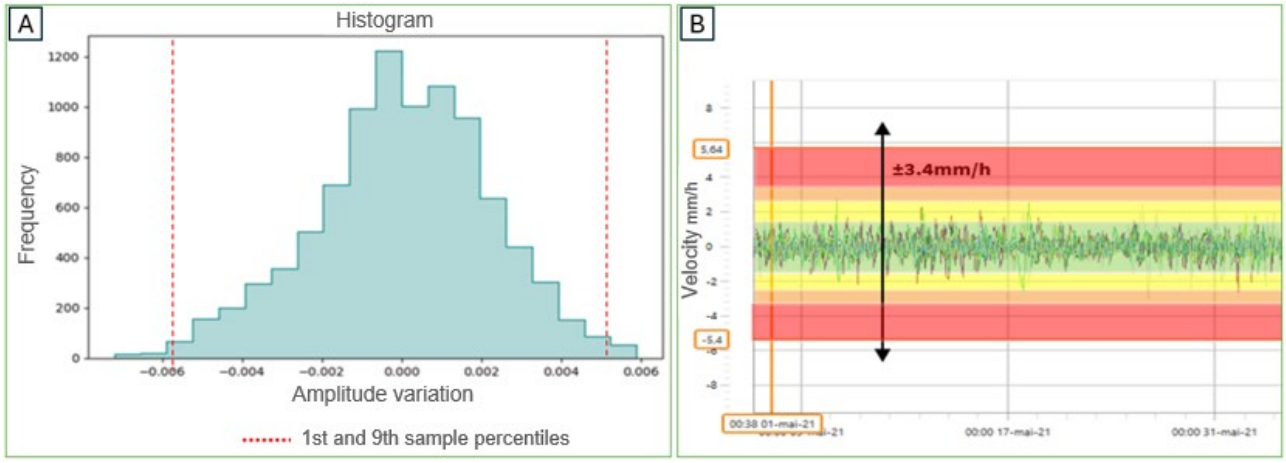

Figure 1: Example of control level for an interferometric radar. (A) Analysis of the distribution of displacement speed (B) Methodology for defining control levels

The definition of individual control levels for each piezometry instrument was based on percolation/ seepage analyses carried out in a 3D model using the Rocscience RS3 software. This model considered the finite element method and saturated and unsaturated flow conditions in a steady state. Based on individual control levels, it was possible to divide the dam into sectors, considering the behavior of piezometers and water level indicators through an individual calculation of the hydraulic loads observed in each sector, and associating the position and level of importance of the instrument with the respective minimum safety factors obtained in the analysis. The result is the maximum TARP for each region of the dam. It is important to highlight that the overall TARP of the structure represents the highest TARP (worst condition) observed in the assessments of the individual sectors.

For this assessment to occur in real time, it is important that readings from manual instruments are automated. Instruments considered critical were automated and the monitoring system sends data 24 hours a day, which is a premise for the access protocol. Figure 2 shows how the level of control is applied to each region of the dam.

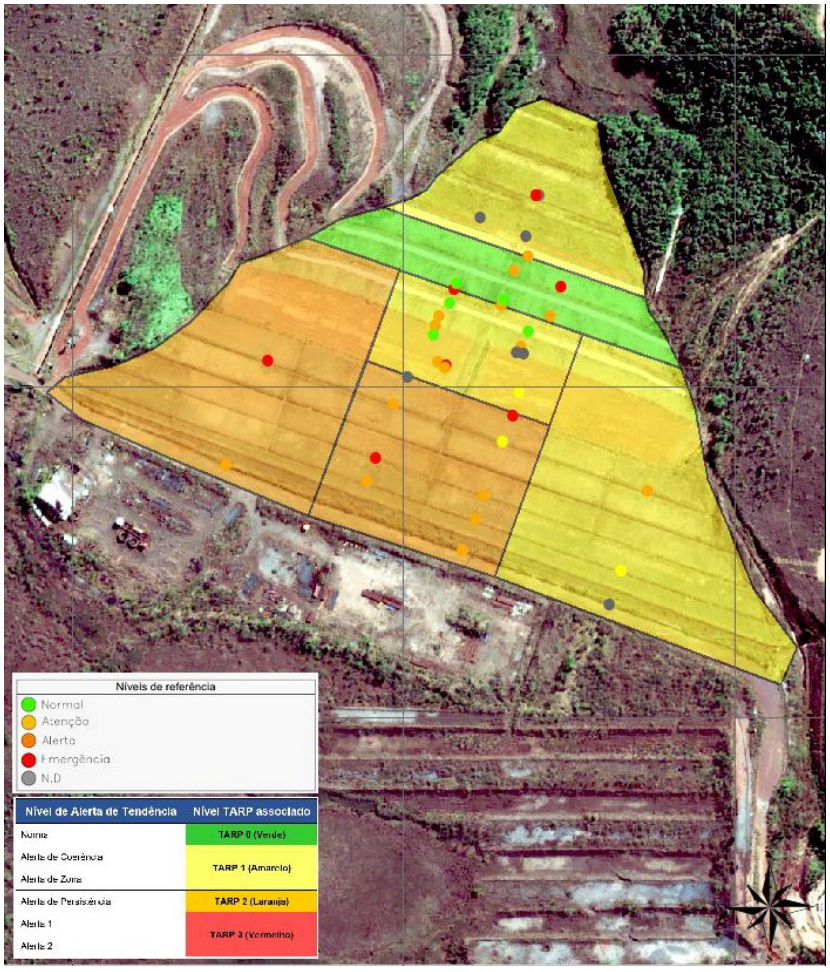

Figure 2: Control levels and TARPs applied to piezometers

It should be noted that in addition to the control levels established for embankment's piezometry and water level indicators, control levels were also established for displacements, water level in the reservoir, and allowable vibrations.

As mentioned, Deviation Response Action Protocols are tools designed to assist in risk management, according to performance criteria based on risk controls and critical controls of the tailing facility. The activation of each TARP is associated with a particular communication flow depending on its severity, and its main objective is to mitigate consequences, which must be checked periodically or on demand.

Automated graphs and tables were created, and every morning a one page report is sent describing the system's operation throughout the night. It includes any anomalous situations observed. This report is analyzed by the geotechnical team, which authorizes access to the dam and area of influence defined in a Dam Break analysis. This cycle of evaluating the conditions of each dam is repeated every new day. The automation of systems and reports previously formatted in software is essential to avoid human error.

An emergency TARP is not expected to require evacuation or access restrictions. In TARP 2, monitoring of the entire structure is intensified. When changing from TARP 2 to TARP 3, it is preventatively requested that activities be interrupted, and employees be evacuated. Activities are resumed after a detailed assessment by the structure's RTFE and EoR, detailing the reasons and likely consequences for activating the TARP, in addition to the assessment of the risks vs. benefits of the activities being continued. TARP 4 activation blocks routine access of people to the dam until a more favorable condition is restored.

Access plan operationalization

The cycle starts with the Activity Planning of essential elements, contained in maintenance planning. This document contains all the anomalies, audit recommendations, monitoring plan, and works necessary to guarantee the safety of the dam. From this, the activities are detailed in terms of execution productivity, number of people, and specific services, such as the use of tools or equipment. Also, in the Planning phase, the work procedures and safety requirements that must be met are evaluated.

The workers involved in the activities must undergo specific training on access, focusing on compliance with safety evacuation rules, and detailing escape routes, access control procedures and communication plans. All these requirements are found in the Safety Plan.

On the day that the activities begin, the conditions of the dam are evaluated through a one page report, which considers the TARPs (explained in the previous item) and is used to determine whether a certain activity is called for or not. This is detailed in the Geotechnical Monitoring Plan. When necessary and authorized, professionals fill out specific documents, such as a Preliminary Task Analysis, and request a

Work Permit. At this time, each team carries out a Health and Safety Dialogue, so as to be aligned with the risks of the task and the requirements for performance of the activity.

A weekly safety meeting is held with the geotechnical team, occupational safety team, and auditors team. Points for improvement are raised and the access plan is updated. Figure 3 shows the flow of the previously detailed activities.

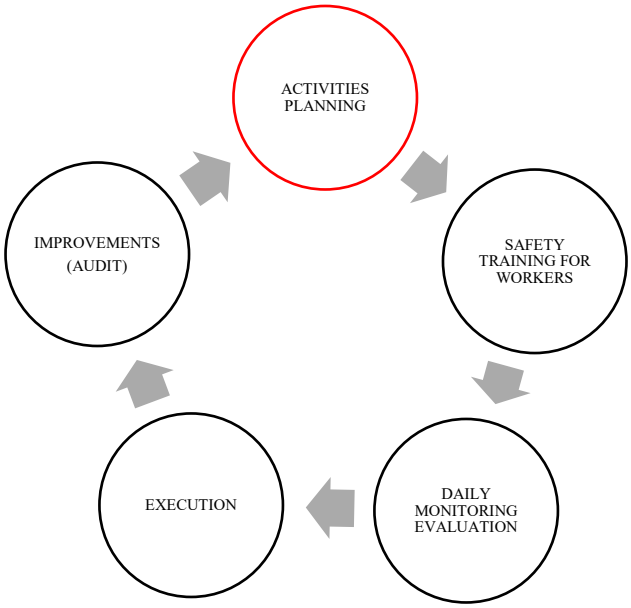

Figure 3: Activity flow within the access plan routine

Results

One of the parameters that measures maintenance efficiency is Adherence to Activity Programming, which is a direct relationship between what was planned and what was accomplished.

Before implementing the Plan, deviations of 300% were observed in relation to what was programmed. Since the beginning of this project, implemented in September 2022, compliance has reached 98% of what was planned. Figure 4 shows the situation from before implementation to present day.

Another improvement observed is in a parameter called Conservation Status Note, defined by current legislation, and evaluated every fortnight by the geotechnical team within the official government system. The Conservation Status Note is the sum of the criteria presented in Table 2 (ANM, 2017). All anomalies receive a score from 2 to 10, depending on severity, with 10 being the most serious. Therefore, the higher the sum, the worse the condition of the dams. This methodology is formalized in the biannual EoR audits.

Figure 5 shows that after implementing this methodology, the conservation of dams improved by 79% compared to their initial condition.

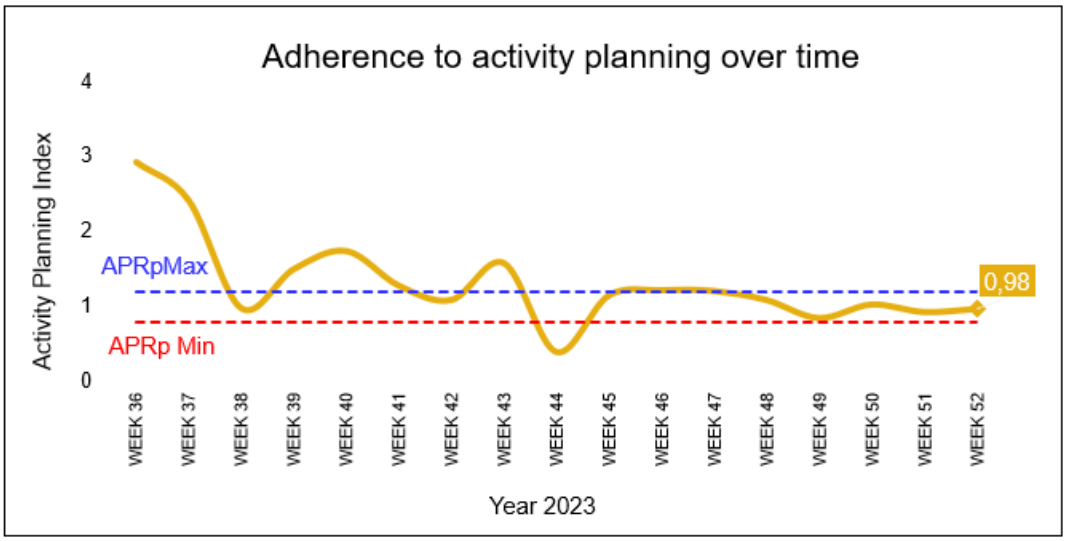

Figure 4: Maintenance adherence over time (total for 6 dams)

Table 2: Risk category classification matrix – Conservation Status (ANM, 2017)

Conservation status (EC)			
Spillway (f)	**Seepage (g)**	**Settlements (h)**	**Deterioration of Slopes (i)**
Well-maintained civil facilities operating normally / dam does not need outflow structures (0)	Seepage is fully controlled by the drainage system (0)	There are no disturbances and settlements that can potentially compromise the safety of the facility (0)	Slopes and parameters have deteriorated (0)
Facilities with identified problems and remedial measures are being implemented	Moisture or uncontrolled seepage in downstream areas, stable and monitored facings, slopes and abutments	Remedial measures for existing cracks and slumps are being implemented (2)	Slope and facing protection faults, presence of shrub vegetation (2)
Facilities with identified problems and no required remedial measures are in place (6)	Moisture or uncontrolled seepage in downstream areas, facings, slopes or abutments without required remedial measures in place (6)	There are cracks and slumps with no required remedial measures in place (6)	Surface erosion, exposed reinforcements, presence of trees, no required remedial measures in place (6)
Facilities with identified problems, with reduced spilling capacity and no remedial measures are in place (10)	Seepages in downstream areas with material transport, growing flow or contained material infiltration, with potential to compromise safety of the facility (10)	There are cracks, slumps or slides that can potentially compromise the safety of the facility (10)	Steep depressions in slops, slides, deep erosion grooves that can potentially compromise the safety of the facility (10)

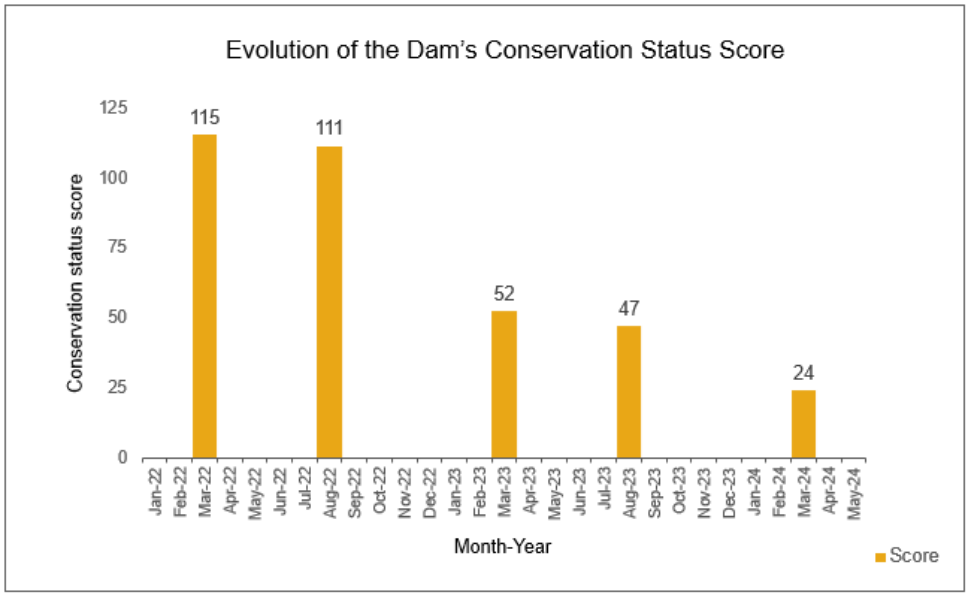

Figure 5: Evolution of the dam's Conservation Status score (total for 6 dams)

Conclusion

The dam management model presented in this paper, entitled "Emergency Level Dam's Access Plan," has enabled Vale to improve the conservation status of tailings storage facilities with access restrictions according to the Brazilian regulations.

Since applying this model, at this specific site, 79% improvement has been achieved in the assessment of dam conservation status, increasing safety conditions in the structures. Additionally, based on a standardized and systematic risk assessment method enabled to increase the access time to those dams, adherence to maintenance planning has improved by 98%. This shows how planned activities are safer and more efficient for workers.

Furthermore, after attending to some maintenance and correction activities, one of the six dams covered by the Access Plan had its emergency level removed, bringing its status back to normal condition.

Passive Seismic and Interferometry Techniques in Dam Decharacterization Monitoring

Camilla Rodrigues, Nanometrics, Canada
Marc Lambert, Nanometrics, USA
Ben Witten, Nanometrics, Canada

Abstract

Decharacterization of monitoring dams is crucial to ensure structural stability and mitigate environmental risks. It enables the early detection of potential issues, thereby safeguarding nearby communities and ecosystems. In this study, a complete overview of the installation procedures for seismic systems deployed in dams undergoing the decharacterization process is provided. Moreover, the application of passive seismic and seismic interferometry in the monitoring of ground motions and medium changes is discussed. Our findings demonstrate that the ground motion level induced by operations can be one hundred times greater than the background level, and that peaks of ground motion are usually induced by operations near seismic stations, detonations in the mine site, or natural events. The authors demonstrate that with noise-based monitoring, it is possible to detect velocity changes related to operations and determine the occurrence of structural changes in the dam's body.

Introduction

The decharacterization process marks a significant stage in reintegrating a dam into its natural surroundings, releasing it from its primary function of containing tailings. This transition ensures minimal environmental risks and safeguards nearby communities. The decharacterization process typically involves several key stages (ANM, 2017; Schaper et al., 2020):

- Decommissioning: closing operations and removing associated infrastructure, such as spigots and pipelines, except those intended to ensure the safety of the structure.
- Hydrological and hydrogeological control: adopting effective measures to reduce or eliminate the inflow of surface and groundwater into the reservoir.
- Stabilization: implementing measures to ensure the long-term physical and chemical stability of the structures that remain in place.

- Monitoring: observing for the necessary period to verify the effectiveness of the stabilization measures.

Geotechnical instrumentation has traditionally played a key role in monitoring this process; however, its limitations lie in spatial coverage, presenting discrete data points over time and space.

To overcome this constraint, Passive Seismic (PS) and Seismic Interferometry (SI) techniques have emerged as promising tools for assessing the medium during decharacterization. PS methods evaluate high-amplitude ground motions induced at the dam in terms of velocity and acceleration, while SI uses ambient noise (background noise) to monitor velocity changes related to alterations in the medium's stiffness. SI offers cumulative monitoring, detecting the evolution of the dam's response from the initial state at the array deployment moment, making it a valuable tool for understanding how the dam reacts to the decharacterization process. In other words, if the system has been deployed before the start of the decharacterization process, the SI response will highlight changes in the dam during the entire decharacterization process.

In this study, the application of both techniques for tailings dams undergoing the decharacterization process is discussed. Initially, a complete overview of the installation and network deployment is provided, highlighting the best practices adopted during the decharacterization. The processing workflow applied in these two monitoring approaches is described. Next, ground motion levels and the main sources of strong ground motion that can be characterized are presented. Furthermore, velocity changes are correlated with operations performed during the decharacterization process.

Installation and network deployment

A fully operational network, where waveforms are acquired by all receivers and streamed to a server for processing and analysis, is essential for the continuous acquisition of ambient noise. The hardware components, e.g. receivers, data acquisition and communications equipment, are built to collect and digitize information with high sensitivity and send it to a seismic server, where the data should be processed.

The seismic array is typically deployed near the surface in a non-invasive manner. In this installation procedure, the soil is excavated and compacted into a cylindrical shape with a diameter larger than the sensors. Then a posthole receiver, designed for shallow depths, is inserted into this hole, aligned with North and horizontally and vertically leveled. In the case of wired sensors, the cables are run from the hole towards a trench with a depth of 20 – 50 cm. For increasing depths, as shown by De Paula (2020), a borehole receiver can be fixed using grouting material that corresponds to a water-cement mixture with an acoustic impedance similar to the surrounding material. To place the receiver, the hole must have an adequate diameter to accommodate the sensor and the tubes that inject the grouting solution.

The spacing between sensors depends on the sensitivity required. For PS monitoring, an initial sensitivity analysis must be performed to estimate the magnitude of completeness (minimum magnitude detectable) and location uncertainty. Usually, a microseismicity level with a magnitude greater than -2 (ML, local magnitude) is recommended, while a small epicentral uncertainty of a few tens of meters is recommended. For SI, the inter-station distance should be less than one wavelength (λ). For example, with an S-wave velocity (v_S) of approximately 200 m/s in tailings and a frequency (f) of 1 Hz, the maximum inter-station distance should be roughly 200 meters ($< \lambda = v_S / f$).

The usual seismic configuration deployed in mining dams is shown in Figure 1.

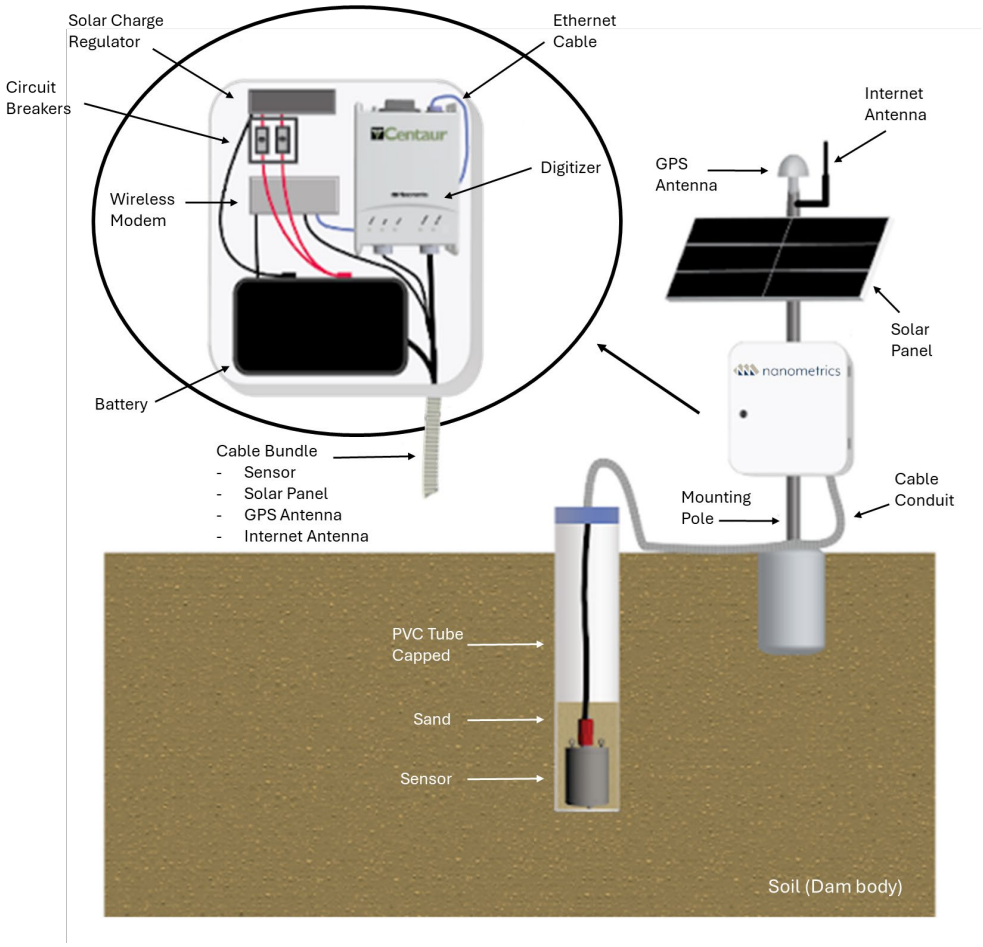

Figure 1: Seismic system architecture

Besides the receivers, all devices are stored inside a seismic station, powered by solar energy. The seismic station is affixed to a pole that serves as a mast for solar panels and communication antennas. This should be as close as possible to the seismic array, in an area of easy access, to allow maintenance. This distance is influenced by the signal strength loss (attenuation) caused by the transmission process. As

suggested by Xiao et al. (2016), the distance between receivers and seismic stations "should be less than the maximum distance that signal reduction affects the monitoring data," which is usually less than 300 meters. The pole height can be designed and customized for each monitored area. For instance, in areas with any incidence of vandalism, a tall pole can be designed to discourage unauthorized access.

The continuous analog signal registered by the receivers needs to be converted into a discrete digital signal before the data collection and processing on a seismic server (Xiao et al., 2016; Mendecki, 1996). This conversion process is performed by equipment known as a digitizer or analogue-to-digital converter.

This converter equipment has a finite number of channels for digitization. The uniaxial receiver requires one channel, while a triaxial requires three channels. Thus, depending on the seismic array, the number of required digitizer devices inside the seismic station varies.

All the aforementioned equipment is connected to a GPS, which provides time information via satellite to ensure synchronization within milliseconds. A poor time synchronization can lead to a poor location and create instability in the SI measurements. Thus, if an instrument is not synchronized, its data is generally unusable. Hence, the GPS is a crucial device for seismic monitoring.

To guarantee continuous monitoring and prevent power outages, an independent energy source can be implemented. Usually, for one seismic station, two photovoltaic modules, two stationary batteries, and a charger controller are installed. The charger controller is responsible for managing the batteries, and the supply of energy in the seismic station devices and network equipment.

The communication between the seismic station and the server can be made via internet. The wireless communication network needs to be stable, as the amount of data collected can be high. Eventually, it is recommended to work with redundancy to ensure the system will always be online. Still, if the transmission network fails, a data storage device (USB flash drive) can be connected to the station to store data during this period. Once the communication has been restored, the storage data is sent to the server. However, should the disruption last long, the newest data could overwrite the oldest, and then the data is lost.

Furthermore, for cases where the seismic system uses the same web network communication as other systems, a Virtual Private Network (VPN) can be employed to isolate all networks. The processed data can be visualized using online tools for quick assessment and interpretation.

For dams undergoing the decharacterization process, careful installation of monitoring equipment is crucial. This involves the precise demarcation of station and network equipment locations. As continuous operations are conducted on the dam body, the operational team must be vigilant about the locations of stations and cables. This awareness is essential to avoid interference with these areas, which could lead to issues such as cable breakage and subsequent interruption of monitoring.

Passive seismic monitoring

The objective of seismic monitoring is to quantify exposure to seismic activity, providing critical inputs for risk management strategies and protocols. Acquired and processed data can be utilized by geotechnical engineers for preventive measures, alert determination, Trigger Response Action Plans (TARP), and predictive analysis.

Ideally, the seismic array should be deployed before the decharacterization process begins to establish a baseline of background vibrations and event history – i.e., the vibrations and number of events the dam experienced prior to the start of the process.

The seismic waveforms recorded by the system can amount to around 50 to 100 GB per month. This data undergoes a processing scheme designed to estimate source parameters (e.g., magnitude and location) and classify the source mechanism (Figure 2).

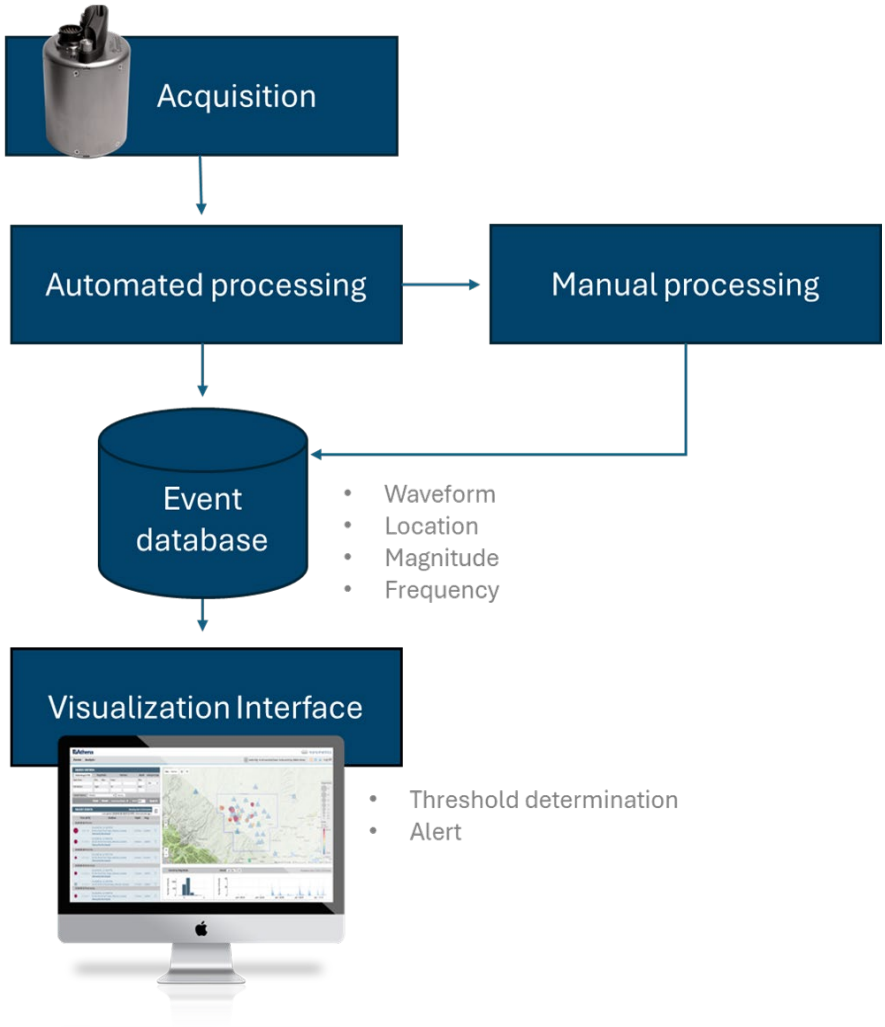

Figure 2: Simplified processing workflow

Two approaches can be applied: automated and/or manual processing. When both approaches are used, differing results may arise not only due to the subjectivity inherent in manual processing but also because of the varying quality of the automated algorithms. Consequently, the quality of the data is influenced by the seismologist's expertise.

As a best practice, automatic processing is typically applied to all databases, while manual processing is reserved for specific data samples, such as events that exceed a certain threshold. In the case of dams undergoing a decharacterization process, routine analysis is essential for identifying outliers, particularly in terms of unusual strong ground motions, and for characterizing their sources. This requires active communication between the mining operators and the monitoring team. A thorough analysis should include the event waveform, spectral content, source parameters, magnitude, and source location.

Seismic Interferometry monitoring

The Seismic Interferometry (SI) technique originated from the potential to extract valuable information from ambient noise data. SI comprises two distinct processing techniques: Seismic Ambient Noise Interferometry (SANI) and Coda-Wave Interferometry (CWI). The SANI concept was introduced in the 1960s by Claerbout (1968), who suggested the feasibility of cross-correlating noise signals recorded between a pair of receivers. This approach allows for the reconstruction of the signal that would be recorded at one receiver when a source is positioned at the other. Thus, considering two stations located at x_A and x_B and a noise source at x_S, the response at one receiver A can be described as $G(x_A, x_S, t_A)$, where G corresponds to the Green's Function, and its arguments represent the receiver, source and travel time, respectively. As described by Wapenaar et al. (2010), the process of convolving two-time reversal responses acquired by two stations ($u(x_B, x_S, t)$ and $u(x_A, x_S, -t)$) turns into a correlation. This correlation yields the Green's function between stations, which represents the response at one receiver if a source was placed at the other ($G(x_B, x_A, t)$), convolved with the noise wavelet $N(t)$ autocorrelation ($S_N(t) = N(t) * N(-t)$) :

$$G(x_B, x_A, t) * S_N(t) = u(x_B, x_S, t) * u(x_A, x_S, -t). \quad \text{(Eq. 1)}$$

$$u(x_A, x_S, t) = G(x_A, x_S, t) * N(t) \quad \text{(Eq. 2)}$$

$$u(x_B, x_S, t) = G(x_B, x_S, t) * N(t) \quad \text{(Eq. 3)}$$

$$G(x_B, x_A, t) = G(x_B, x_S, t) * G(x_A, x_S, -t) \quad \text{(Eq. 4)}$$

These wavefields are estimated at regular time intervals and serve as a representation of the medium between pairs of stations (Figure 3). The CWI technique uses this data as input, measuring changes in phase

and amplitude by comparing these wavefields. This comparison is conducted in the scattered waves within the tail of the Cross-Correlation Functions (CCF) obtained by the SANI technique. These scattered waves, known as coda-waves, are more sensitive to small perturbation in the monitored structure, as they spend more time propagating through the medium. Thus, changes that are not visible in the direct arrival can be seen in the coda portion (Figure 3).

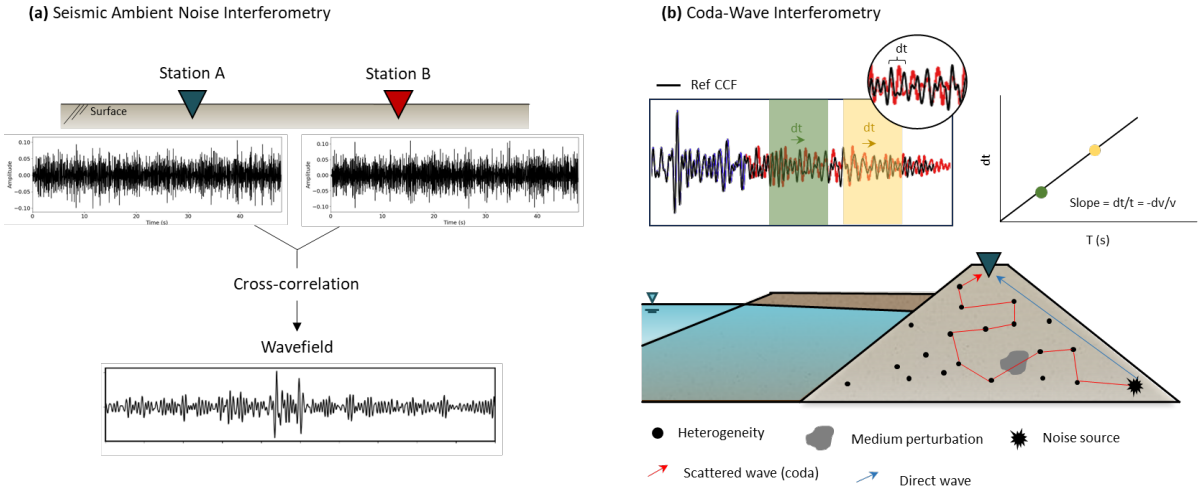

Figure 3: Seismic interferometry. (a) Seismic ambient noise interferometry: cross-correlation of signal recorded at two fixed locations, yielding a wavefield that represents the medium between these points; (b) Coda-wave Interferometry: time perturbations measured in scattered waves provide velocity changes (modified from Rodrigues et al., 2024)

To estimate the velocity changes, the Moving-Window Cross-Spectral (MWCS) method, also known as the doublet method, was applied. As explained by Le Breton et al. (2021), the MWCS method consists of measuring the time shifts (dt) between two CCF over a narrow moving window. This procedure can be executed in either the time or frequency domain. By extracting the slope ($dt/t = -dv/v$), changes in velocity can be estimated.

In the context of monitoring dams, it is crucial to emphasize that velocity changes are cumulative, serving as a reflection of the dam's evolving behavior in relation to the initial monitoring point (the first CCF measured). In practical terms, this implies that, for example, if a dam exhibited the presence of water, cracks, or any structural complications prior to the deployment of the system, the monitoring would assess whether there has been an increase or not from these pre-existing conditions.

Seismic data of a decharacterization process

To illustrate the response of a decharacterization process, this study will analyze data from real tailings dams located at active mine sites. These dams were monitored using an array of posthole stations installed near the surface. The array was deployed after the beginning of the decharacterization process, not allowing

the establishment of a baseline level of ground motion. In this case, for the PS monitoring, an alternative process adopted was the confrontation between the ground motion data registered during periods with active and without active operations. As some operations may be continuously performed (e.g., pumping), major operations responsible for strong ground motions will usually be conducted during business hours, such as detonations on the mine site, drilling, excavation, etc.

Figure 4 shows the Peak Ground Velocity (PGV, in m/s), where daily variations are observed with peaks during working hours and lower vibrations at night. Considering the low ground motions, it is possible to establish a baseline, in this case 0.00004 m/s. Decharacterization operations and detonations induced a maximum of 0.007 m/s, 100 times greater than the background level.

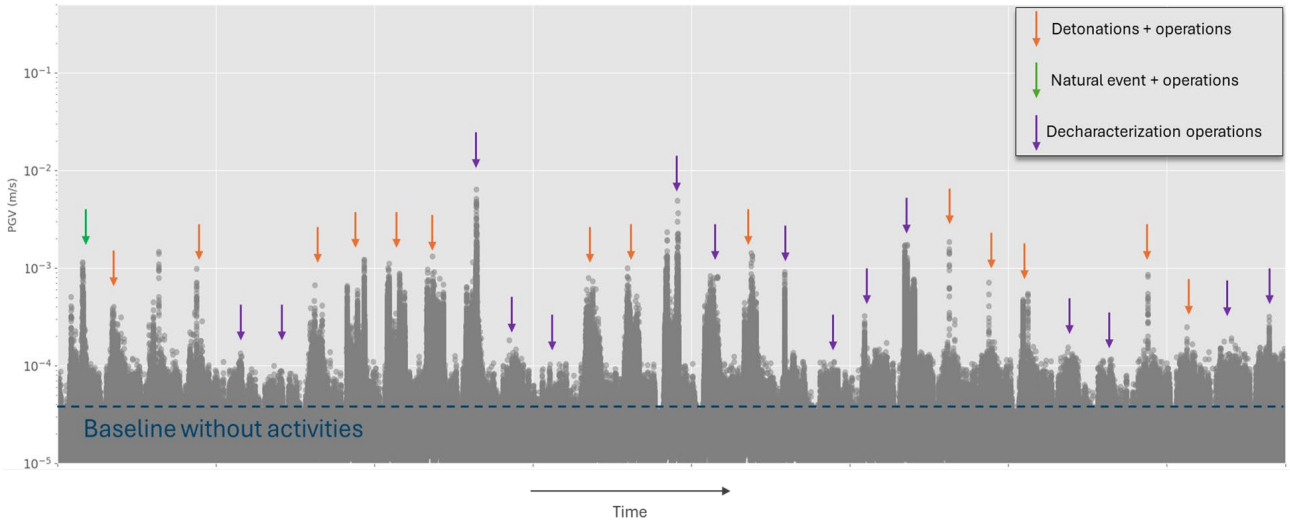

Figure 4: Vibration levels variation – peaks induced by operations

The peak ground motion observed in the data was carefully analyzed during a manual processing stage. Three types of sources were identified as responsible for this level of ground motion: operations near the stations, detonations, and natural seismic events. Figure 5 presents examples of waveforms. For the ground motion data generated by operations, the location was not determined, as the data is mainly noise and did not exhibit clear arrivals necessary for the picking process (Figure 5a).

However, in the context of a decharacterization process, this data is the most important, as it provides the level of ground motion propagated in the dam body induced by decharacterization activities. Nonetheless, for a more accurate source type characterization, collaboration from the operational team is essential. Their access to mine plans allows them to share critical information on the timing and location of activities.

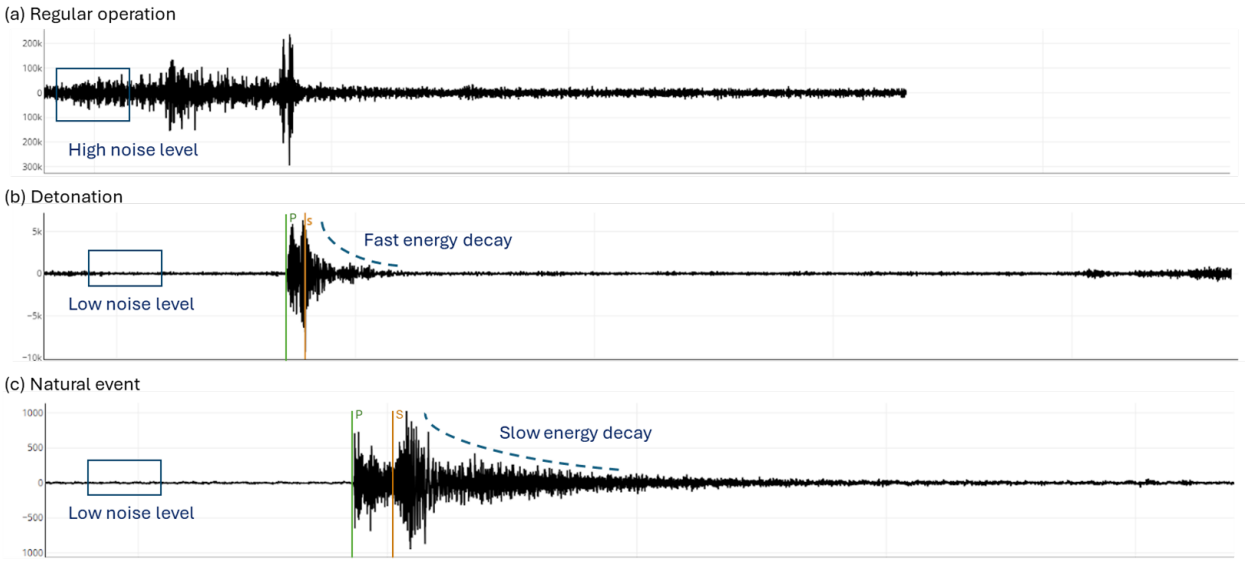

Figure 5: Seismic waveforms (a) decharacterization operation conducted near stations; (b) detonations performed in the mine site; (c) natural events

Despite the ongoing decharacterization process, normal activities at the mine site continued, resulting in significant ground motions due to detonations (Figure 5b). Additionally, natural seismic events (i.e., earthquakes) were also detected at the site (Figure 5c). During their characterization, a common feature used to identify natural events was the slow energy decay. This characteristic is notable because natural events typically exhibit a high content of S-waves, which are more energetic, resulting in a slower energy decay compared to mine detonations, which have a lower content of S-waves (Figure 5).

These events, characterized by a favorable signal-to-noise ratio, were initially located using automatic picking and were re-evaluated during manual processing for final characterization and comparison with the mine blast plan and the local public seismographic network.

In parallel with ground motion monitoring, velocity changes were estimated. Due to the system not being deployed prior to the decharacterization process, a baseline of typical changes observed in the dams before decharacterization could not be established. However, the SI method was utilized to detect new perturbations within the dam body.

Figure 6 provides examples of responses due to typical operations during the decharacterization process, as well as potential issues arising from these operations.

- The removal of tailings from the reservoir resulted in decrease of velocity changes due to the loss of material compared to the reference (Figure 6a).
- Local operations led to a small landslide in the dam slope, which led to a loss of stiffness in the area and consequently a decrease in velocity changes (Figure 6b).

- During the rainy season, the water content in the dam's body increases, which results in a decrease of velocity changes (Figure 6c).

Due to the high sensitivity of SI measurements, even minor perturbations can induce small velocity changes, typically oscillating around a specific threshold. However, when significant alterations in dam behavior occur, a new plateau may emerge. This can indicate a physical change in the medium, reflecting potential structural modifications within the monitored area.

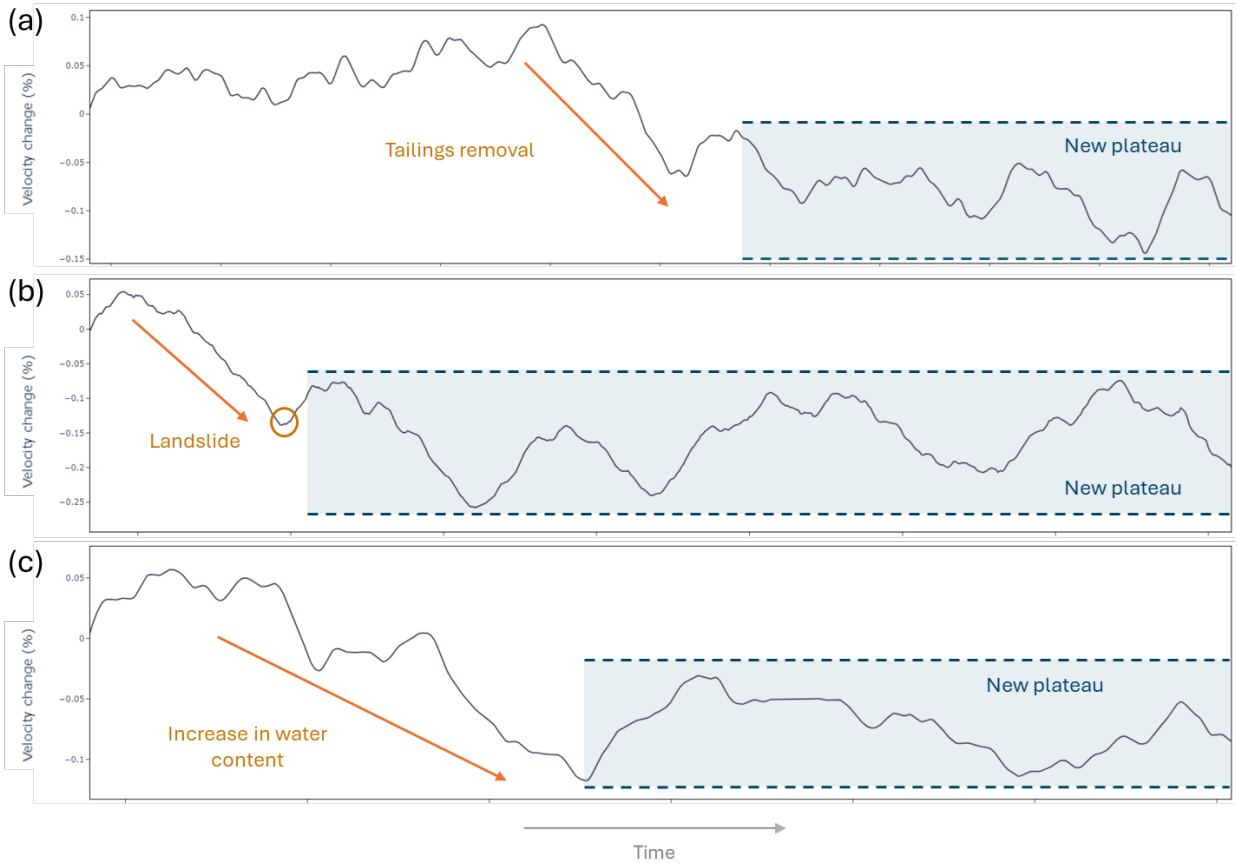

Figure 6: Example of velocity changes response (a) tailings removal during decharacterization; (b) landslide caused by decharacterization operations; (c) increase in water content during the rainy season

Conclusion

Passive seismic monitoring and seismic interferometry can be valuable tools for monitoring dams, especially those undergoing the decharacterization process. By deploying a non-invasive seismic array covering the dam's body, it is possible to measure ground motion induced not only by decharacterization operations but also by regular mining activities and natural events. This approach enhances the ability to detect and analyze changes within the dam structure, providing critical data for ensuring the stability and

safety of the dam during and after decharacterization.

In this study, best practices for seismic system deployments were discussed, emphasizing the importance of active communication between the operational and monitoring teams. The passive data demonstrate that ground motions induced by decharacterization processes and regular mine operations can surpass background levels. Finally, it was demonstrated that with a high-sensitivity SI approach, effective monitoring of the physical changes in dams induced by decharacterization processes (e.g., tailings removal) can occur, as well as during local incidents and the rainy season.

Acknowledgements

The authors would like to express our gratitude to the Nanometrics team for their support and dedication in developing these technologies. Their valuable contributions and insightful discussions were instrumental in the development of this study.

Abstract

One of the major challenges in the modern mining industry is the disposal and management of its tailings. Following significant accidents in the last decade, the mining industry has been pursuing viable and safer alternatives for tailings disposal, aiming to make mining a more sustainable activity. One alternative is drained stacking of tailings, which involves creating a dry stack pile with waste that has been drained through filtration processes or other dewatering methods. The material is transported to the storage location by trucks or conveyors, then disposed of and compacted with suitable equipment. One of the major concerns about this type of storage is its geotechnical performance throughout the structure's lifetime, from construction to closure. Parameters such as material consolidation, deformation, saturation, and density are crucial for understanding performance and ensuring geotechnical safety. Effective management of this type of structure necessitates a robust geotechnical monitoring program from the implementation phases onwards to understand all aspects of performance and safety.

Given that these structures are still uncommon in the mining industry and their behavior is not well known, monitoring from the initial stages of project implementation – including the foundation and tailing layers as they are deposited and compacted – is extremely important.

The most common technologies in geotechnical monitoring currently face challenges related to the infrastructure needed for reading and supplying power to the sensors. Most sensors require cables connecting the monitoring point to a power source and/or equipment for data reading, making installation difficult in areas with constant equipment movement for material deposition. Additionally, there is a risk of damaging these cables, potentially compromising the monitoring system. In response, a new technology comprising wireless sensors with high-durability batteries, capable of collecting information on the water table level and deformation over approximately 10 years, has been tested for monitoring such geotechnical

structures. This greatly facilitates installation and real-time data collection during the execution of drained stacking, thus providing vital information for geotechnical understanding.

Introduction

This work presents the initial monitoring results of a trial project of a dry stack deposited over hydraulic tailings material inside a non-operational open pit. The monitoring system aims to evaluate the behavior of the foundation of the dry stack in response to the loading generated by the construction of the dry stack on top of the hydraulically deposited tailing material. The focus here is not to evaluate the performance of the structures, but to assess the functionality of the monitoring system for this application.

Traditional geotechnical monitoring systems (e.g., piezometers, inclinometers, shape arrays) typically need to be connected to a datalogger and power source using cables. One of the biggest challenges in this application is to have a system that can be installed in an operational area without the risk of damaging the communication and power cables, and without requiring complex operational procedures to protect those cables.

Geotechnical engineers cannot risk losing relevant information about the performance of the structure due to infrastructure problems (Aguirre and Lloyd, 2020). Therefore, the Geo4Sight Platform was selected – a wireless in-ground monitoring system developed for underground mines, especially block caving mines, capable of monitoring tilt and water pore pressures.

Monitoring system overview

According to Aguirre and Lloyd (2020), the Geo4Sight Platform is a wireless system for monitoring tilt and water pressure in challenging geotechnical environments, where cables have a significant potential to be damaged by operational work or by moving ground.

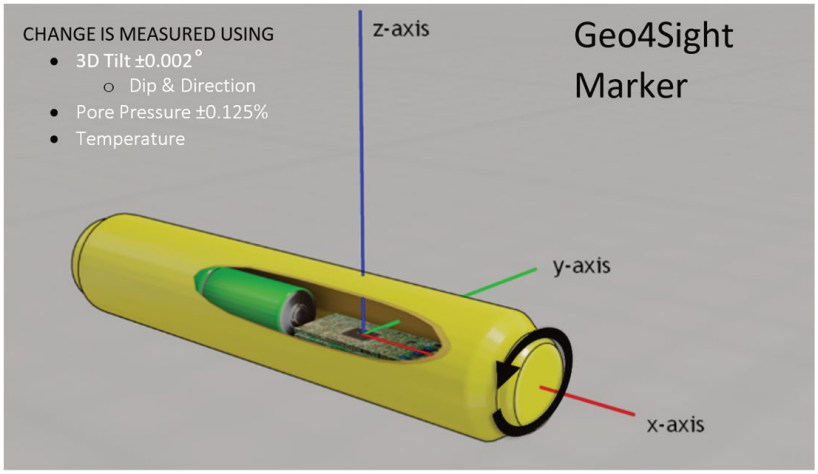

Figure 1: Geo4Sight sensor

The sensor (Figure 1) is a rugged, waterproof, blast-proof, battery-powered system with on-board accelerometers, magnetometers, thermocouples, and pressure transducers used to determine device 3D tilt and water pore pressure. An on-board radio transceiver transmits measurement data to the surface in a daisy-chain fashion.

The Geo4Sight can monitor movement, ground deformation, and groundwater. Changes are measured by 3D tilt with an accuracy of ±0.002˚, dip and direction, pore pressure with an accuracy of ±0.125%, and temperature with an accuracy of ±1%.

System topology

The system operates in an ultra-low-power in-ground radio mesh network of Markers. The Markers have a radio communication range of ~5 meters through the ground. However, for redundancy and to account for ground movement, they are installed much closer to each other, typically at 2-meter intervals (Kamp et al., 2020).

Communication from the surface datalogger to any underground Marker is conducted by sending "queries" down the chain, passing from one to the next until reaching the destination Marker. When the query command is received, the destination Marker takes measurements and sends the data back up the chain to be recorded and transmitted to a database for analysis (Figure 2).

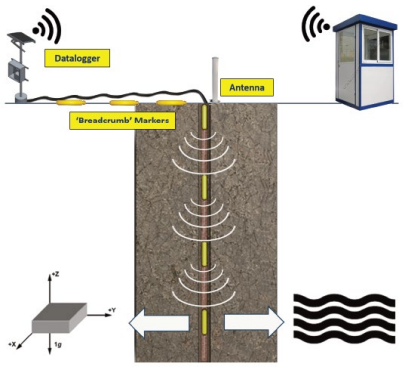

Figure 2: Typical system topology

Installation

As mentioned, the installation was carried out in the foundation of a dry stack under construction. The foundation primarily consists of tailing materials hydraulically deposited in an old pit. A layer of coarse material was deposited between the tailings of the foundation and the dry stack, acting as a filter. The sensors were installed at this interface before the coarse material was positioned (Figure 3). The geotechnical team identified the installation location as one of the critical sections for analyzing the future stability of the pile.

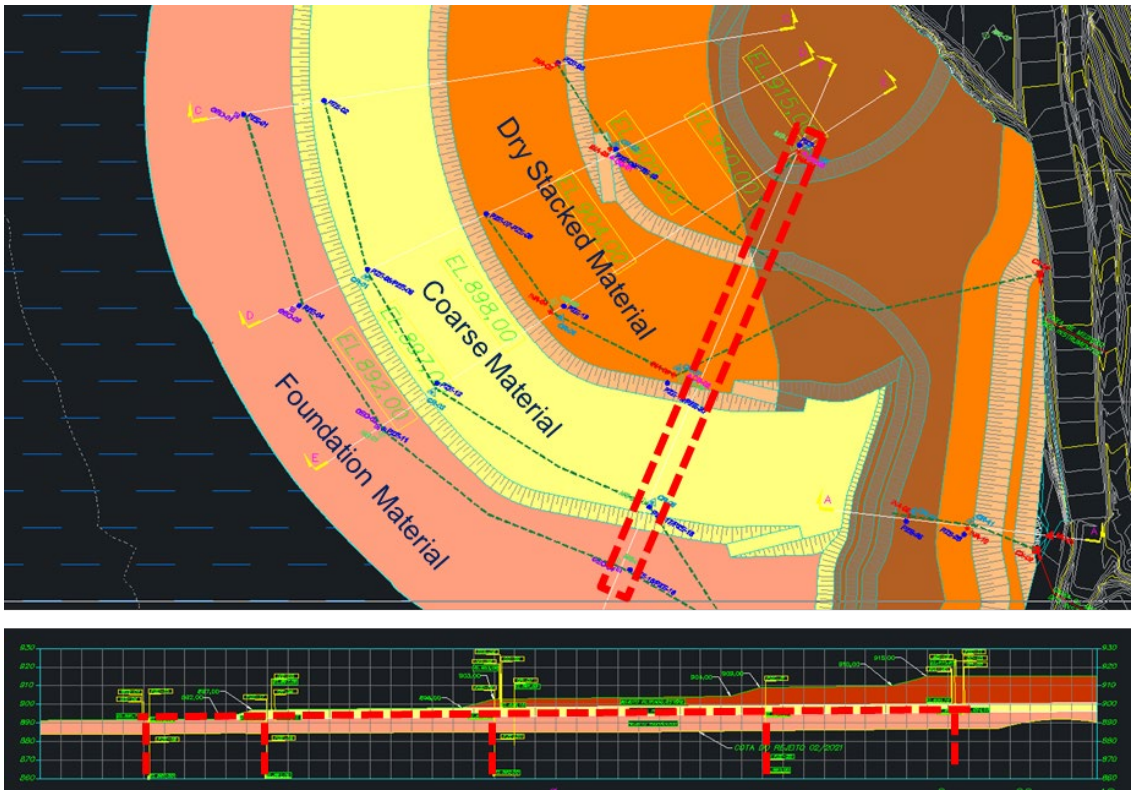

Figure 3: Schematic map and cross-section of the sensors location

A total of 260 sensors were installed with a 2-meter spacing in a trench 400 meters long and in 5 boreholes with a total length of 120 meters. Of these, 240 sensors measure tilt only and 20 measure both tilt and pore pressure. The sensors in the boreholes (Figure 4) were installed using a traditional drilling rig. First, the holes were drilled, and then the sensors were placed inside with the help of a fiberglass rod to prevent them from collapsing to the bottom. Once in place, the holes were filled with the same tailing material from the drilling process, thereby grouting the sensors in position.

Figure 4: Sequence of images showing the installation process in a vertical borehole

For the horizontal installation (Figure 5), a 400-meter-long by 0.5-meter-deep trench was opened with a small digger. The sensors were attached to a coaxial cable with 2-meter spacing and then laid inside the trench. The coaxial cable serves two purposes: it ensures ideal spacing during installation and enhances the sensor signal, facilitating safe wireless communication between the sensors. The trench was then closed with the excavated material.

Figure 5: Horizontal trench with the sensors in place

To collect sensor data, a mobile data logger was installed at one end of the trench. This data logger was mounted on a solar generator trailer (Figure 6), responsible for data collection and processing.

Figure 6: Datalogger mounted in a solar generator trailer

The solar trailer provides power and communications (4G), making the system robust and negating the need for additional infrastructure. It also allows for easy relocation if operational activities require intervention in the area.

After the installation, the system began collecting data once a day, processing it locally. This frequency was selected to maximize the sensor battery life, estimated at 8 to 10 years depending on conditions. The data collection interval can be adjusted as needed.

First results

Two types of sensors were installed: 240 with tilt sensors only and 20 with both tilt and water pore pressure sensors. The analysis is divided into two sections: tilt results and pore pressure results. The data analysis period is from January to May 2024.

Tilt analysis

During the analysis period, the system registered several instances of deformation in different locations. The cumulative tilt variation is shown in Figure 7, where the dots represent sensor locations, with their size and color indicating the amount of variation during the period.

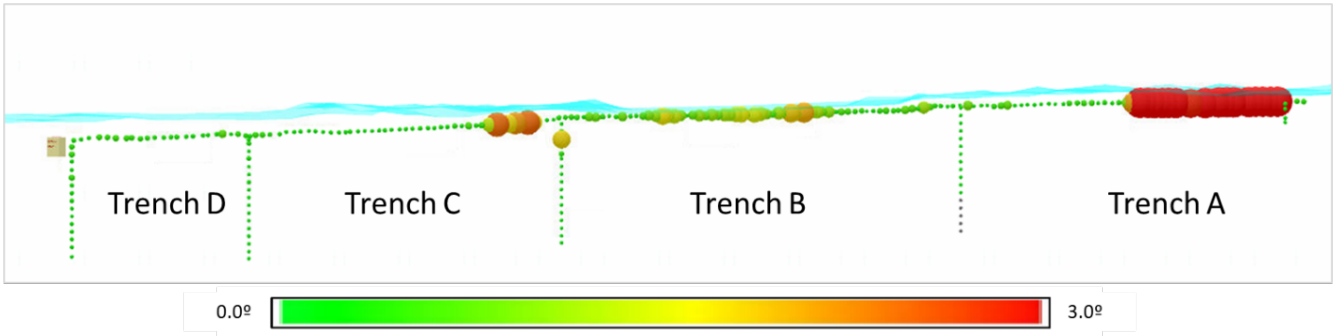

Figure 7: Cumulated tilt variation of the sensors.
For practical reason the trench was divided into 4 sectors (A to D)

Time-based data analysis reveals that deformation occurs at different times depending on sensor position, correlating with the operational moments of the structure. One sector shows deformation early in the period, while others show it later (Figure 8).

A spatial analysis correlating sensor deformation with local topography changes shows a direct relationship (Figure 9). The areas with material volume changes align with sensors showing higher deformation. Notably, the blue area with negative volume variation is related to the main access where trucks deposit material. In this case, deformation is associated with truck loads on unconsolidated material.

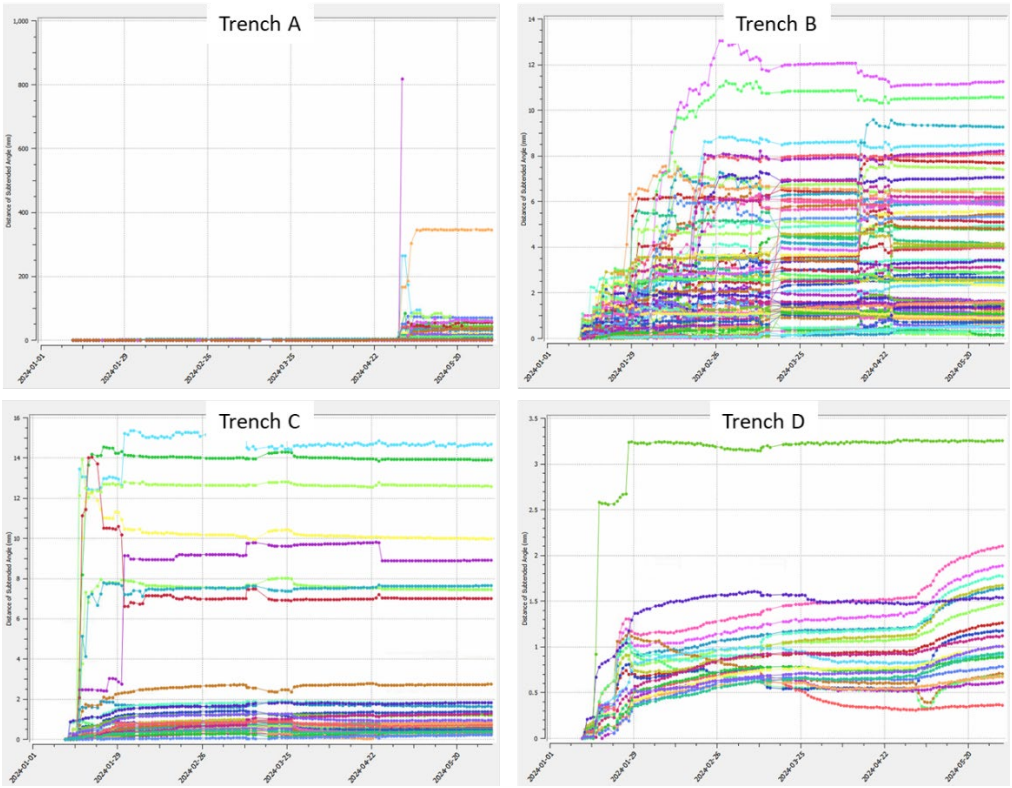

Figure 8: Tilt variation along time in the different sectors of the trench

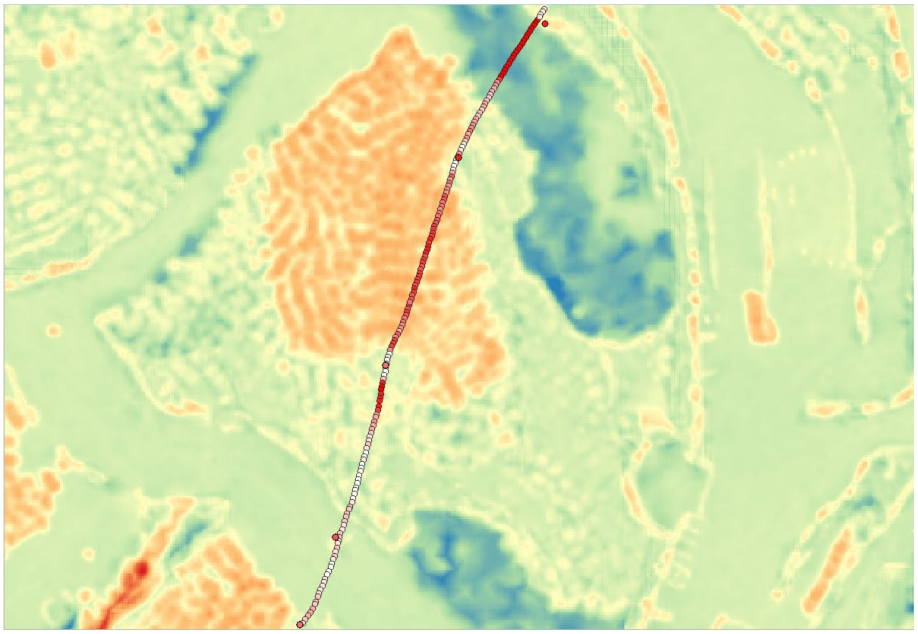

Figure 9: Map showing the correlation of the tilt results with the change in the local topography. The points represent the location of the sensors in the trench, the colors of the dots represent the cumulative tilt change over the period (white to red). The color of the map shows the areas where the thickness of the material over the sensors changed, hot colors mean increase of material and cold colors reduction of thickness

Pore pressure analysis

In the pore pressure charts (Figure 10), two data sets are visible: one with values higher than 250 Kpa and another averaging close to 100 Kpa. The higher values correspond to sensors in boreholes within a saturated zone with a water column over 15 meters, while the lower values correspond to sensors near the surface in non-saturated areas or local high aquifers.

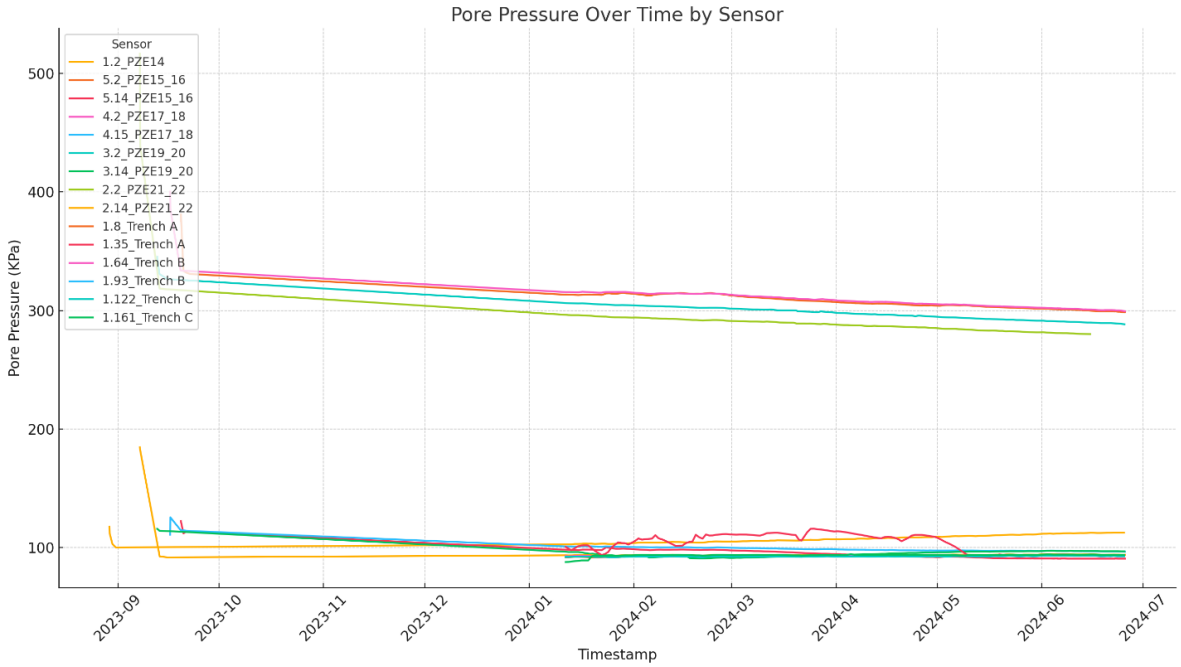

Figure 10: Pore pressure variation chart

Saturated zone sensors show a clear trend of reducing pore pressure values over time, indicating an overall water level reduction in the foundation. Near-surface sensors mainly show variations related to atmospheric changes and local suspended water levels. One sensor near the surface correlates water level increase with rain (Figure 11).

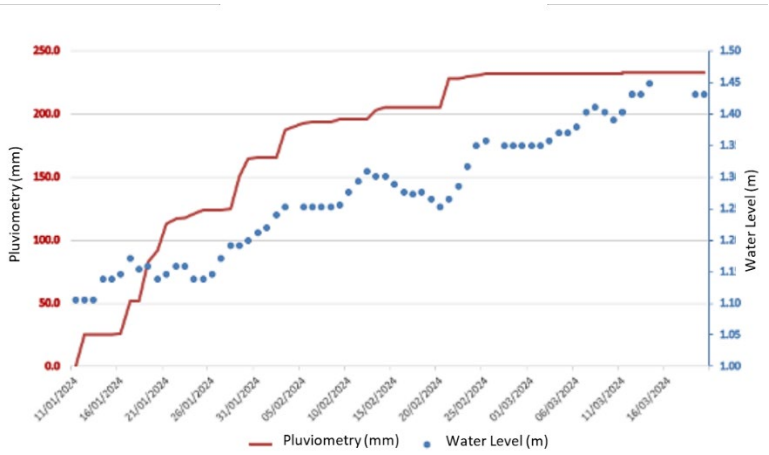

Figure 11: Water level correlation in time with local rain cumulation

Conclusion

The system demonstrates significant value in monitoring geotechnical structures from the initial construction stages. It offers an easy installation solution with the robustness of wireless technology, reducing the risk of damage compared to traditional cabled solutions. This makes structure construction more efficient by eliminating the need to manage, protect, or extend cables.

In terms of results, the system provides reliable data output, showing excellent correlation between collected data and field activities. The tilt sensors respond directly to material disposal and soil settlement in operational areas. The pore pressure sensors show a direct response to rain near the surface, and for deeper sensors, a clear trend of water level reduction is evident.

UPLOAD – ANALYSE – ACT: Artificial Intelligence-assisted Faster, Seamless, and Almost Real-time Tailings Dam Construction Quality Assurance is Knocking at our Doorstep

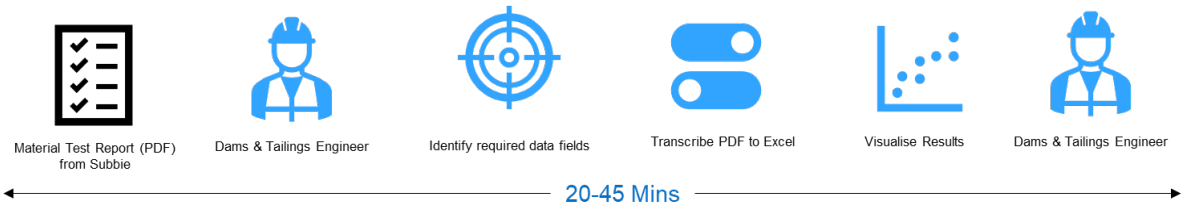
Anjan Kundu, GHD Pty Ltd, Australia

Abstract

Tailings dam construction involves managing vast data volumes over extended periods, presenting challenges in data handling and quality assurance. This paper introduces an artificial intelligence (AI)-assisted approach that streamlines material quality control data analysis, significantly reducing human effort. The method intelligently identifies, extracts, analyzes, and visually presents data, flagging inconsistencies for further investigation. Our trial shows a reduction in effort from 45 minutes to 3 minutes. This innovation enhances real-time communication between remote teams, improves construction compliance visibility, and elevates quality assurance standards. Furthermore, the broader applications of AI in tailings dam management are explored, highlighting its potential in operational planning and safety assessments through predictive analytics and real-time monitoring.

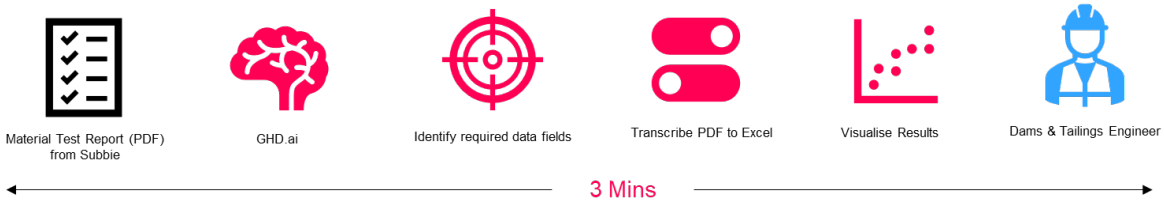
Introduction

The construction of tailings dams is a complex process involving numerous lots in line with technical specifications. Managing data from various formats, such as those from contractor organizations and testing laboratories, has been a continuous challenge, especially where legal certification is required. Ensuring data consistency and quality in such a multifaceted environment is crucial but remains difficult with traditional methods.



In recent years, the emergence of artificial intelligence (AI) has revolutionized various industries by automating complex tasks, enhancing data analysis capabilities, and improving decision-making processes. Despite its proven benefits in fields such as healthcare, finance, and manufacturing, the application of AI in tailings dam management remains relatively unexplored.

This paper aims to bridge this gap by introducing an AI-assisted approach designed to streamline the analysis of material quality control data in tailings dam construction. By leveraging AI's ability to intelligently identify, extract, analyze, and visually present data, our method significantly reduces the time



and effort required for data handling, from an average of 45 minutes to just 3 minutes. This not only enhances real-time communication between remote teams but also improves visibility into construction compliance and elevates quality assurance standards.

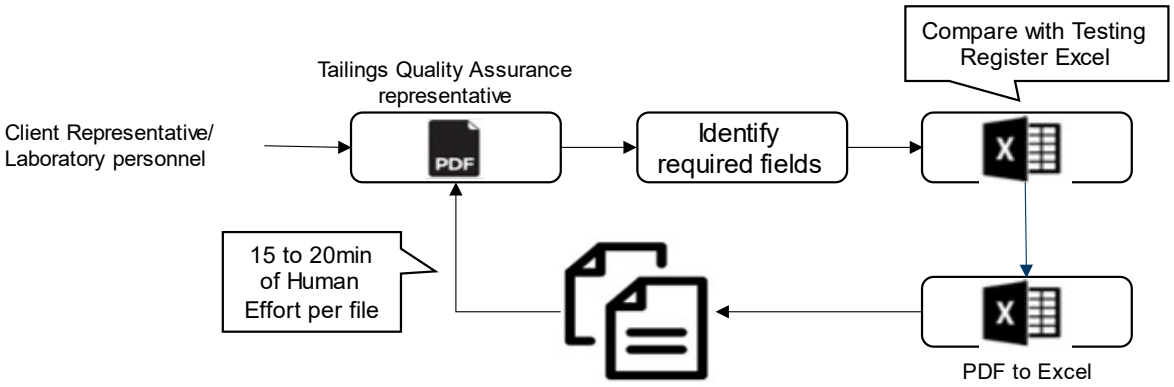
The current process involves a Dams and Tailings engineer to extract the required information from the PDF file to an Excel file and perform visual analysis that is shared with the wider teams to perform necessary actions.

- Current approach

- AI-assisted approach

Furthermore, we explore the broader potential of AI in tailings dam management, highlighting its applications in operational planning and safety assessments through predictive analytics, and real-time monitoring. Our findings suggest that the integration of AI technologies can lead to more efficient and safer tailings dam operations, setting a new standard for data management in the mining industry.

In the following sections, we detail our methodology, present our findings, and discuss the implications of AI adoption in tailings dam management, offering insights into the future of this critical field.



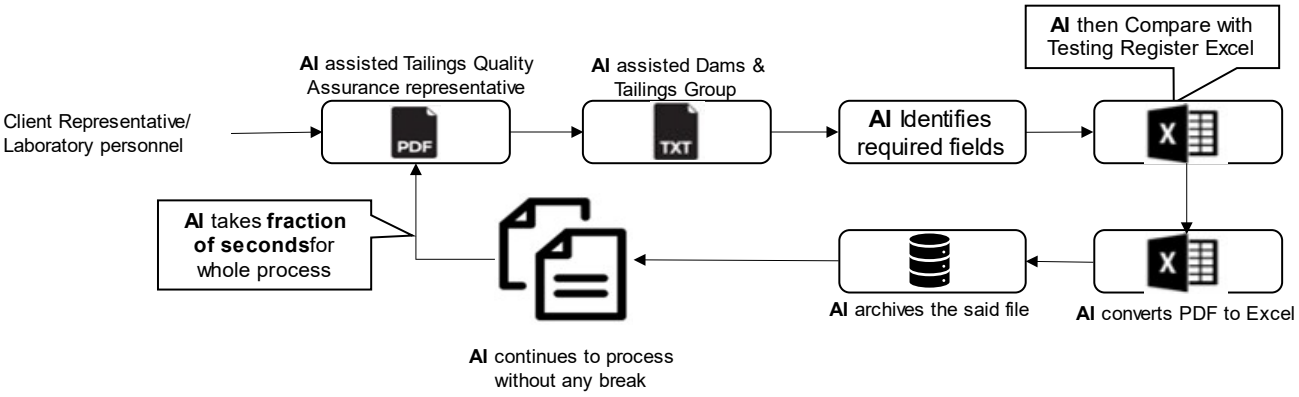
Methodology

Current process

The current process for managing quality control data involves several manual steps. Initially, data is extracted from PDF files, which requires significant human effort. Once the data is extracted, the next step involves identifying the required fields within the extracted data. This step is also performed manually and requires careful attention to detail to ensure that all necessary information is accurately captured.

After identifying the required fields, the data is manually compared with a Testing Register Excel file. This comparison is crucial for ensuring that the data meets the specified quality standards and technical

specifications. However, this manual process is time-consuming, typically taking between 15 to 20 minutes per file. The reliance on human effort introduces the potential for errors and inconsistencies, which can affect the overall quality assurance process.



AI-assisted process

By contrast, the AI-assisted process significantly streamlines these tasks, leveraging advanced technologies to enhance efficiency and accuracy. The process still begins with handling PDF files, but from this point onward, AI takes over the tasks that were previously done manually.

AI automates the extraction and identification of required fields from the PDF data. This automation not only speeds up the process but also ensures a higher level of accuracy by minimizing the potential for human error. Following the identification of the required fields, AI then automatically compares these fields with the Testing Register Excel file. This comparison is done swiftly and accurately, further enhancing the reliability of the quality control process.

One of the most significant advantages of the AI-assisted process is the drastic reduction in time required. What used to take 15 to 20 minutes per file is now accomplished in a fraction of a second. This immense improvement in efficiency not only saves time but also allows for real-time communication and better compliance visibility. The enhanced speed and accuracy of data handling contribute to improved quality assurance standards, ensuring that construction compliance is maintained consistently.

The proposed AI-assisted system also integrates several key technologies to manage and analyze quality control data:

- **Data Collection and Integration:** Automated systems for data collection from various sources (electronic documents, paper scans) and in various formats (PDFs, Word documents, Excel sheets).
- **Data Processing and Analysis:** Machine learning algorithms to extract relevant data points, identify patterns, and detect anomalies. We used Computer Vision and an Optical Character Recognition approach to identify the relevant data to extract, analyze, and generate insights that would have been a manual task otherwise.
- **Visualization:** Advanced data visualization tools to present analyzed data in user-friendly formats, aiding in quick decision-making.

The system's efficacy was tested on multiple projects and multiple document formats, showing a drastic reduction in human effort from 45 minutes to 3 minutes per lot analysis.

Data and discussion

Our analysis involved a comprehensive evaluation of multiple tailings dam construction projects to assess the effectiveness of an AI-assisted approach in data management. By implementing AI technology in these projects, we were able to gather substantial data and insights that highlight several key findings:

- **Efficiency Gains:** One of the most remarkable outcomes of our study is the significant time savings achieved using AI in data processing and analysis. Traditional methods of handling quality control data in tailings dam construction are labor-intensive and time-consuming, often requiring 15 to 20 minutes per file. However, the AI-assisted process reduces this time to mere seconds. This dramatic reduction in processing time not only enhances operational efficiency but also frees up valuable human resources, allowing staff to focus on more strategic and complex tasks. The increased efficiency contributes to faster decision-making and project progression, ultimately leading to cost savings and improved project timelines.
- **Accuracy Improvement:** Accuracy in data management is crucial for maintaining high standards of quality control in tailings dam construction. Manual data entry and analysis are prone to human errors, which can compromise the reliability of the data and lead to potential compliance issues. Our analysis revealed that the AI-assisted approach significantly reduces errors in data entry and analysis. By automating these processes, AI ensures that data is consistently and accurately extracted, identified, and compared with the Testing Register files. This reduction in errors enhances the overall integrity of the data, leading to more reliable quality control outcomes and reducing the risk of non-compliance with technical specifications and regulatory requirements.
- **Real-Time Monitoring:** The implementation of AI also brings substantial improvements in real-

time data monitoring and anomaly detection capabilities. Traditional data management methods often involve delays in data processing and reporting, hindering the ability to detect and respond to anomalies promptly. With AI, data from various sources can be processed and analyzed in real time, providing immediate insights and alerts. This enhanced capability allows for active monitoring of tailings dam construction activities, enabling teams to identify and address potential issues before they escalate. Real-time monitoring not only improves the responsiveness to anomalies but also enhances overall project management and risk mitigation strategies.

The integration of AI into the data management processes of tailings dam construction projects demonstrates significant potential for transforming the industry. The efficiency gains achieved through AI-driven models led to faster and more streamlined operations, reducing the burden on human resources and improving project timelines. The marked improvement in data accuracy enhances the reliability and consistency of quality control, ensuring that all data meets stringent technical and regulatory standards.

The findings from our analysis emphasize various benefits of adopting AI technology in tailings dam construction. It is even more favorable where the mine waste is used as construction material. The significant improvements in efficiency, accuracy, and real-time monitoring capabilities highlight the transformative potential of AI in enhancing quality control and operational excellence. As the industry continues to evolve, the integration of AI-driven solutions will play a pivotal role in driving projects and ensuring the sustainable development of tailings dam infrastructure.

Results

The implementation of the AI-assisted approach yielded substantial improvements:

- **Time Efficiency:** Reduced processing times by over 90%.
- **Error Reduction:** Lowered the incidence of data entry errors by 80%.
- **Enhanced Communication:** Facilitated better communication among geographically dispersed teams through real-time data sharing.

Applications of AI in tailings dam management

Beyond quality control, AI has broad applications in tailings dam management, including:

- **Predictive Analytics:** Using historical data to predict potential issues and optimize resource allocation, AI will be able to determine the root cause of any non-compliance and trigger precautionary measures.
- **Safety Assessments:** Real-time monitoring and analysis to enhance safety protocols. For a fast-track construction, it will have the power to remove any detected deficiency for future work.

- **Proactive Decision-Making:** AI-driven insights to support strategic planning and risk mitigation.

These are some examples only. The opportunities to make tailings dams safer are unlimited.

Conclusion

The AI-assisted approach for tailings dam construction quality assurance offers significant advantages in efficiency, accuracy, and real-time monitoring. The broader application of AI in tailings dam management holds promise for transformative improvements in operational planning, safety, and decision-making. Future research should focus on expanding these capabilities and integrating them into standard practice.

Vale Base Metals Modernization of Instrumentation Monitoring System for Dam Safety at Canada Tailings Storage Facilities

Wing-Keat (Wayne) Wong, Tetra Tech, Canada
Greg Puro, Vale Base Metals, Canada
Lucas Lobato Ribeiro, Vale Base Metals, Canada

Abstract

The failure of the B1 Dam in the Córrego do Feijão Mine, in Brumadinho, Brazil, has underscored the need for Vale to further enhance dam safety through the modernization of instrumentation monitoring systems at tailings storage facilities. This endeavor resulted in the creation of an automatic real-time telemetry monitoring system, facilitating the connection and installation of approximately 400 existing and new instruments, alongside the design and installation of over 110 monitoring stations across seven Vale Base Metals (Vale) sites in Canada. This paper offers a case study showing the establishment of the real-time telemetry system, illustrating how the field dam monitoring instruments transmit the data to an online software platform. It discusses considerations pertinent to instrumentation data management, result output displays, and alert notifications aimed at monitoring both instrument health and dam stability to enhance safety. The project entailed collaboration with various stakeholders, including Vale Base Metals' dam safety management, IT security, communication teams, instrumentation vendors, installation contractors, dam Engineers of Records (EoRs), Responsible Tailings Facilities Engineers (RTFEs), and engineering consultants across Canada.

Each site's real-time monitoring system was engineered with radio and cellular wireless signals, enabling monitoring stations to intercommunicate and transmit monitoring data from remote tailings storage facilities to the central hub at the local site, before disseminating it beyond the mine site. An array of alert notifications for instrumentation and monitoring station health has been established to inform RTFEs of any disruptions, prompting on-site assessments. Collected field instrument data has been integrated into Vale's mine operation system utilizing OSISoft's PI System (PI), with instrumentation locations depicted on site aerial layouts and dam structure cross-sections within the PI program. Real-time monitoring data, in conjunction with historical data, is presented through graphical plots and values of site instrumentations.

Introduction

Modern technology has advanced recently with unprecedented speed, with the invention of smart phones, and cloud computing, and the advancements on fast computing microchips. Technological advances over the past 20 years have improved instrumentation capability and reduced costs. Therefore, most the mine operators worldwide have installed more advanced monitoring instruments system to improve dam safety as part of their Operation, Maintenance and Surveillance (OMS) programs. Despite technological advancements, most mine operators still manually execute their dam instrumentation monitoring programs. The adoption of real-time instrumentation data collection systems with wireless data transmission for a remote telemetry dam monitoring has been relatively slow.

The failure of the B1 Dam in Brumadinho, Brazil, has underscored the imperative for Vale to further enhance dam safety programs through modernization of instrumentation monitoring systems at Tailings Storage Facilities (TSF). This initiative was applied globally by Vale and included all of Vale Base Metals' TSFs in Canada. The key objectives of the initiatives that were established by the Vale Base Metals' Dam Safety Group were to improve dam monitoring data collection practices, to enhance the visibility of dam status, and to implement an early warning system; while at the same time, modernizing and standardizing the monitoring system.

Modernization of instrumentation monitoring system

The modernization of the instrumentation monitoring system commenced in 2019 with the establishment of a framework for a preferred dam monitoring system and the formulation of design criteria. A comprehensive technology review and market study were conducted to evaluate potential systems and product options aimed at selecting a more reliable and robust system applicable across all mine sites in Canada. Another project goal was to standardize and unify the instrumentation monitoring platform for the dam safety program. Following the study's completion, a fully automated and self-sustaining data collection system was developed, designed to accommodate additional instruments easily and capable of operating on existing electrical power and communication networks.

The monitoring system was required to have lightning protection to protect the integrity of the instruments and its dataloggers. Due to the critical nature of dam instrumentation monitoring for dam safety, each component and function involved in instrumentation data collection, storage, communication paths, and data outputs includes redundancy measures. These measures ensure backup options, both primary and secondary, in case of failures at the primary option. Figure 1 illustrates the concept of field data collection and its wired and wireless communications from the field to the network server, further delivering instrumentation data to end users.

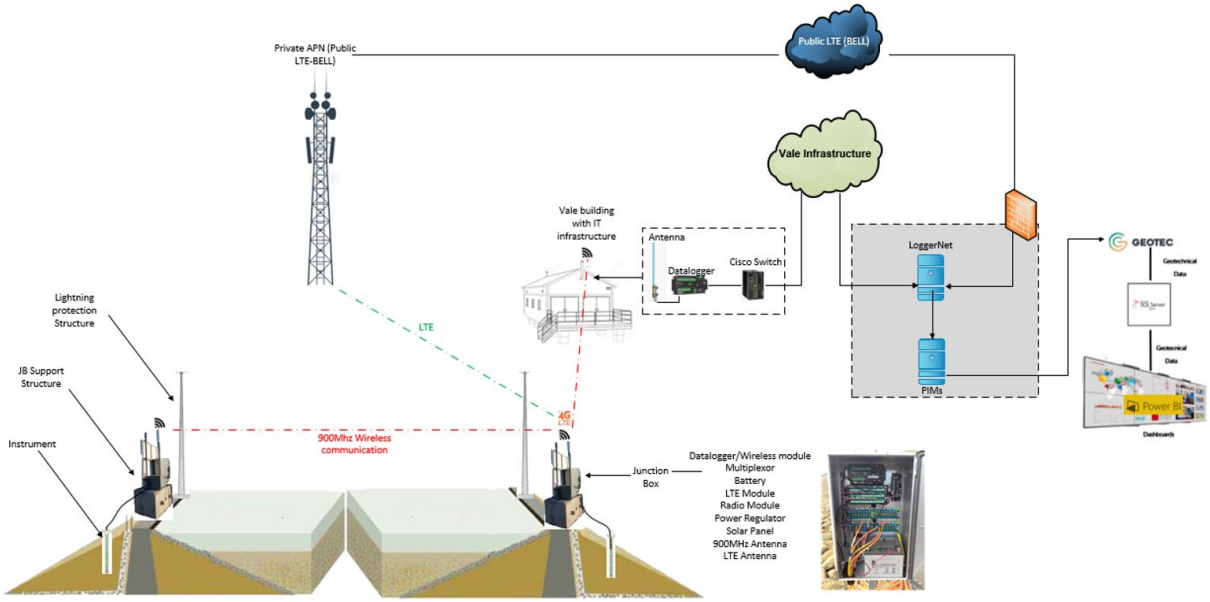


Figure 1: Conceptual diagram of the instrumentation data communication network

Based on the communication and design concepts selected by Vale, the instrumentation telemetry system was developed to consist of field monitoring stations connecting nearby instruments embedded in the dams. Each monitoring station location includes approximately 5-meter-high Junction Box Structures (JBS) and approximately 8-meter-high Lightning Protection Structures (LPS), as shown in Figure 2. These structures were erected on granular foundation pads to ensure stability and visibility.

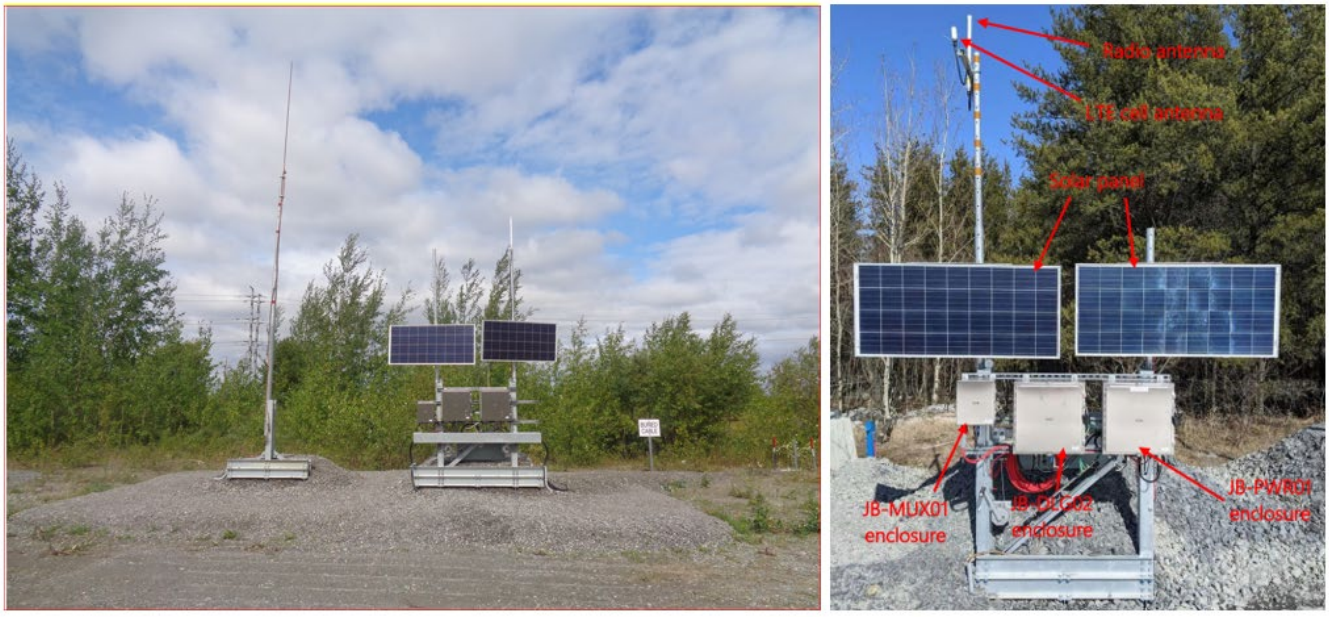

Figure 2: Typical instrumentation monitoring station with Lightning Protection Structure (LPS) on the left and Junction Box Structure (JBS) on the right

The JBS typically includes a radio antenna to establish a wireless communication network with nearby monitoring stations, featuring designated primary and secondary communication paths. Selected monitoring stations within each dam area group also house an LTE cell antenna at the top of the JBS pole. This setup enables transmission of instrumentation data from the field to the mine plant server via LTE cellular towers, as depicted in Figure 1. In case of communication challenges at the primary station, the system automatically switches to a secondary monitoring station to transmit field monitoring data. The front rack of the JBS accommodates two to four enclosures for instrumentation cable connections, power control and distribution, data storage, and wireless communication components.

The LPS is a galvanized metal structure with extendable tele-masts, topped with a 1.5-meter-high copper lightning rod, creating a total height of 8 meters. The LPS height is designed to provide an umbrella of protection against lightning strikes, safeguarding connected instruments across the station. The project established minimum safe distances from the LPS to the JBS, buried routed cables, instruments, associated grounding rods, and established maximum distances to ensure effective lightning protection. Ground resistivity requirements for the number of grounding rods were specified and confirmed on site post-installation.

Implementation of the modernization system on site

Implementing the telemetry system to connect all field instruments necessitated a comprehensive understanding of the quantity, quality, type, location, and identity of existing site instruments. Additionally, various new instruments were designed and installed on site. By project completion, over 400 dam monitoring instruments were interconnected, with 110 monitoring stations erected across all seven mine sites in Canada.

The feasibility and constraints of cable trenching, routes, burial methods on dam crests and slopes, and the positioning of monitoring stations, including the load on granular foundation pads, were evaluated on site in collaboration with local stakeholders. These findings were subsequently submitted to the EoR of each tailings storage facility for approval. During site visits, assessments were also made regarding the availability of power sources, such as nearby 120 VAC electrical cable lines, or the necessity for solar panels to power monitoring stations in remote locations.

Preliminary tests were conducted to assess the availability and LTE signal strength at each dam structure. This is crucial for establishing wireless communication and data transmission paths at each dam location. Figure 3 illustrates a sample of cable routing and monitoring station locations at one of the tailings storage facilities.

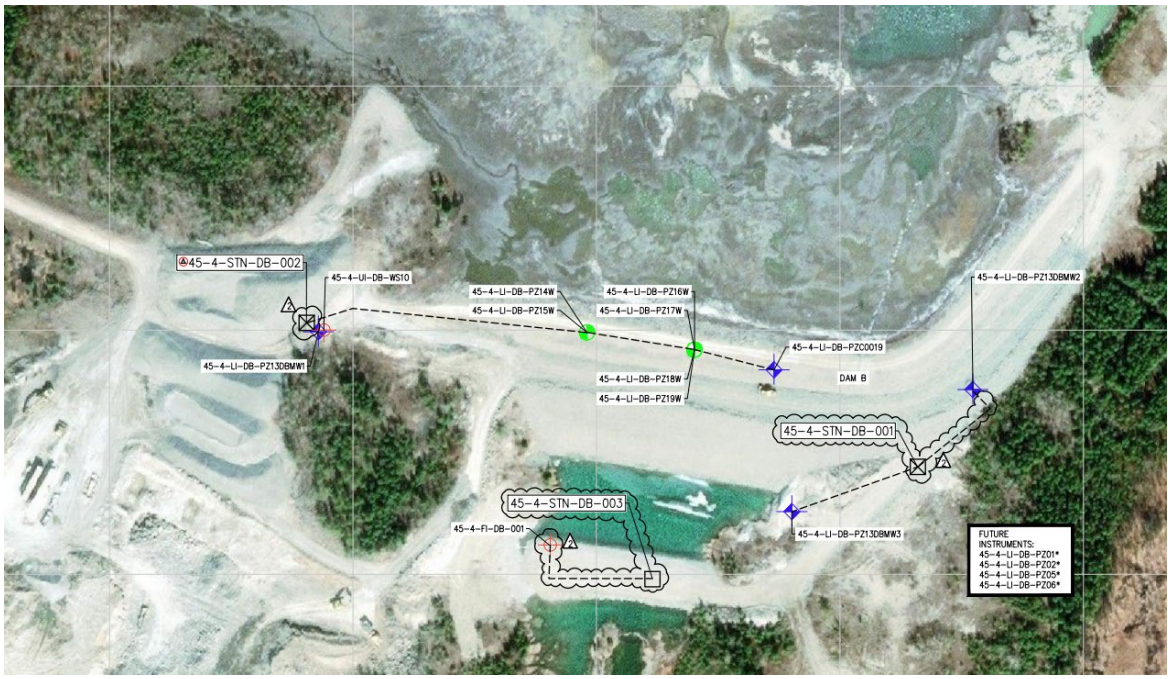

Figure 3: Sample instrumentation cable routing and monitoring station (STN) locations at a tailings storage facility

Types of dam monitoring instruments

As previously mentioned, over 400 dam monitoring instruments have been integrated into the monitoring stations. These instruments comprise both existing ones from the sites and new installations during the construction of the monitoring stations. The types of instruments deployed include:

1. Vibrating wire piezometers
2. Radar water level sensors
3. Laser water level sensors
4. Vented pressure level sensor
5. Shape Arrays (SAA)
6. Vibration sensors (geophones)
7. Weather stations
8. Temperature and humidity sensors

Site instruments vary in shape and condition. Therefore, instrument condition assessment and calibration are essential to confirm instrumentation measurement accuracy for the project. Calibration of the instruments was conducted on-site, encompassing existing accessible instruments (not grouted) as well as all newly installed instruments for the project. Figure 4 illustrates typical site instruments.

Figure 4: Sample site instruments

Instrumentation data management using OSISoft PI System

Instrumentation data management and dashboard monitoring displays are crucial components for the new automated monitoring system. All raw data from field instruments is collected within a centralized program platform. This raw data undergoes extraction by the OSIsoft PI (PI) program for further processing and calculations. Processed data is then stored and presented in PI, enabling end users to remotely review real-time measurements collected on-site, thus facilitating assessment of dam structure conditions.

Early in the project, all instrument data underwent comprehensive review and calibration to validate calculation accuracy. Throughout the project lifecycle, Vale Base Metals' IT team collaborated with local RTFEs and EoRs, as well as the Dam Safety Group and other stakeholders, to develop user-friendly output

interfaces within the PI program. These interfaces include features such as presenting aerial plan views of dam structures and the relative positions of instruments, illustrated in Figure 5.

The system continuously monitors instrumentation data collection and communication health conditions. Various health categories are rated to provide stakeholders with insights into the continuous and uninterrupted collection and reporting of data from each specific instrument. In cases of interruptions, the system evaluates the duration and frequency, thereby assessing the reliability of site instruments and overall monitoring station performance. Figure 6 displays a cross-section view detailing the depths and positions of installed instrumentation sensors, along with real-time site measurement values.

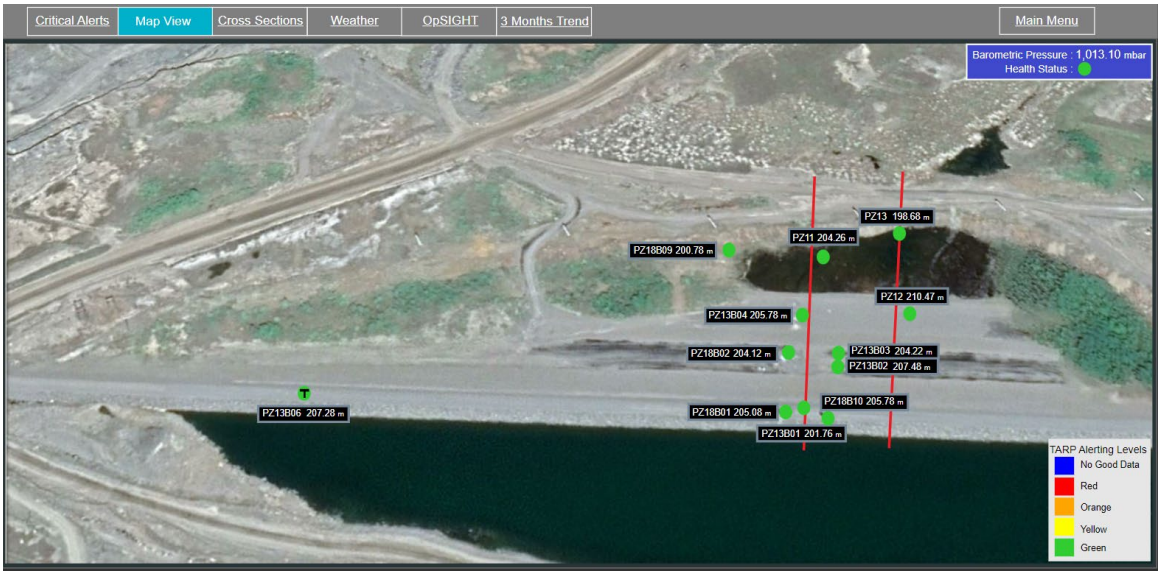

Figure 5: Plan view of site instruments on dam structure in PI

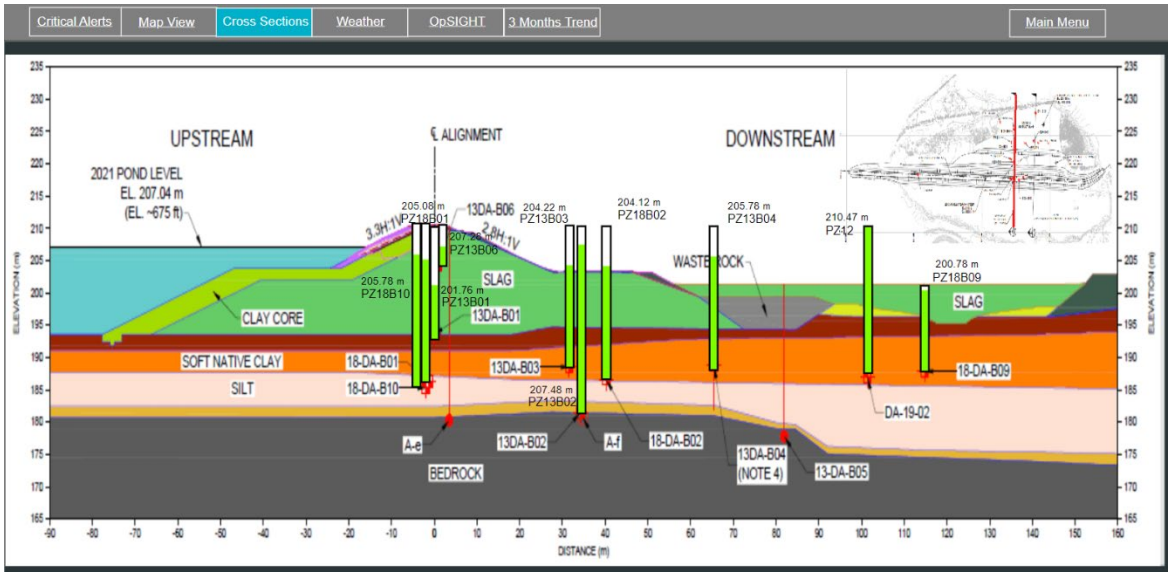

Figure 6: Cross-section view of the site instruments in PI

Monitoring the health conditions of instruments and monitoring stations provides a unique and valuable feature enabling stakeholders to promptly identify potential issues. Health alert notifications have been established to cover various instrument conditions, including:

- Instruments not reporting data or experiencing stale data issues.
- Monitoring station conditions such as temperature and humidity measurements within enclosures, wireless communication signal strength, solar panel charges, and battery voltage levels.

Details of the health measurement interface are shown in Figure 7.

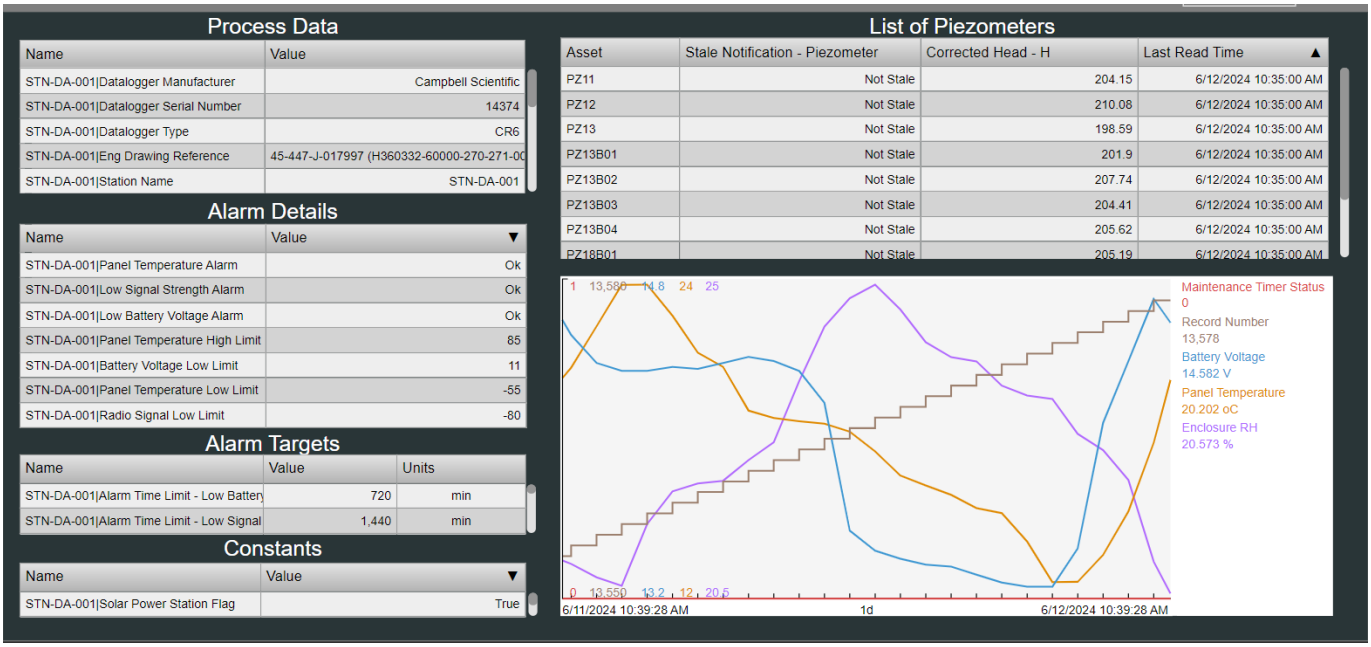

Figure 7: Instruments and monitoring station health condition measurement interface

In addition to health condition monitoring and associated alert notifications, thresholds for allowable instrumentation measurement values have been set for each dam structure. When field measurements approach these thresholds, email notifications are triggered to inform RTFEs and other critical stakeholders. Sample instrumentation measurements and their threshold alert or alarm configurations are presented in Figure 8.

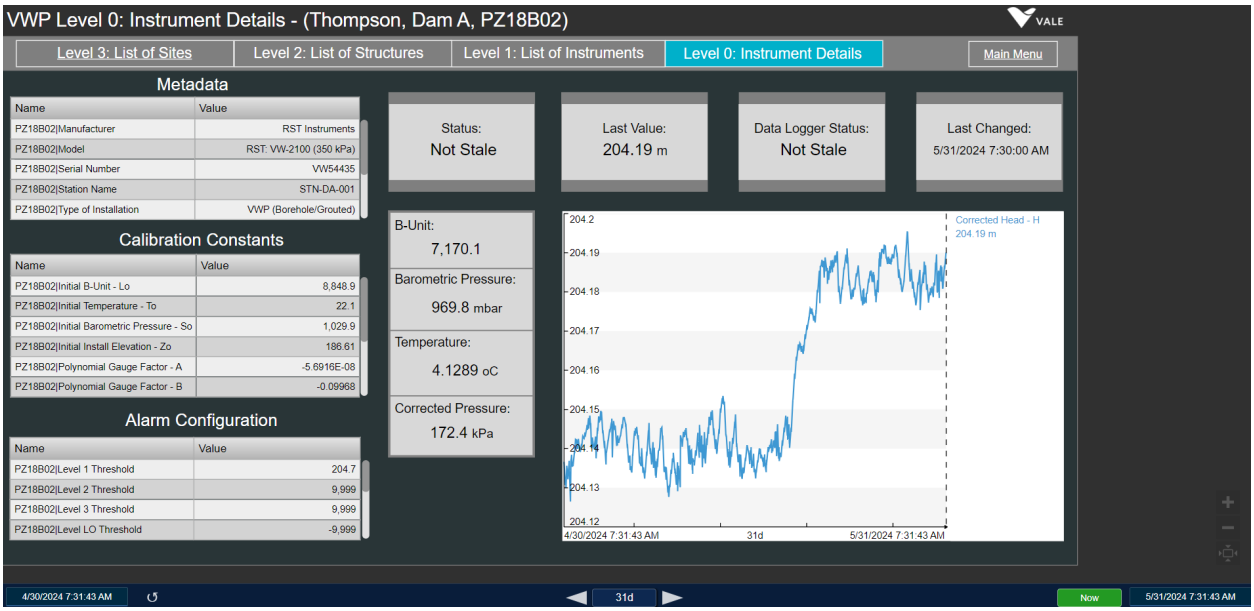

Figure 8: Instrument measurement details and alarm configuration

Conclusion

The Tailings Storage Facilities Monitoring Systems (TSFMS) Project aimed to establish a fully automated data collection system for geotechnical sensors in remote environments. Upon completion of this project, several significant benefits had been realized through enhanced data collection practices:

- Digitization of data: the project successfully transitioned to digital data collection, improving accessibility and data management efficiency.
- Increased resolution and frequency of data samples: by automating data collection, the system achieved higher data resolution and frequency, providing more detailed insights into dam conditions.
- Standardization across Vale Base Metals: the implementation standardized monitoring practices across all business units, enhancing consistency and reliability in dam safety monitoring.
- Visibility and situational awareness: stakeholders gained improved visibility and situational awareness of dam conditions, facilitating proactive decision-making and risk management.

The project successfully achieved its objective of automating instrumentation data collection, enabling authorized users to remotely access dam monitoring data. As a result, the instrumentation monitoring system for dam safety has been modernized across all seven sites in Canada.

Acknowledgements

We extend our sincere thanks to all Vale Base Metals stakeholders who worked tirelessly to ensure the

success of the project aimed at enhancing the dam safety program. The substantial investment made by Vale Base Metals to achieve the project goals is greatly appreciated and deserves recognition within the mining industry.

Assessing SAR, InSAR and Multispectral Optical Data for Mapping Supernatant Pond Evolution

Abstract

The effective management of mine Tailings Storage Facilities (TSF) is a high priority for mine operators, communities, and governments to mitigate the risks associated with water contamination, pollution, and dam failures. The Global Industry Standard on Tailings Management (GISTM) guidelines identify TSF water management as a key requirement for the safety of mining operations. Commonly used methods for monitoring the location and spatial extent of surficial moisture and supernatant ponding within TSFs include the use of multispectral optical satellite imagery. This application requires high accuracy in identifying small water bodies and frequent updates due to the high dynamicity of mining operations; however, freely accessible imagery from Sentinel-2 and Landsat satellites have a pixel resolution of 10 to 20 m and 30 m, respectively, and the temporal coverage can be affected by the presence of cloud cover, illumination differences, and terrain shadow. These limitations can be overcome using high-resolution Synthetic Aperture Radar (SAR) amplitude satellite data, as SAR signals can penetrate cloud cover.

In this study, machine learning techniques are used to characterize TSF saturation changes by combining both Sentinel-2 optical images and high-resolution (3 m) TerraSAR-X SAR data. This study investigates (i) the differences between the supernatant pond areas classified using multiple satellite data sources (SAR amplitude and multispectral optical imagery), (ii) the factors driving the accuracy of SAR water maps in TSF impoundments, and (iii) developing guidelines for the combined use of optical, SAR, and InSAR data for TSF water mapping.

Mapping TSF supernatant water bodies solely with Synthetic Aperture Radar (SAR) data presents major challenges since fully saturated sediments or slurry often appear indistinguishable from water bodies in SAR amplitude data. However, we find that optical, SAR, and InSAR data complement each other well for water body mapping and provide a substantial improvement over the use of each input individually.

High-resolution SAR can provide detailed water body maps over time and space, and when available, cloud- and shadow-free multispectral water indices are reliable indicators of surface water to use as refinement and validation.

Introduction

Mine tailings are the finely ground residuals, including heavy metals and toxins, that remain after the mill process has removed the valuable metals from the ore. Tailings are typically stored permanently in tailings storage facilities (TSFs), ground impoundments retained by dams. The effective management of TSF supernatant ponds (that form due to process and pumped water and natural precipitation) is critical for mine operators, the environment, and communities that would be affected by a dam failure. Different tailings dam databases (ICOLD, WISE, World Mine Tailings Failures, CSP) indicate that, since 1915, a total of 257 failures have been recorded with circa 2,650 fatalities and 250 Mm^3 of contaminated residues released to the environment (Piciullo et al., 2022). As attested to by the different analyses and investigations, the control of water stored inside the TSF reservoir area is a critical issue (Cacciuttolo and Cano, 2023). The Global Industry Standard on Tailings Management (GISTM) guidelines, published in August 2020, also identifies TSF water management as one of the main requirements for the safety of mining operations. In this framework, TSF supernatant pond maps can be effective operational tools for mine operators to identify unexpected or unpredicted behaviors that may contribute to embankment failure.

Remote sensing methods provide cost-effective ways of monitoring water bodies and the saturation levels of tailings facilities over large areas (e.g., Koleshwar et al., 2023), particularly with freely available datasets such as the European Space Agency's Sentinel-1 Synthetic Aperture Radar (SAR) satellite and the Sentinel-2 satellites' multispectral (MS) sensors, as well as the National Aeronautics and Space Administration and United States Geological Survey's MS Landsat sensor. These platforms image most of the surface of the Earth at regular intervals, providing up-to-date data without the need for in-situ measurements or instrumentation.

SAR satellites are active, meaning they emit radar pulses and detect the energy backscattered off the ground. The amplitude of the measured signal represents the fraction of the emitted signal that is reflected in the direction of the satellite and can be used to identify features on the ground. The phase of the returning signal is a function of the distance travelled, and by combining the phase data of successive acquisitions, Interferometric SAR (InSAR) can be used to map ground displacements at a precision on the order of millimeters (Ferretti et al., 2011; Ferretti, 2014). In contrast, MS sensors are passive, and measure the radiation emitted by the sun that reflects off the Earth's surface in the direction of the satellite. While SAR platforms emit and detect a specific wavelength of the electromagnetic spectrum, MS sensors detect a stack

of images with each acquisition, each representing the total reflected energy within a specific band of the electromagnetic spectrum.

The most well-established remote sensing methods of mapping of water bodies and saturation levels use MS data, as different bands of the electromagnetic spectrum have different reflective properties over various types of material such as water, dry soil and vegetation, allowing for land cover classification (e.g., Townshend et al., 1991). These methods include the use of water and moisture indices such as normalized difference water index (NDWI), modified normalized difference water index (MNDWI) and normalized difference moisture index (NDMI) (e.g., Gao, 1996; Xu, 2006; Acharya et al., 2018). For example, the NDWI exploits the contrast in reflectance values of green (500 – 600 nm wavelength) and near-infrared (700 – 1,400 nm wavelength) radiation over water bodies and dry material. One of the main limitations of MS sensors is that electromagnetic radiation at these wavelengths does not penetrate through cloud cover, which can result in lengthy and/or regular temporal data gaps in certain parts of the world. However, SAR satellites operate at wavelengths that are capable of imaging the Earth's surface in any weather, as well as at night.

In this study, we explore the feasibility of using SAR amplitude data to monitor the extent of supernatant ponds using a machine learning (ML; using k-means clustering) and Deep Learning (DL; with a convolutional neural network; CNN) approaches, as this greatly expands the number of datasets available for remotely monitoring supernatant ponds within TSFs. We apply these algorithms to four anonymized TSFs located in a drought-prone area. Two TSFs (referred to as TSF1 and TSF2) are constructed with an upstream raised method, and two are integrated waste landforms (IWL1 and IWL2). The primary TSFs are purposed for storing waste material produced during mining operations, whereas the IWLs are used for both waste storage and controlled seepage recovery of return water from the primary TSFs to reduce the amount of fresh water required from external sources.

The results obtained using a preliminary CNN algorithm show that SAR imagery can successfully identify combined wet beach and ponding areas. The results also reveal different SAR reflectance behaviors over different TSF materials, providing clear directions for further refinement of the algorithm. Additionally, we demonstrate the compatibility of TSF ponding and saturation mapping and InSAR displacement measurements for monitoring and understanding the relationship between TSF activity and embankment stability.

Data and methods

SAR water body mapping

In this study, supernatant ponds within TSFs are mapped using SAR data from different satellite missions with different polarizations, wavelengths, spatial and temporal resolutions. The polarization refers to the

plane in which the electromagnetic wave of the SAR sensor oscillates (vertical or horizontal). Targets imaged on the ground can have different polarimetric properties which may affect the results of a SAR-based water mapping approach (Brisco et al., 2011). The first dataset is the freely available C-band (5.6-cm wavelength) Sentinel-1 data in the VV polarization (i.e., both emitted and return signal are vertically polarized) from the European Space Agency. Its ground resolution is 20 m × 5 m, and the revisit period is 12 days. The second dataset was also acquired by the Sentinel-1 satellite, but in the VH polarization (i.e., the emitted signal is vertically polarized, and the return signal is horizontally polarized). The third dataset is obtained from the TerraSAR-X satellite constellation in the HH polarization (i.e., both emitted and return signal are horizontally polarized). These are commercial X-band data (3.1-cm wavelength), have a ground resolution of 3 m × 3 m and a revisit period of 11 days. The acquisition period for each dataset is listed in Table 1.

Table 1: Datasets used in this study. ML label refers to dataset used for machine learning-based water mapping. InSAR label refers to dataset used for multi-temporal InSAR analysis

Constellation	Sensor	Wavelength	Resolution (m)	Revisit Period (days)	Geometry	Analysis Period
Sentinel-1	SAR	5.6 cm	20 × 5	12	Descending	2018-12-15 to 2024-02-18 (ML) 2021-01-09 to 2024-02-23 (InSAR)
TerraSAR-X	SAR	3.1 cm	3 × 3	11	Ascending	2018-10-30 to 2023-10-19 (ML) 2021-01-10 to 2024-02-28 (InSAR)
Sentinel-2	MS	543 – 578 nm, 785 – 900 nm, 1,565 – 1,655 nm	10 × 10, 10 × 10, 20 × 20	5	Descending	2018-12-14 to 2024-02-16

The SAR data are first pre-processed (i.e., co-registered, amplitude calibrated/normalized), and a Deep Learning speckle filter is applied to reduce noise (*cfr.* Lattari et al., 2019). Two ML water classification algorithms are then used: (i) a statistical approach using K-means clustering and the Sobel operator (Kanopoulos et al., 1988) to define the location and outline of the pond areas, and (ii) a Convolutional Neural Network (CNN) trained on waterbodies such as lakes and rivers using Sentinel-1 data in the VV polarization and MS images. The CNN uses unfiltered SAR data to increase the spatial resolution of the water classification result. While the differences between the backscattering properties of lakes and TSFs are substantial, the results of the CNN algorithm are expected to provide preliminary insights on the use of SAR for TSF water body mapping and help determine directions to refine a CNN specifically tailored to TSFs. A block diagram of the water classification algorithms is shown in Figure 1A. The output is a

raster map of the probability that a pixel is water. A binary map is then created, in which pixels with a probability greater than 0.9 are classified as water.

The results of the SAR water mapping algorithms are validated using the NDWI derived from the green and near-infrared bands of the Sentinel-2 constellation (Table 1). Therefore, we only process SAR images acquired within 1 day of a cloud-free Sentinel-2 acquisition. The NDWI can range from -1 (i.e., dry ground) to 1 (i.e., water) where there is a short transition between dry ground and supernatant ponding near 0 (Gao, 1996). NDWI water classification was performed using two methods: one with a dynamic threshold selected using k-means clustering, and the other where all pixels with an index value greater than 0.3 are selected (Figure 1B). The latter threshold was selected using the statistical distribution of indices in this dataset and a visual check of true color imagery derived from Sentinel-2 data.

Since SAR amplitude data can have similar backscatter behavior over shallow water and saturated material, we classify pixels corresponding to saturated tailings (moisture levels between dry and standing water) using MNDWI, which uses the green and shortwave infrared bands (central wavelength: 1,610 nm) and also ranges from -1 to 1 for dry ground and water, respectively. Its transition zone from dry ground through wet material to water is wider than with NDWI, therefore its water threshold is typically higher and it can better detect beach wetness. We classify MNDWI index values between 0.1 and 0.6 as saturated material and values greater than 0.6 as supernatant pond based on the statistical distribution of indices in this dataset and a qualitative visual assessment of Sentinel-2 true color imagery).

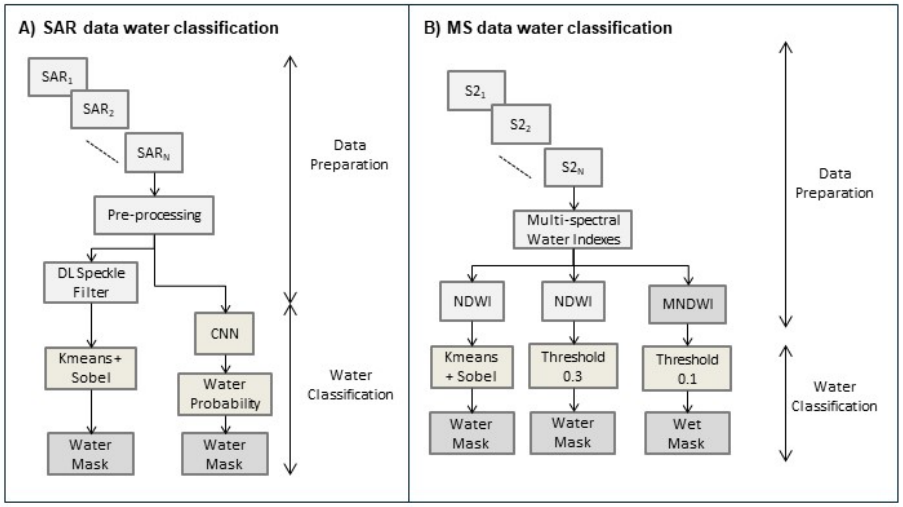

Figure 1: Water classification block diagrams. DL = Deep Learning

Multi-temporal InSAR

Multi-temporal InSAR is a commonly used method for monitoring the stability of TSF embankments. It involves processing dozens to hundreds of SAR phase data acquisitions to extract time series of gradual, millimeter-scale displacements. We use TRE Altamira's proprietary SqueeSAR algorithm to find and follow

natural reflectors on the ground that are statistically reliable throughout the analysis period (Ferretti et al., 2011; Ferretti, 2014). InSAR detects displacements along the satellite line-of-sight (LOS) vector, which "looks" to the right of the satellite's roughly north-south-oriented path. When travelling from south to north (referred to as the "ascending" geometry), the satellite is east-looking. Conversely, when travelling from north to south ("descending" geometry) the satellite is west-looking. We estimate the vertical and east-west components of displacement by decomposing the ascending and descending vectors of displacement occurring at approximately the same time and location.

Results and discussion

Tailings storage facility supernatant pond mapping with synthetic aperture radar

In this section we use the pixels classified as water using NDWI as the reference for the ponding areas. Figures 2a, 2c, 2e and 2g show the time series of the area that was classified as standing water using area within TSF1 and TSF2. The % area within the TSF that has a MNDWI greater than 0.1 (including saturated tailings and ponding areas) is also shown. Figures 3a, 3c, 3e and 3g show the time series of the % area that was classified as standing water using NDWI, saturated material using MNDWI, and the ML statistical (k-means/Sobel) and CNN SAR algorithms, as a percentage of the total TSF and water (ponding) using MNDWI, and the ML statistical (k-means/Sobel) and CNN SAR algorithms, within IWL1 and IWL2, respectively. Some observations are common to all four TSFs: firstly, hardly any pixels of the Sentinel-1 VH-polarized data were classified by the CNN as having a probability of being water greater than 0.9 leading to the % area being 0 or near 0 throughout. We therefore show, for the VH-polarized data only, the % area of pixels with a probability of being water greater than 0.7, and we refer to this dataset for the remainder of the section.

In general, the area classified as water using SAR tends to be greater than the pond area mapped using NDWI. The statistical Sentinel-1 results in the VV polarization are slightly lower and similar to the combined area of saturated material and ponds as mapped by MNDWI, compared to the results from the Sentinel-1 VH polarization and the TerraSAR-X results (HH polarization; Figures 2a, 2e, Figures 3a, 3e). The difference between the VV polarization results and the other two datasets is greater when using the CNN. Furthermore, there are many data acquisitions where the CNN failed to identify any water or saturated material in the VH polarization only. Within TSF1 and TSF2, the statistical and CNN approaches were successful in identifying dry material in the absence of moisture using the VV and HH polarizations (Figure 2a, 2c, 2e, 2g). Starting in September 2022, many dry pixels in TSF1 and TSF2 were identified as water by the statistical and CNN approaches using the VH-polarized data. This is not the case for IWL1 and IWL2, where all datasets were successful at identifying dry pixels in the absence of moisture throughout the

analysis period (Figure 3a, 3c, 3e, 3g). Figure 4 shows an example of the areas classified as water by the different algorithms.

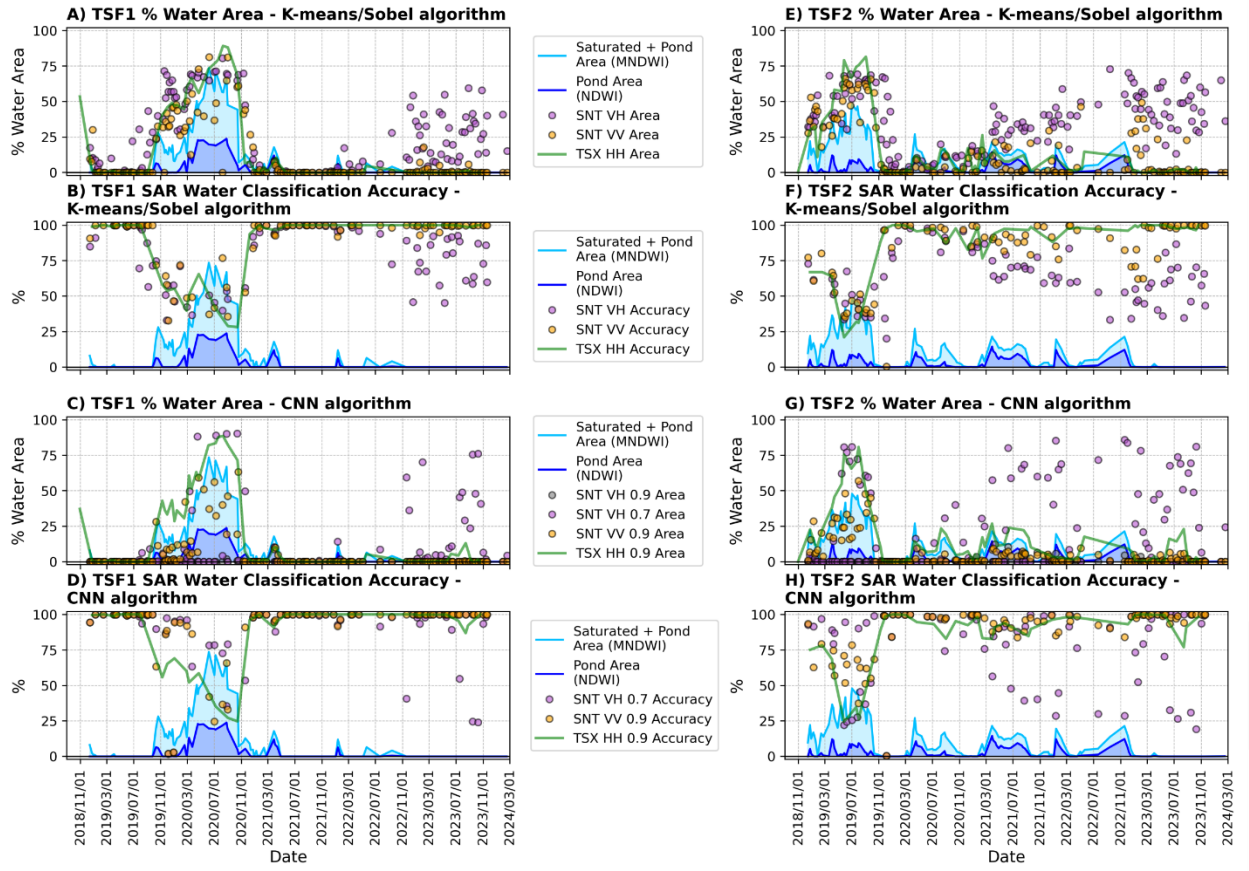

Figure 2: Time series of percentage of tailings storage facility (TSF) area mapped as water using SAR machine learning algorithms and their accuracy. Percentage area of pond and saturated material as measured using normalized difference water indices are shown in each plot as a reference. A-D: TSF1 results. E-H: TSF2 results

The accuracy of the ML algorithms is calculated using a pixel-by-pixel comparison of the SAR and NDWI water masks, with the latter used as the reference for water vs. dry material. Binary SAR water masks are resampled to the same grid as the NDWI masks, and pixels are classified as (i) true positives (TP): SAR and corresponding NDWI pixel are classified as water; (ii) true negatives (TN): SAR and corresponding NDWI pixel are classified as dry; (iii) false positives (FP): SAR pixel classified as water and corresponding NDWI pixel classified as dry; (iv) false negatives (FN): SAR pixel classified as dry and NDWI pixel classified as water. Accuracy is calculated using the following equation:

$$\frac{TP + TN}{TP + TN + FP + FN}$$

Time series of the accuracy of the statistical and CNN SAR water masks for TSF1 and TSF2 are shown in Figures 2b, 2d, 2f and 2h. The accuracy of the statistical water mask is comparable between input

datasets, with high accuracy during dry periods and lower accuracy when there is significant coverage of saturated material, except starting in September 2022 when the Sentinel-1 VH data starts identifying many false positives. The statistical and CNN results are comparable, however in some instances the CNN performs better (e.g. between 11/2019 and 03/2020; Figures 2b and 2d). Note that the higher accuracy of Sentinel-1 VH data during periods with extensive saturation is misleading and is due to the algorithm failing to classify any (or hardly any) pixels as water, resulting in no true positives but still numerous true negatives.

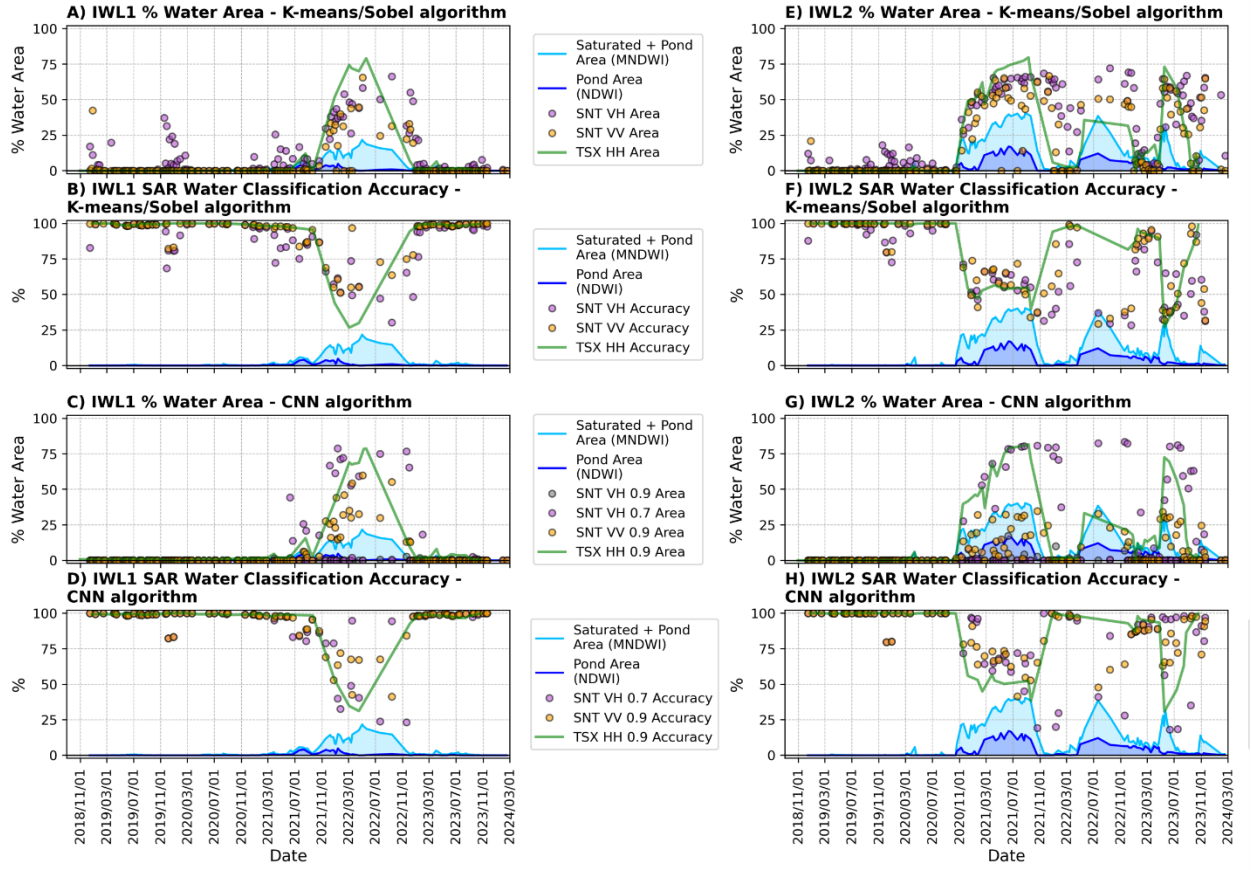

Figure 3: Time series of percentage of integrated waste landform (IWL) area mapped as water using SAR machine learning algorithms and their accuracy. Percentage area of pond and saturated material as measured using normalized difference water indices are shown in each plot as a reference. A-D: IWL1 results. E-H: IWL2 results

Time series of the accuracy of the statistical and CNN SAR water masks for IWL1 and IWL2 are shown in Figures 3b, 3d, 3f and 3h. In general, Sentinel-1 VV results (0.9 probability threshold) are slightly more accurate than Sentinel-1 VH polarization results (0.7 probability threshold), which in turn are slightly more accurate than TerraSAR-X HH polarization results (0.9 probability threshold). Similarly to TSF1 and TSF2, there is a higher accuracy for all datasets during dry periods and lower accuracy when there is a significant amount of ponding and/or saturated material as identified by NDWI and MNDWI.

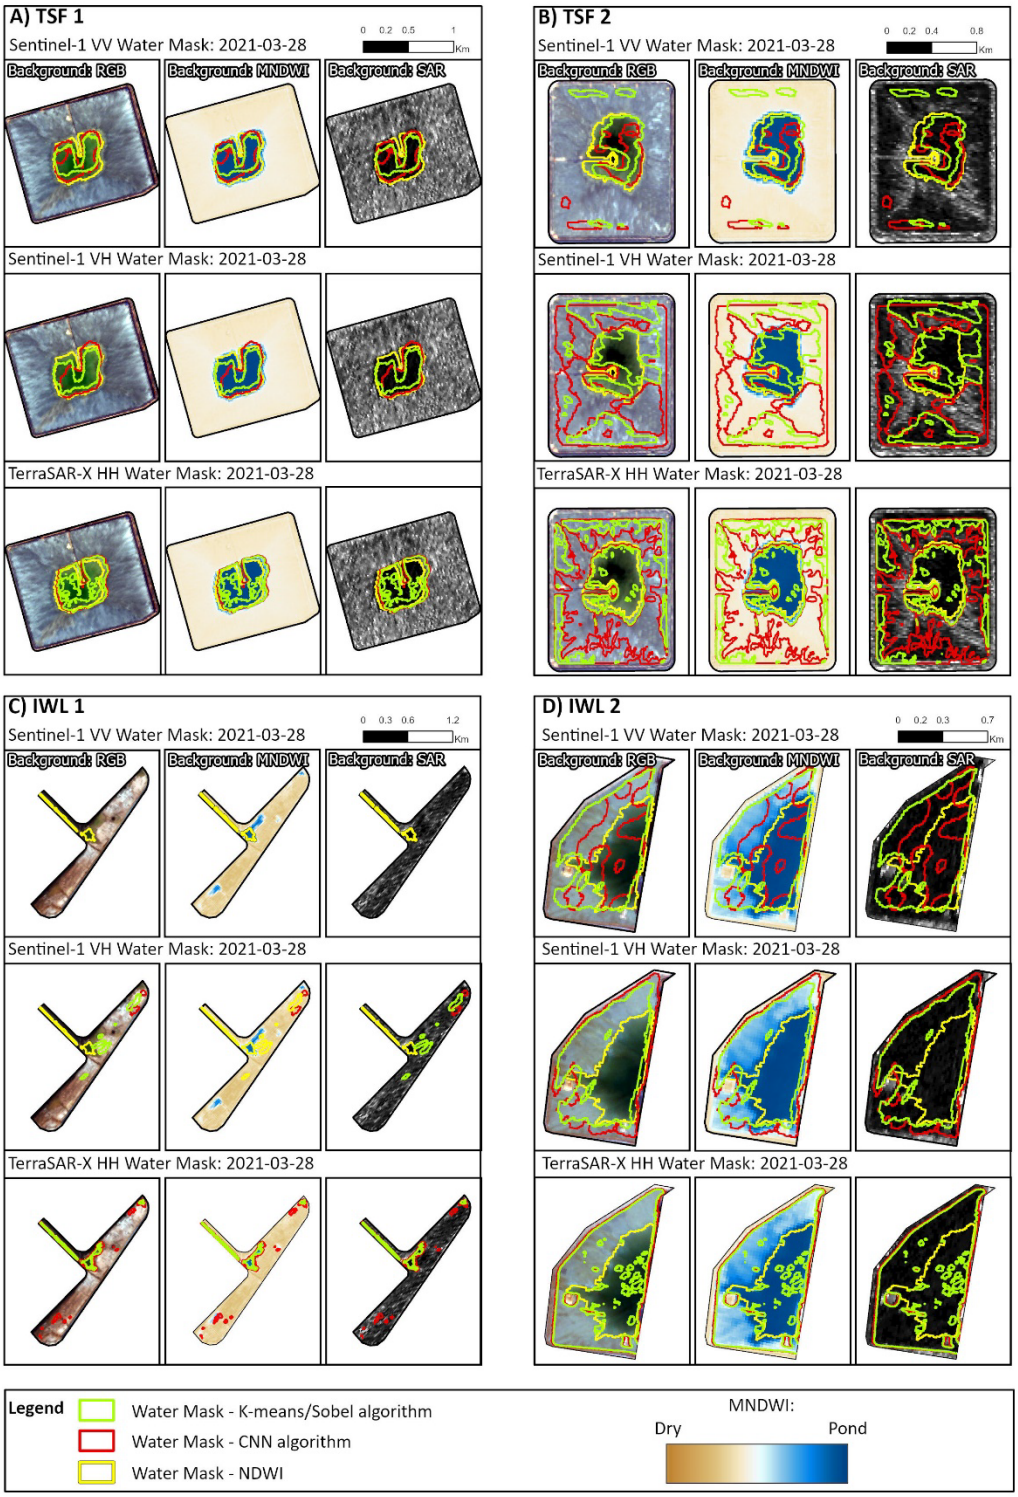

Figure 4: Water mask extent polygons produced using the k-means/Sobel and CNN algorithms (SAR data) and k-means/Sobel (NDWI) overlaid over true color (labelled RGB), MNDWI and SAR amplitude rasters for A) TSF1; B) TSF2; C) IWL1; D) IWL2

The low accuracy of the SAR water masks during periods of high-water content is explained by the algorithm often classifying wet beach areas as water, therefore there are many false positives since the reference water masks correspond only to supernatant ponds as classified by NDWI. This is likely due to the lack of contrast between wet material and pond areas in the SAR amplitude data for some acquisitions (e.g., SAR amplitude panel in Figure 4d). The notable discrepancies between the Sentinel-1 VH results and the other polarizations are limited to one of two TSF categories presented in this study (i.e., TSF1 and TSF2) and occur within a specific period (Figures 2a, 2c, 2e and 2g). This may suggest that specific types of material deposited within these TSFs may be indistinguishable from moisture in the VH polarization with the statistical and CNN algorithms used.

This preliminary CNN algorithm proved to be successful at detecting TSF moisture despite being trained on very different water bodies such as lakes and with data limited to Sentinel-1 in the VV polarization. Differences in the backscatter properties of SAR are expected to be significant between natural water bodies and tailings due to sediment content and water depth, as are differences in the spatial distribution and the saturation gradient around standing water. Based on the results of this analysis, a CNN trained on TSFs may be able to better discriminate between wet beach and supernatant ponds.

Integration of water mapping and InSAR monitoring results

In this section, InSAR is used in conjunction with supernatant pond and saturation mapping to demonstrate the relationship between TSF activity and embankment stability, with a focus on the integrated waste landforms. Embankment stability can be affected by variations in moisture content. Moisture from the material deposited in the TSFs can saturate the embankment, increasing pore pressure and therefore the stresses acting on the embankment. Increased moisture content also increases the weight of the tailings, which can negatively impact embankment stability, as well as settling of the material (Han et al., 2012; Dimitrova and Yanful, 2011). Finally, dry conditions leading to desiccation, cracking and erosion, can also undermine the stability of the embankment (e.g., Vardon, 2015).

The SqueeSAR algorithm provides measurements over areas where the natural radar targets on the ground surface have not changed significantly over time – areas with significant surface changes will contain gaps in data coverage. IWL1 was constructed during the first 6 months of the analysis period, therefore the SqueeSAR analysis resulted in displacement measurements only on the undisturbed portions of the embankments. IWL2 was constructed prior to the start of the SqueeSAR analysis. At IWL1, two areas of subsidence are identified (Figure 5a). The displacement history is similar for both, with three main phases of subsidence as follows: (A) slow average displacement velocity (-9 mm/yr) from approximately January 2021 to January 2022; (B) increased displacement velocity (-24 mm/yr) from approximately January 2022 to July 2023; (C) decreased displacement velocity (-12 mm/yr) from approximately July 2023

to the end of the analysis in February 2024 (Figure 5c). Fifty-three mm of cumulative subsidence are measured over the analysis period.

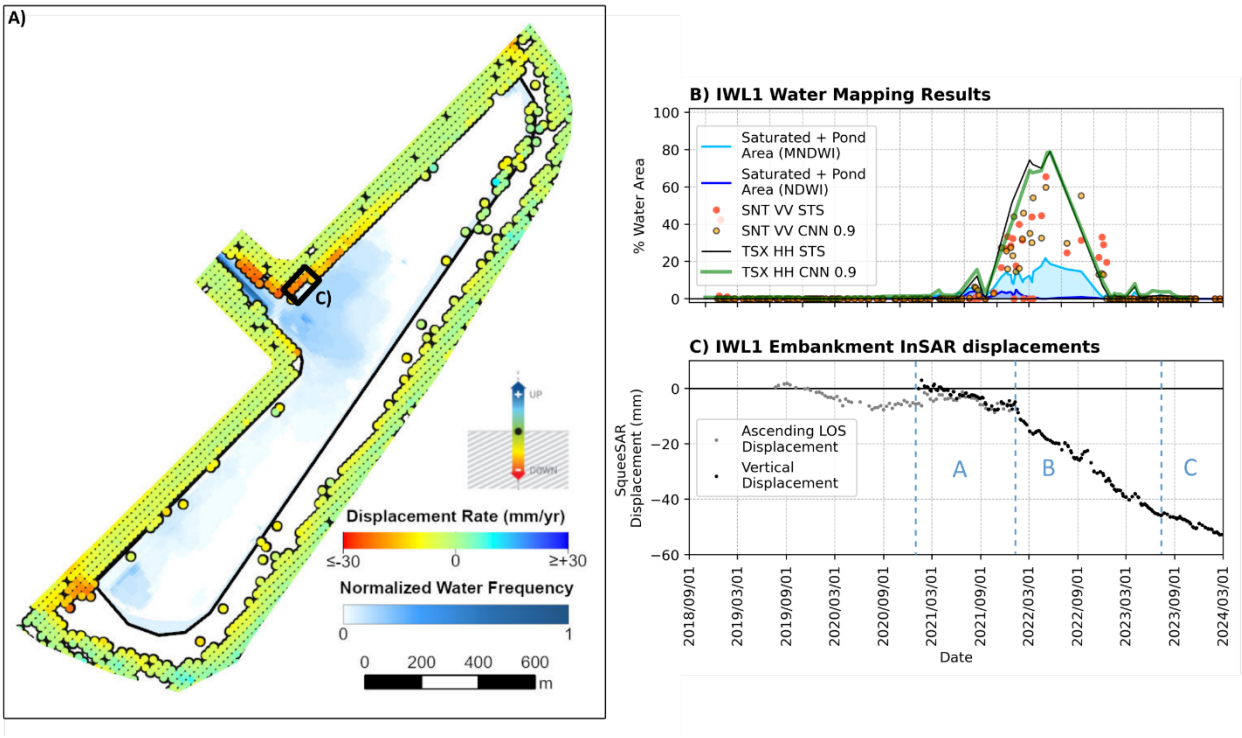

Figure 5: A) Points represent the average velocity of the multi-temporal InSAR analysis on the embankments of IWL1. Colors within the TSF represent the normalized frequency at which each pixel was classified as water during the analysis period using NDWI (1 being the most frequent). B) Percentage water area mapped within this TSF using MS and SAR data. C) Average time series of displacement at the location denoted by thick black polygon in A)

For IWL1, while the main ponding areas shown in Figure 5a correspond to the higher displacement areas, the relationship between the prolonged period of higher InSAR velocity (phase B) and the relatively short period of supernatant ponding is not straightforward. However, the period of increased % area of combined saturated and water pixels (based on MNDWI pixels > 0.1 and SAR-derived water classification) has a similar time scale (Figure 5b), only the phase B InSAR velocity increase is delayed by approximately 6 months. The supplementary monitoring of saturated material rather than ponding only may therefore provide valuable information on the interplay between TSF activity and embankment instability.

An area of subsidence was also identified at IWL2, as shown in Figure 6a. The main phases of displacement are as follows: (A) relatively low average velocity (-13 mm/yr) from the beginning of the analysis (January 2021) to approximately August 2021; (B) higher average velocity (-40 mm/yr) from approximately August 2021 to March 2022; (C) lower velocity (-18 mm/yr) from approximately March 2022 to August 2022; (D) higher velocity (-51 mm/yr) from approximately August 2022 to January 2023;

and (E) lower average velocity (-17 mm/yr) and gradual deceleration from approximately January 2023 to the end of the analysis period (Figure 6c). Eighty mm of subsidence occurred throughout the analysis period.

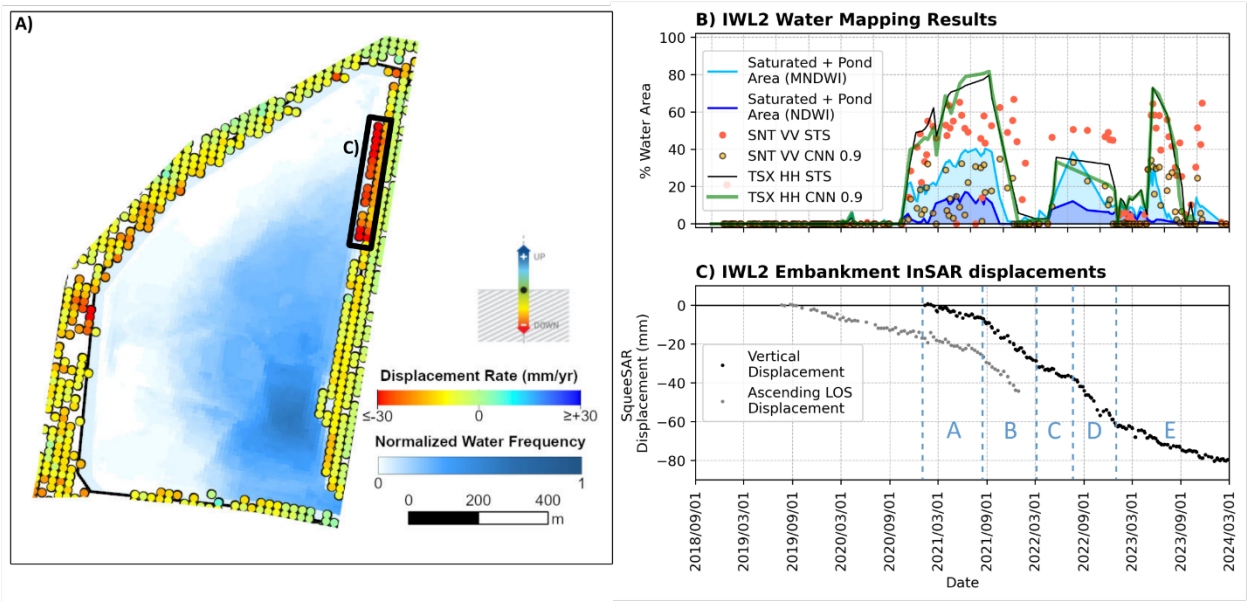

Figure 6: A) Points represent the average velocity of the multi-temporal InSAR analysis on the embankments of IWL2. Shades of blue within the TSF represent the normalized frequency at which each pixel was classified as water during the analysis period using NDWI (1 being the most frequent). B) Percentage water area mapped within this TSF using MS and SAR data. C) Average time series of displacement at the location denoted by thick black polygon in A)

Similarly to IWL1, the less stable portion of the IWL2 embankment is in proximity of an area frequently classified as water (Figure 6a). Furthermore, there are higher InSAR velocity periods starting a few months after periods with large areas covered by ponds and saturated material (Figure 6b). The delay may be related to the gradual change in the stress field due to the saturation and increase of pore pressure of the embankment reducing its shear strength, and other factors such as the weight of the settled tailings, seepage leading to embankment erosion, or the draining of water away from the IWL (Clarkson and Williams, 2021; Saad and Mitri, 2011).

These results illustrate the complementarity of surface water indices, SAR amplitude data and multi-temporal InSAR in monitoring and assessing the impact of the TSF operations on embankment instability. While remote sensing methods can provide long-term history of data over large areas, determining the exact deformation mechanisms in play in the locations identified by InSAR and their causes will require input from the mine operator on their operational schedules and in-situ measurements such as pore pressure, tilting and settlement data, and signs of cracking and tension.

Conclusion

This study demonstrates the ability of two ML algorithms (i.e., a k-means/Sobel operator approach and a preliminary CNN trained on lakes and rivers with VV-polarized SAR data) to identify saturated material within TSFs using SAR amplitude imagery alone. The outcomes are impactful, as well-established methods of detecting TSF moisture and ponding rely on MS imagery that can be heavily impacted by cloud cover.

The results outline specific recommendations for the use of these algorithms in monitoring TSF moisture. Firstly, although further refinement is required to accurately discriminate between fully saturated tailings and standing water, the ML algorithms using SAR data were able to detect large areas corresponding to the combined saturated and pond areas detected by MNDWI. Secondly, the choice of SAR data polarization, and potentially the wavelength (and therefore spatial resolution), significantly affect the results. Of the datasets used in this analysis, Sentinel-1 VV and TerraSAR-X HH-polarized data were generally more successful at mapping TSF moisture than Sentinel-1 VH polarized data. The spatial and temporal trends of saturated material detected using Sentinel-1 VV and TerraSAR-X HH data are also shown to be useful in interpreting TSF embankment displacements measured by InSAR, with periods of extensive saturated material followed by periods of faster embankment subsidence.

The accuracy of the CNN in mapping supernatant ponds is expected to improve with a network trained on TSFs and a variety of SAR polarizations and resolutions. Additionally, information on the operational schedules and specific tailings material deposited is required to fully characterize the polarimetric properties of the TSFs.

The Application of a 3D Inclinometer in Monitoring the Performance of a TSF near an Active Mine Pit

Zhen Ran Yung, Red Earth Engineering: A Geosyntec Company, Australia
Qing Zhan, Red Earth Engineering: A Geosyntec Company, Australia

Abstract

Tailings storage facilities (TSFs) present significant safety and environmental challenges in the mining industry due to the potential for catastrophic failure. TSF operators and engineers have for many years relied on monitoring instruments to assess the performance of a TSF against the design intent and to facilitate early detection of potential hazards, which in turn enables a timely response in the form of a Trigger Action and Response Plan (TARP). The monitoring program for a TSF may include the use of extensometers, survey monuments, and inclinometers to detect embankment movements. However, these instruments typically provide unidirectional (single axis) measurements, which alone may not provide sufficient data for an engineer to make an informed decision that may inadvertently affect TSF stability.

This study introduces the use of an in-place 3D inclinometer settlement system (IPIS), an advanced tool capable of monitoring lateral (horizontal) movement and settlement (vertical) in slopes, embankments, retaining structures, and dams. An IPIS was installed on a TSF embankment at a depth of 40 m, extending into the foundation, founded on a loosely compacted mine spoil material. The implementation of the IPIS was to monitor the stability of the TSF while active open pit mining was occurring downstream of the facility.

Unlike conventional inclinometers and other systems, the IPIS excels in its ability to record both real-time vertical and horizontal deformations at various depths, which are subsequently linked to a cloud-based telemetry system. The movement tolerance or exceedances are programmed into the telemetry, which when exceeded triggers an automated alert (i.e., TARP) to the TSF engineer or dam owner. This monitoring technology and approach is therefore considered to be well suited for high-risk geotechnical structures such as tailings dams, and within the context of this study.

This paper presents an overview of the IPIS with actual site monitoring data to demonstrate the applicability of the equipment to improve stability monitoring of a TSF located adjacent to a 30 m deep

open pit mine. It is envisaged that adopting the IPIS, in conjunction with existing instrumentation monitoring tools such as survey monuments and vibrating wire piezometers (VWPs), will add to the robustness of the monitoring program and allow designers and dam operators a wider range of monitoring options to suit site-specific conditions.

Introduction

TSF monitoring is a critical component within the tailings management framework as it allows engineers to assess the performance of a TSF against the original design parameters, predictions, and overall behavior of the facility. The Global Industry Standard on Tailings Management (GISTM) (ICMM, 2020) requires many of its members to implement a comprehensive and integrated TSF monitoring program for the purpose of verifying design assumptions and monitoring potential failure modes under Requirements 7.1 and 7.2. This must be applied to all phases of the facility lifecycle, including the Closure and Post-Closure phases.

There are a vast variety of commercially available monitoring technologies, and many new and improved instruments are rapidly emerging, or are at various stages of development. Recent advances in the development of new sensors, analytics, and remote monitoring techniques have provided the mining industry with more opportunities and tools to access real-time monitoring information, allowing for a more rapid detection of potential issues, which in turn enables a more proactive response. However, most of these conventional instruments are purpose-built to measure a single source of data, which when used in isolation may not be sufficient for an engineer to make an informed decision affecting the stability of a TSF.

This gap in monitoring was realized at a mine site located in Northern Australia, where open pit mining was carried out to extract valuable minerals within 50 m of an active TSF. This paper discusses the implementation of a “new” 3D in-place inclinometer settlement system (IPIS) that was installed on a TSF to monitor both lateral and vertical displacement of the embankment and foundation soil. This provided dam owners and mining operators increased coverage and confidence to assess the condition of the facility while active mining was occurring downstream.

Facility description

The TSF was constructed circa 2019 as a downstream raise facility comprising a perimeter embankment with a maximum height of 14 m, founded predominantly on loosely compacted overburden mine spoil up to 25 m thick. The TSF is designed to store a total of 14.1 Mm^3 of fine slimes tailings generated from processing mined ore, with the distribution of tailings shared with adjacent TSFs through cyclic deposition to promote consolidation and overall increase in the in-situ settled dry density of the tailings. In 2021, mining was proposed west of the facility, which initiated additional geotechnical investigation through cone

penetrometer testing (CPT) with the intent of reducing geotechnical uncertainty regarding the mine spoil foundation material. Figure 1 shows the location of the existing TSF and the mine pit. Although there are existing monitoring instruments installed on the facility, the risk of embankment failure resulting from the adjacent mining activities was determined to be critical to downstream receptors. Therefore, further dam safety initiatives with a more robust monitoring system were considered necessary.

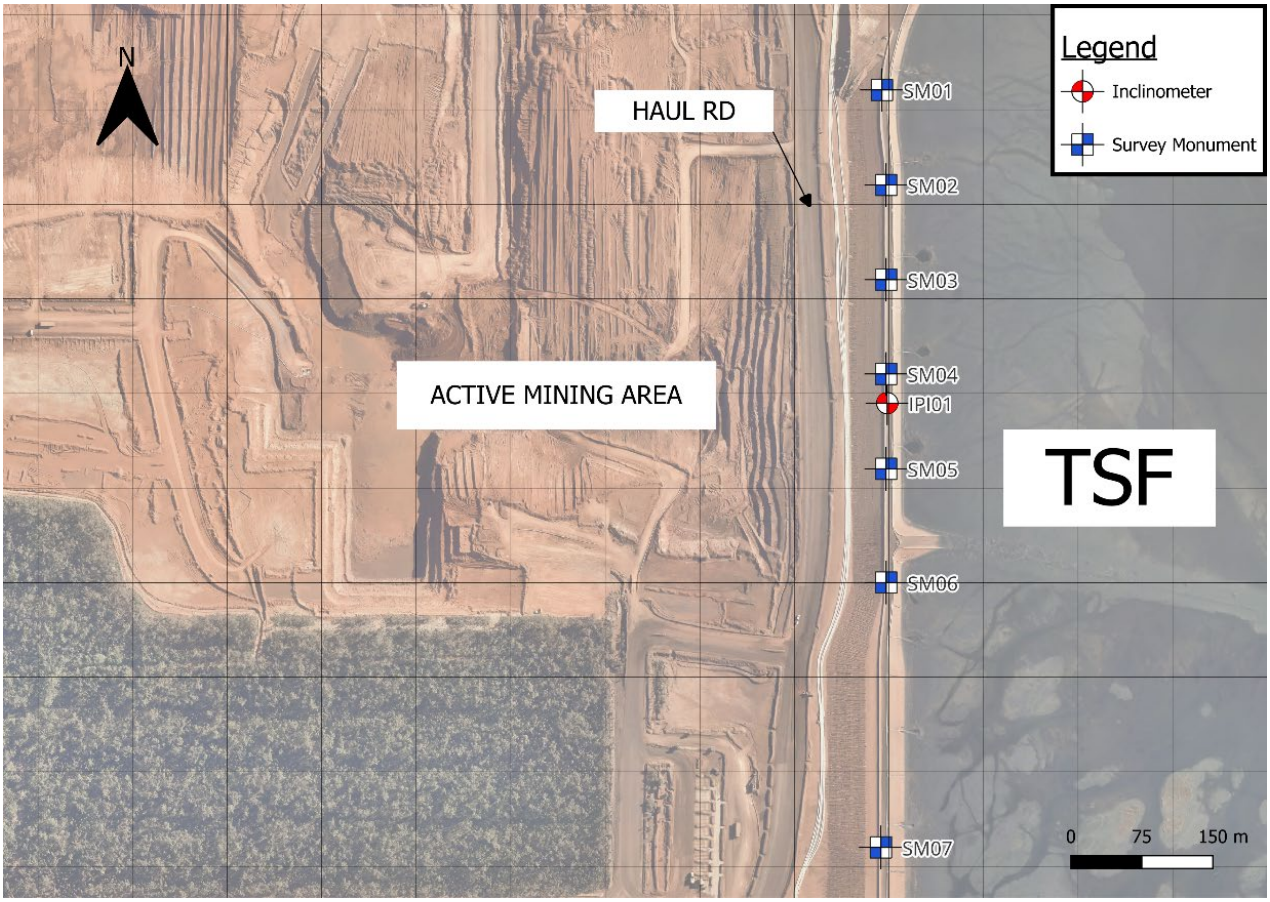

Figure 1: Overview of TSF and adjacent mine pit

Current monitoring practices and challenges

The mine site is situated in a tropical savanna climate that produces two distinct seasons (tropical wet and dry seasons). During the wet period, increased rainfall intensity and frequency result in enlarged ponds and reduces drying time of the tailings surface, which is managed carefully as per the facility operations, monitoring, and surveillance manuals. Currently, the facility utilizes a range of monitoring tools consisting of survey monuments (SMs) and vibrating wire piezometers (VWPs) that are connected to a telemetry system that provides an automated response to the TSF Engineer should a TARP alarm be triggered. Interferometric Synthetic Aperture Radar (InSAR) technology is also employed to monitor the displacement of the TSFs on a bi-weekly basis.

A risk assessment was undertaken by key stakeholders to assess the impact on mining progression near the TSF. A key action arising from the review was to rationalize the existing monitoring program with a view to improving the quality and reliability of the data to detect potential slope instability, recognizing the limitations of current monitoring methods. For example, lateral movements below the embankment and foundation layers cannot be accurately monitored using SMs and InSAR, as these are surface-based monitoring tools (i.e., propagation of movements is delayed). During normal operation, the settlement would in some instances trigger yellow (>25 mm movements) and/or amber (>50 mm movements) TARPs, which were often found to be erroneous due to potential issues of "noise" and/or bias movement readings. These issues can be attributed to the limitations on the accuracy of survey instruments, satellite duration, and surveyor experience when undertaking SM readings. Additional filtering of the data, as investigated by Han et al. (2023), is required.

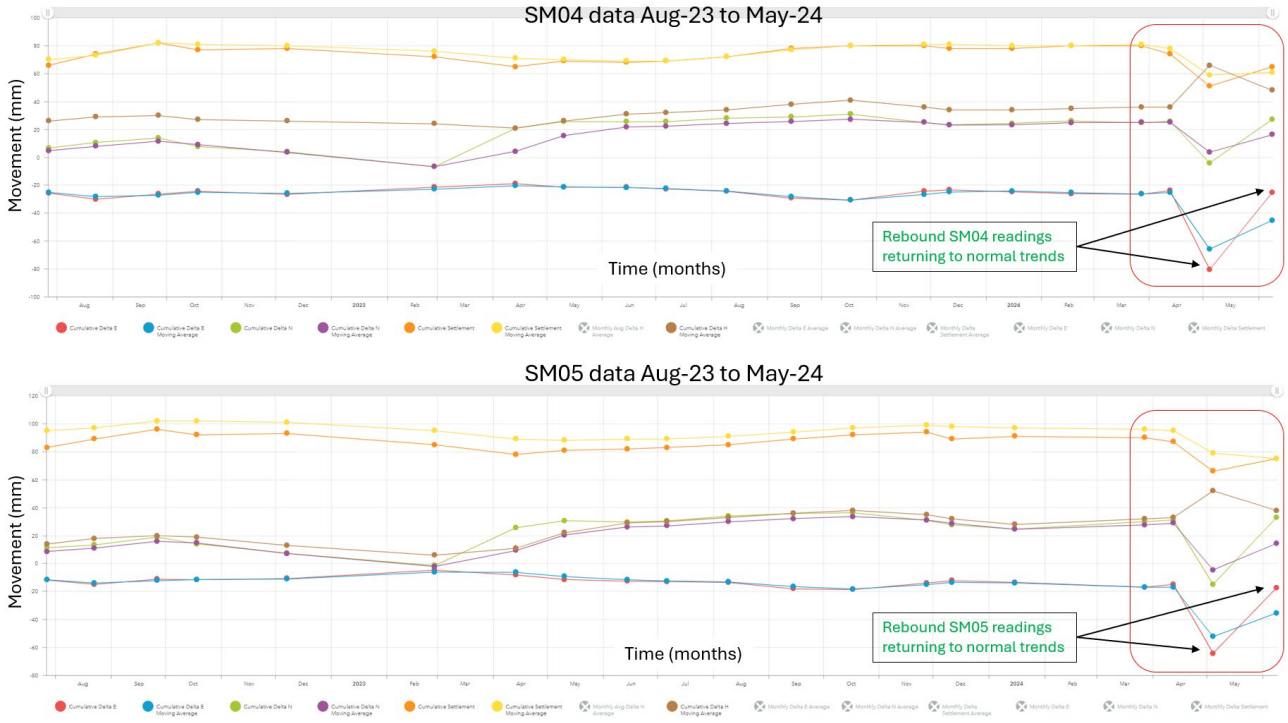

Figure 2: Survey monuments (SM04 and SM05) readings showing "false" embankment movements

An example of this reliability issue is presented in Figure 2, which shows the real SM data from the TSF presented in this study. The SM04 and SM05 have a set trigger tolerance of 25 mm for both horizontal and vertical displacement per month. The example in Figure 2 clearly shows the exceedance of this tolerance of up to approximately 60 mm movement in the month of May 2024. This is nearly triple the prescribed threshold, which would put the facility at a serious Amber trigger alert. However, the readings

received in the next month's data show a rebound of the movement, which is consistent with historical trends and is clearly an indication of data error. The reliability and consistency of the data thus become questionable – is the monitoring program robust and can we rely on this when carrying out high risk activities?

Application example of IPIS

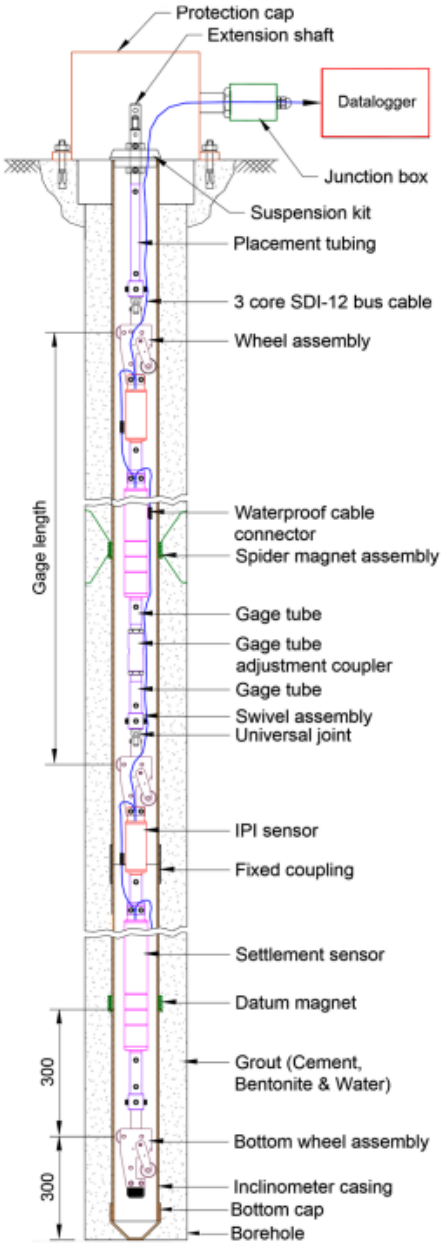

Figure 3: Schematic of the 3D IPIS and protective cover (Encardio Rite, 2020)

Overview

The 3D IPIS has wide applications where monitoring lateral movement and settlements in soils and embankments is required (i.e., potential faults and landslide zones) (Encardio Rite, 2020). It is used to provide quantitative data on the magnitude of settlement and inclination or tilt of a foundation and embankment (or slope) and its variations over time in a single borehole.

A typical schematic of the IPIS is illustrated in Figure 3, comprising an in-place inclinometer (IPI) and spider magnets (consisting of sensors and magnet rings).

When subsurface movements occur laterally, the IPIS detects the movement by showing a tile in the sensors. The same principle applies when settlement takes place that changes the vertical position of the outer magnet rings relative to the internal sensors. The range of the settlement sensors used at this site is up to 100 mm, within and below the estimated theoretical settlement prediction. The vertical displacement (settlement) is simply calculated by subtracting the total vertical differences from the point of reference (i.e., datum).

Installation and setup

The 3D IPIS model EAN-61MS was installed on the critical embankment section relative to the direction of the downstream mining area. The IPIS setup of the casing and positioning of the spider magnets is shown in Figure 4, which consists of sixteen inclinometer arrays and seventeen spider magnets installed at a nominal 2 m spacing.

Figure 4: Example of installation preparation of the 3D IPIS on embankment crest and the lowering of IPIS casing and spider magnets into the borehole

The IPIS was lowered into a 40 m deep borehole (cased) incrementally to target depth before being fully grouted in stages. At the top of the IPIS is the "Junction Box," which is connected to a datalogger on the TSF with remote monitoring capabilities, which feeds the data to a centralized monitoring database server (telemetry) where the data is automatically reviewed and compared against a site-specific trigger tolerance.

Discussion

The IPIS was installed before mining works commenced, providing an ideal scenario to establish a baseline reading for the instrument, which effectively allows for the monitoring of the progressive mining and excavation downstream works and their effects on the performance of the TSF. Approximately 18 months of monitoring data is presented in the figures below, showing minimal total vertical (<10 mm) and horizontal (<1 mm) displacements in Figure 5 and Figure 6 respectively.

The monitoring data indicates that the foundation, comprised of poorly compacted layers of mine spoil, has potentially fully consolidated under the embankment load. This is supported by the outputs from the survey monuments in Figure 2, despite the issues of intermittent trigger exceedance warnings.

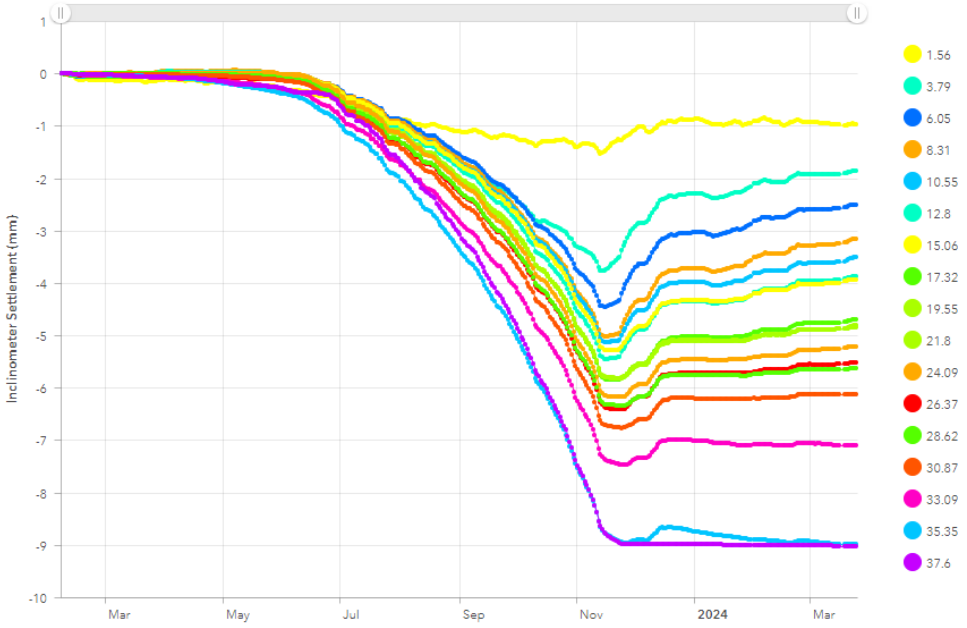

Figure 5: Monitoring IPIS showing cumulative settlement (vertical movement) readings

A key performance indicator of the performance of a facility is the analysis of trends and comparison with past data (i.e., moving averages), and it can be seen from the following figures that all the recorded readings have been consistent since its inception. Monitoring of the embankment is still ongoing in the

field; however, it is worth noting that the mining activities have since transitioned to backfilling of the pit void, which will improve overall TSF stability.

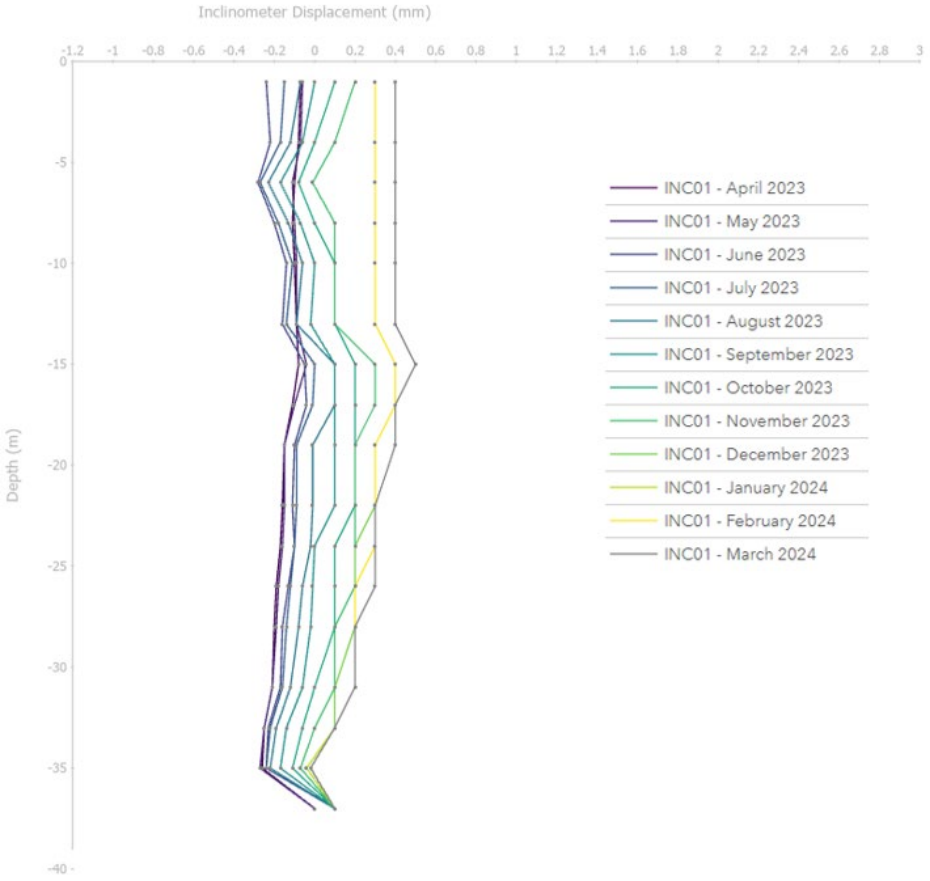

Figure 6: Monitoring IPIS showing lateral (horizontal) movement readings

The use of an IPIS thus avoids survey accuracy limitations that are pertinent in some of the current monitoring practices that rely on GPS receivers or satellites to monitor tailings dam movements. It also removes the need for complex noise reduction algorithms to filter survey noise ("the data is the data") and in retrospect, perhaps even bias interpretation from TSF engineers. The instrument is considered a useful tool to validate the geotechnical models or to demonstrate that the critical deformation behavior, as in the case of this TSF example, has already been exceeded, and what remains is just the residual settlement, which is relatively minor.

Conclusion

Implementation of a robust monitoring program is critical and is one of the key conformance protocols required by GISTM. The monitoring programs need to be designed, implemented, and operated to monitor facility performance and validate design assumptions for all phases of the facility lifecycle. Throughout this

paper we have highlighted the importance of understanding the limitations of monitoring instrumentations and the need to adopt alternative monitoring strategies to suit site-specific needs. Combining the inclination and settlement behavior of the monitored embankment is considered practical and provides spatial information at discrete points of observation in similar embankment materials.

This paper presents an alternative tool to monitor embankment movements using a 3D in-placement inclinometer and settlement system, which is considered to offer a robust and reliable way to monitor TSF movements, in conjunction with existing instrumentation tools such as survey monuments and piezometers.

Abstract

This paper presents the results of a synergistic application of three different but complementary monitoring technologies for a tailings storage facility (TSF) in Canada currently undergoing a transition from active operations to closure. The monitoring technologies discussed are Global Navigation Satellite Systems (GNSS), Interferometric Synthetic Aperture Radar (InSAR), and Light Detection and Ranging (Lidar). Monitoring has become a mandatory part of TSF management. Monitoring ensures TSFs meet their performance goals during construction, operations, and post-closure. A key method to prevent TSF failures is to monitor parameters such as ground displacement as part of early-warning systems. GNSS refers to the use of satellites for determining highly accurate, localized measurements of position. New satellite constellations and advancing technologies have contributed to the endorsement of satellite-based assessments for infrastructure assets. The use of InSAR as a means of monitoring ground displacements is also presented in this paper. Taking advantage of the wide area coverage within a single analysis, InSAR provides an efficient and effective way of identifying developing trends. LiDAR, on the other hand, can provide digital elevation models of a site.

Introduction

The TSF covers an area approximately 10 km^2 and has a maximum dyke height of approximately 60 m. Land clearing for the TSF began in approximately 1999, and starter dyke construction started in 2001. The structure reached its full design height in 2013 and is currently transitioning from operation as an active storage facility for fluid tailings into decommissioning and closure.

Within the TSF, various tailings streams have been deposited, including coarse sand tailings (CST), whole tailings (WT), fluid tailings (FT), thickened tailings (TT), and tailings solvent recovery unit (TSRU) tailings. FT and TT are classified as high-fines tailings, which are known to be compressible, having low hydraulic conductivity, and relatively long consolidation times that may extend into the closure time frame. Settlement analysis is crucial for the closure of TSF because it directly impacts the stability and sustainability of the reclaimed landform. Understanding the settlement behavior helps in predicting long-term land deformation, which is essential for designing effective closure strategies.

As part of a pilot project, this study compares several methods of settlement monitoring. Three existing settlement plates that were surveyed manually for the past 6 years were re-purposed with solar-powered Global Navigation Satellite Systems (GNSS) receivers (Basetime) in early 2024. Manual monitoring was maintained to compare the quality of the results with this novel method. Moreover, large-scale validation was conducted with satellite-based interferometric Synthetic Aperture Radar (InSAR) and satellite-based Light Detection and Ranging (LiDAR). These methods can be compared on a sliding-scale: GNSS are point measurements that are attached to a specific point in space but are completely automated. Manual survey is also point-monitoring but is very flexible, as monitoring points can be added or removed as needed without additional investments. At the other end of the scale, large-scale methods such as InSAR and LiDAR can monitor large areas but have a slow acquisition rate and can require specialized analysis to extract high-accuracy data. In this paper, we show that GNSS, InSAR, and manual surveying have similar repeatability and accuracy, while LiDAR appears to be less reliable. The methods are shown to be complementary, fulfilling different, but related, requirements.

Methods

GNSS

Monitoring with GNSS and global positioning systems (GPS) for ground movement has been used since the 1990s for landslide monitoring and structural health monitoring. It is currently being introduced to tailings and tailings dams to track slow long-term movements. The GNSS monitoring system used in this project was developed specifically to monitor large settlements over long periods of time. The position determination is based on calculated post-processed baselines using a reference station that utilizes a star-shaped pattern method. It is equipped with a multiband GNSS receiver and antenna (186 channels), collecting data from the following bands: GPS L1C/A and L2C, GLONASS L1OF and L2OF, Galileo E1B/C and E5b, and BeiDou B1I and B2I. For a standard reading the device will do an observation with 1 Hz for 5 minutes counting. Within 30 seconds, they should receive all possible and necessary satellite data within an elevation mask of 10 degrees, yielding 270 epochs that are available to compute positions. The designed accuracy of the system for long-term monitoring is 4 mm (1σ) for a base station located within

a 4 km radius of the monitoring points. The mobile stations were installed in settlement plates that had been surveyed for years prior. A typical installation is shown in Figure 1. The system is self-contained with a solar panel that keeps a supercapacitor charged, providing complete autonomy. It is designed to be attached to settlement plates with a tailor-made bracket.

Manual survey

A manual survey involves the measurement of the elevation of the settlement plate. This process employs Real-Time Kinematic (RTK) GPS technology, which includes a Trimble R8S GPS receiver and a Trimble TSC3 data collector. The GPS receiver is mounted on a fixed post of the settlement plate during surveying. The operator initiates the measurement on the data collector, which records the elevation data with an accuracy of 1 to 1.5 cm. Manual surveying of settlement plates poses challenges such as accessibility issues, worker exposure in active operating areas, high labor costs, time consumption, and potential human errors. Automated surveying addresses these problems by providing continuous, accurate, and consistent data with reduced labor costs and improved safety. This shift enhances efficiency, reliability, and comprehensive monitoring, making automated systems a valuable advancement over manual methods.

The respective positions of the three surveyed locations are shown in Figure 1.

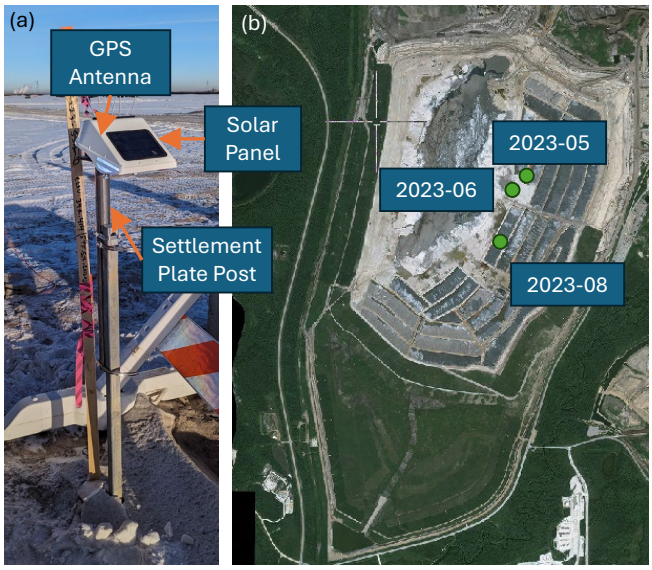

Figure 1(a): Typical automated GNSS installation
(b): locations of the three automated stations with respect to the structure

InSAR

Time series analysis of Interferometric Synthetic Aperture Radar (InSAR) has become increasingly significant in the mining industry due to its efficiency in measuring millimetric-scale displacements by employing multiple SAR images for displacement monitoring. Techniques such as Persistent Scatterer

Interferometry (PSI) and Small Baseline Subset (SBAS) are particularly effective for TSFs that exhibit slow, long-term deformations (Rana et al., 2024). Additionally, InSAR monitoring can detect precursor accelerations, providing valuable information for time-to-failure predictions. When available, results from ascending and descending tracks of the sensor can be used to decompose the line-of-sight (LOS) measurements into horizontal and vertical components.

The widespread availability of Synthetic Aperture Radar (SAR) data, both free and commercial, with global coverage, allows for regular, accurate, and simultaneous monitoring of TSFs using various InSAR techniques. For instance, InSAR is widely utilized for TSF monitoring in several countries, including Australia (Thomas et al., 2019), Brazil (Duro et al., 2020), Poland (Sciortino et al., 2021), South Africa (Perdikou and Lees, 2023), and Egypt (Mohamadi, 2024).

However, due to the ambiguous nature of phase difference between two acquisitions, time series InSAR can only estimate deformations up to a quarter of the wavelength between acquisitions. Any deformation exceeding this threshold is not detected in the time series. Considering this limitation, the maximum deformation that can be measured using Sentinel-1 is 42.6 cm/year (Crosetto et al., 2016).

For the analysis presented in this paper, sixty-four ascending pass Sentinel-1 SLC data in interferometric wide-swath (IW) mode from January 2022 to April 2024 were analyzed using the Small Baseline Subset (SBAS) technique. In the SBAS technique, the phase history of a pixel with respect to the first acquisition is reconstructed from a network of interferograms with small temporal and perpendicular baselines, ensuring maximum interferometric coherence (Berardino et al., 2002). Interferograms were formed by setting a temporal baseline threshold of 40 days. The topographic phase was removed using a Shuttle Radar Topography Mission (SRTM) Digital Elevation Model (DEM). The differential interferograms were filtered using a Goldstein filter and multi-looked to form an approximately 15 m pixel. An unwrapped coherence threshold of 0.1 was used to mask low coherence areas during phase unwrapping, which was performed using the Minimum Cost Flow (MCF) approach. The entire InSAR processing was carried out using ENVI SARscape software.

LiDAR

LiDAR (Light Detection and Ranging) is a remote sensing method that uses laser light to measure distances and create detailed 3D maps of surfaces. The survey was completed using a Riegl VQ-1560ii LiDAR system mounted on an aircraft, operating at a flying height of 1,500 meters and a speed of 160 knots. This system features a pulse repetition rate of 23,000 kHz, a scan frequency of 374 Hz, and a scan angle of 60 degrees. During the survey, the laser scanner emits rapid pulses of light, which bounce off objects and return to the sensor, capturing precise distance measurements. The GPS receiver determines the exact position of the scanner, while the Inertial Measurement Unit (IMU) records its orientation. The collected data is processed

to generate high-resolution, three-dimensional representations of the surveyed area, with an end result of a point density of approximately 10 points per square meter. The system achieves a horizontal accuracy of 30 cm (2σ) and a vertical accuracy of 10 cm (2σ).

LiDAR has been used to survey TSF primarily to estimate elevation changes. Its high precision and accuracy in capturing elevation data make it ideal for creating detailed topographic maps and models. These models are crucial for calculating volumes, which is essential for resource management, environmental monitoring, and infrastructure planning.

Results

The SBAS results are shown in Figure 2. The majority of the InSAR deformation points are located on the outside of the TSF, with very few points observed within the tailings. This lack of observation points within the tailings is attributed to coherence loss over time.

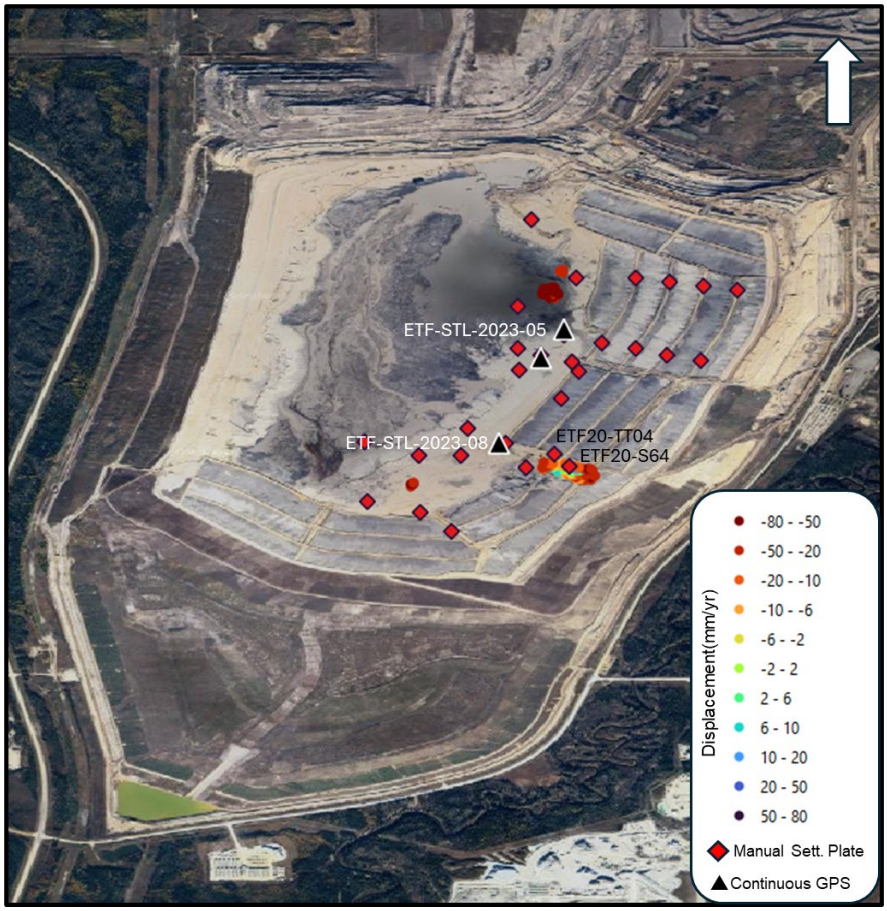

Figure 2: InSAR SBAS results (January 2022 to April 2024) overlaid on Google Earth imagery

The InSAR measurements within a 500-meter radius of the automatic GNSS stations (shown as black triangles in Figure 2) are averaged to facilitate comparison with the GNSS readings.

Figure 3 illustrates the comparison of InSAR, continuous GNSS, and manual GPS measurements of GPS locations as acquired. It can be seen that while InSAR shows the right trend, going much further back in time than the GNSS measurements, it appears to measure a much lower rate of displacement.

Manual survey and automatic GNSS show good agreement for the ETF-STL-2023-05 and ETF-STL-2023-08 locations. Coherence loss prevented performing the InSAR analysis for the ETF-STL-2023-06 monitoring point. For ETF-STL-2023-08, the match was good, but was better for the first part of the monitoring period (from December to February 2024). Due to logistical constraints, the reference station had to be moved from an initial location 1.1 km from the monitoring area to a new location approximately 4.2 km away. This led to a significant increase in noise in the system. The trends appear to hold, but it has made it impossible to compare daily readings directly. Returning the reference station to a location closer to the monitoring points has reduced noise to more acceptable levels. The reference station was in the less favorable location between the two dashed lines on the graphs of Figure 3.

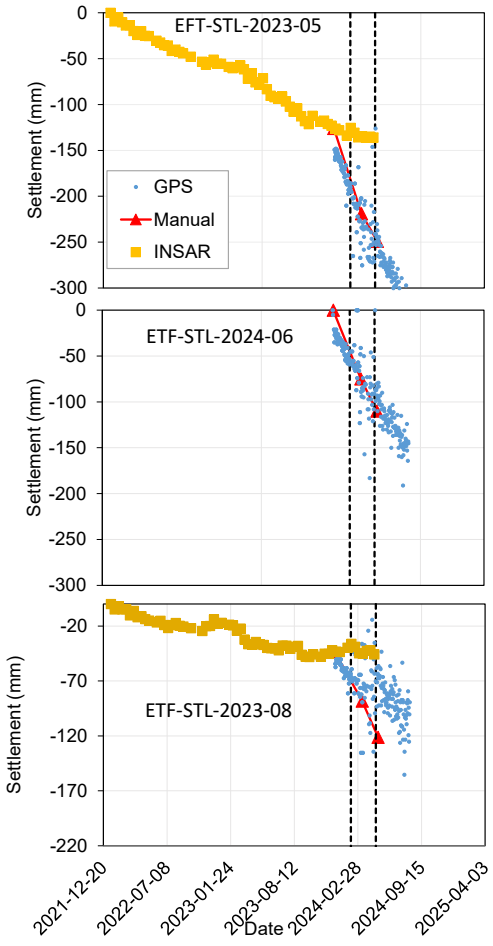

Figure 3: Comparison of InSAR, as-measured automatic GNSS, and as-measured manual survey displacements from January 2024 to June 2025 at select settlement plate locations

The InSAR analysis for these points was begun in January 2022. It was used to zero the measurements, with the GNSS measurements shifted so that their first point matches the corresponding point of the InSAR measurements. InSAR appears to have underestimated the deformation rates compared to the automatic GNSS and manual measurements.

This is partially explained by the angle of incidence and heading of the satellite, which cannot completely discriminate between horizontal and vertical movement. The up-down (Z), east-west (E), and north-south (N) components of the GNSS readings are projected onto the InSAR line-of-sight using Equation (1), where θ and α represent the incidence and heading angles of the Sentinel-1 satellite, respectively (Ng et al., 2011).

$$AutomaticGNSS_{LOS} = Z * \cos\theta - E * \sin\theta\cos\alpha + N * \sin\theta\sin\alpha \quad (1)$$

The GNSS readings are projected onto the InSAR line-of-sight (LOS) using Equation (2). It is important to note that horizontal measurements are not recorded at manual GPS locations. Consequently, the LOS conversion assumes that the observed movement is purely vertical. While this assumption may not precisely reflect the actual field conditions, it enables a reasonable comparison between different independent measurements.

$$ManualGNNS_{LOS} = Z * \cos\theta \quad (2)$$

The adjusted GNSS measurements are shown in Figure 4. While it has reduced the discrepancy between InSAR and GNSS by approximately 40 %, there remains a large difference between the rates of displacement between both sets of measurements, with for instance for 2023-05 InSAR reporting a rate of 5 mm/month and GNSS reporting a rate of 9 mm/month.

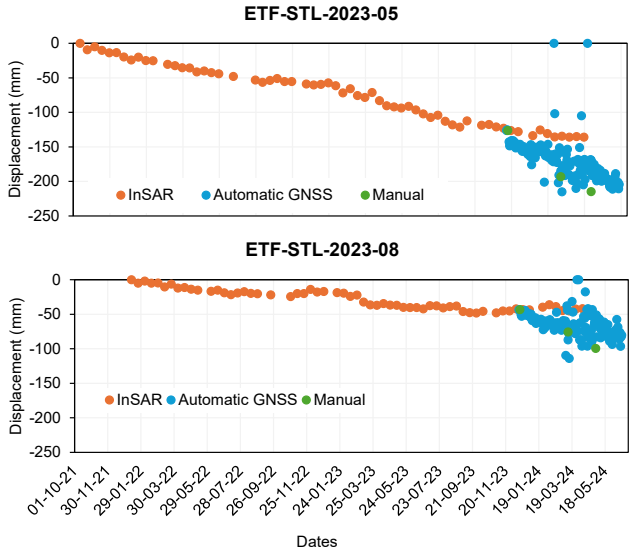

Figure 4: Comparison of adjusted automatic GNSS and Manual survey and InSAR

InSAR measurements within a 200 m radius of the manual settlement plates (shown as a red rhombus in Figure 2) are averaged to facilitate comparison with the manual settlement plate readings. The vertical displacement recorded at the manual settlement plates is projected onto the InSAR Line of Sight (LOS) using Equation (2).

InSAR measurements within a 200 m radius are available for ETF-STL-2023-03, ETF-STL-2023-04, ETF19-S2A-D, ETF20-S5A-B, ETF20-S64, and ETF20-TT04. However, manual survey data during the assessment period are only available for the latter 2. Figure 5 illustrates a comparison of InSAR and manual settlement plate readings for ETF20-S64 and ETF20-TT04. The results exhibit similar trends and values, particularly for ETF20-TT04. Conversely, the values at ETF20-S64 also indicated a similar trend, aligning with the InSAR displacement data.

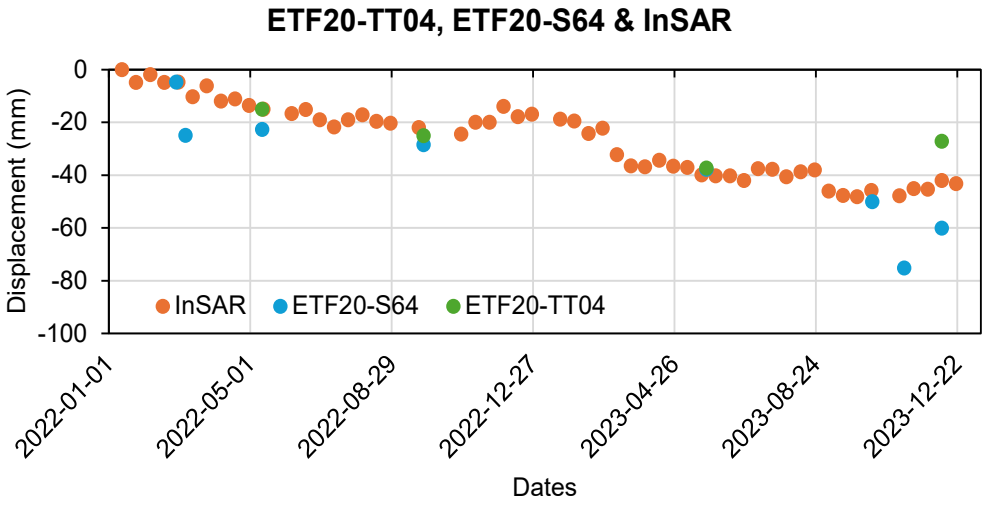

Figure 5: Comparison of InSAR and manual settlement plate readings for ETF20-S64 and ETF20-TT04

The wide area of the InSAR study also allows for comparisons with points that have been monitored with LiDAR. However, the validation of the two measurements against each other is difficult to do, due to the infrequent manual and LiDAR measurements. The plots in Figures 6 and 7 show the comparison between the manual settlement plates, LiDAR, and InSAR, using the closest InSAR acquisition as a reference.

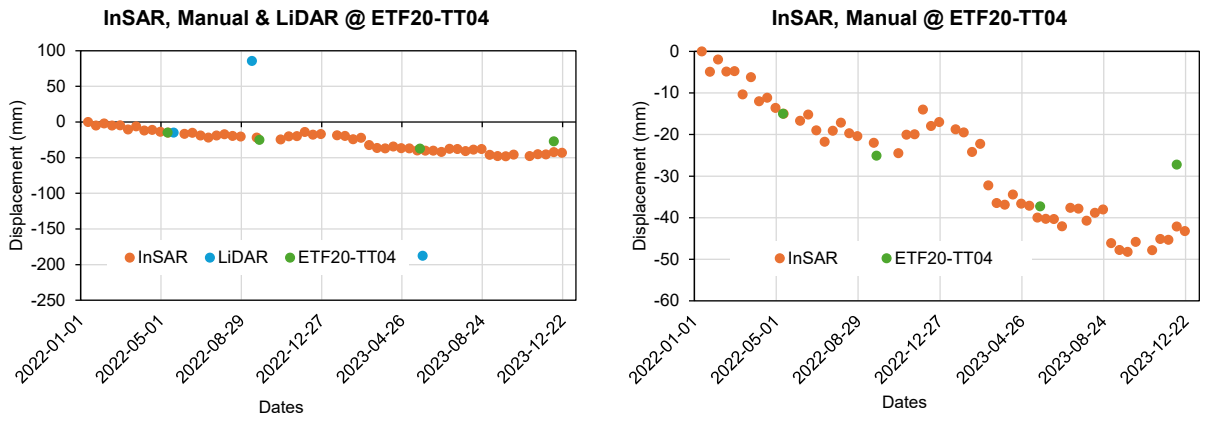

Figure 6: Comparison of a) InSAR, Manual settlement and LiDAR measurements and b) InSAR, manual settlement measurements at ETF20-TT04

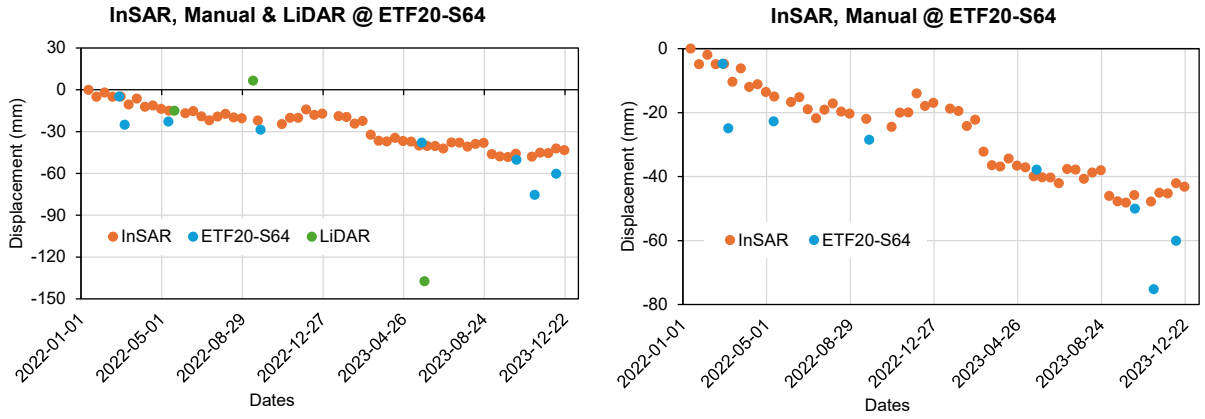

Figure 7: Comparison of a) InSAR, Manual settlement and LiDAR measurements and b) InSAR, manual settlement measurements at ETF20-S64

Automatic GNSS and manual surveys have provided similar results for the three points of interest, as shown by the red triangles of Figure 3. The error on the automatic GNSS increased beyond expected values during operations when moving the reference station to a 4.2 km distance for a period of over one month. This was addressed and the reference station was returned to a more suitable location, limiting noise to an acceptable level. Automatic GNSS allows for much more frequent measurements than manual survey, InSAR and LiDAR; by increasing the frequency of the readings, the noise can be smoothed by methods such as a gliding average to increase the accuracy of long-term monitoring of slow movements.

The agreement between GNSS and InSAR was lower than what was expected for the three points of interest. It was not possible to observe coherence for one of the three points. It appears that InSAR has underestimated vertical displacement by 30 to 50 %, even after applying LOS corrections. There are several possible causes to be investigated that may have led to this discrepancy: atmospheric phase screen,

movements faster than one quarter wavelength, radar speckle and phase unwrapping errors. This will be the subject of future research, which will include the addition of corner reflectors near automated GNSS stations.

We have seen that InSAR is in agreement with LiDAR measurements outside of the GNSS study area, measuring rates up to 30 mm/year. This observation will require further study; the LiDAR system is not designed for settlement monitoring and its repeatability may not be high enough for accurate monitoring. Comparison of the InSAR measurements with the existing LiDAR data was made difficult due to the small number of samples taken over the past years.

Conclusion

The goal of this pilot project was to compare automatic GNSS against manually surveyed settlement plates inside a TSF. In the first 6 months of 2024, settlements of up to 16 cm were measured both with manual surveys and automatic GNSS. The noise levels on the GNSS were higher than anticipated, but this issue will be addressed in future work. The study was extended to include InSAR to validate if this tool could be used to perform the same type monitoring on TSFs. The InSAR measurements demonstrate a generally consistent trend in observed displacements. While InSAR underestimated the deformation compared to the GNSS measurements, the overall subsidence trend was observed in all three independent measurement techniques. For the manual settlement plate locations, particularly ETF20-TT04 and ETF20-S64, InSAR data showed similar trends and values, indicating good agreement.

However, comparisons with LiDAR measurements were less reliable due to the lack of synchronization between data acquisition times. While InSAR is cost-effective and can cover larger spatial areas compared to conventional monitoring methods, GNSS measurements can capture higher rates of deformation that InSAR might miss due to its limitations on differential phase between two successive acquisitions.

Future work will investigate expanding the use of both GNSS and INSAR. Additional GNSS stations will provide a more robust network of measurements and new stations may be installed in locations with horizontal movement and what is assumed to be stable reference areas for InSAR. Pursuing InSAR analysis over the long term against GNSS measurements will provide more insight into the discrepancies observed between the two methods. Future studies will also include auxiliary measurements such as ground-level moisture content.

Integrated Analysis of Dam Surface Displacement Monitoring

Felipe Bolívar Domingos, Vale S.A., Brazil
Alessandra Mazon, Vale S.A., Brazil
Jefferson Barbosa, Vale S.A., Brazil

Abstract

Following recent dam failures in Brazil (Mariana in 2015 and Brumadinho in 2019), mining companies have implemented extensive geotechnical monitoring plans, particularly for tailings dams. To enhance the safety of tailings management, various technologies have been widely adopted for geotechnical surveillance. Interpreting data and making informed decisions remain significant challenges for the mining sector. This paper presents a study of a tailings dam in Brazil, where InSAR (Interferometric Synthetic Aperture Radar), ground-based radar, and Robotic Total Station (RTS) technologies were used to monitor surface displacements. InSAR was initially used for broad assessment and long-term displacement monitoring, similar to RTS. Ground-based radar focused on critical, short-term analysis.

During the first stage of the monitoring strategy, InSAR data identified anomalous physical response zones in the dam. This analysis guided field inspections. The extent of the anomalous area was defined through fieldwork, allowing for improved RTS monitoring. Reflectors were installed around the deformation area to better track movements. In the final phase, data from InSAR and RTS were correlated, revealing a high correlation between the magnitudes of slow movements from both datasets. Meanwhile, ground-based radar showed no significant deformations, supporting its use for detecting rapid displacements due to its line-of-sight limitations. This study underscores the importance of integrating remote monitoring technologies, and the value of a robust monitoring program in deriving accurate conclusions about dam deformation and performance.

Introduction

In recent years, the mining industry in Brazil has faced significant challenges due to catastrophic dam failures, most notably in Mariana (2015) and Brumadinho (2019). These incidents underscored the critical need for robust geotechnical monitoring systems for tailings dams to prevent future disasters. Consequently, mining companies have increasingly implemented comprehensive monitoring plans, utilizing a variety of

advanced technologies. The primary objective of these monitoring efforts is to ensure the safety and stability of tailings dams, thereby protecting both human lives and the environment.

This paper focuses on the importance of integrating multiple monitoring techniques to obtain precise and complementary data for effective dam management. By employing Interferometric Synthetic Aperture Radar (InSAR), Ground-based Radar (GBR), and Robotic Total Station (RTS) technologies, this study aims to demonstrate how different methods can be used synergistically to monitor surface displacements and identify potential risks. InSAR provides broad and long-term displacement data, making it ideal for initial assessments and continuous monitoring. Ground-based radar provides essential short-term analysis, detecting rapid displacements that could indicate potential failure more promptly, contingent on the line of sight. RTS provides precise measurements of surface movements, which are essential for detailed analysis and verification of findings from other technologies.

The integration of these technologies allows for a comprehensive understanding of dam behavior, improving the accuracy of deformation assessments and enhancing decision-making processes. By correlating data from multiple sources, this approach not only identifies potential issues more reliably but also optimizes the overall monitoring strategy, ensuring a higher level of safety and operational efficiency in tailings dam management.

Equipment and technologies used

InSAR (Interferometric Synthetic Aperture Radar)

Satellite InSAR is generally used by mining operations for site-wide deformation monitoring, with acquisition footprints that cover a broad area of the Earth's surface allowing a bird's-eye view and full coverage of a mine site, making this technology ideally suited to deformation monitoring of large tailings facilities (Sharon and Eberhardt, 2020).

The Synthetic Aperture Radar (SAR) is based on the emission of electromagnetic energy in the microwave range (Moreira et al., 2013) during successive passes at different times and under various geometries (Ferretti et al., 2011). SAR systems operate within a wavelength range of 1 mm to 1 m, or a frequency range from 0.3 GHz to 300 GHz. These systems utilize a side-looking geometry, where a microwave beam is emitted at an angle orthogonal to the sensor's velocity vector, aligning with the satellite's path. This configuration allows for the creation of a two-dimensional imaging plane, defined by the dimensions of range and azimuth, which is achieved through the sensor's movement and the periodic transmission of pulses orthogonal to its trajectory (Paradella et al., 2021).

Figure 1 shows the standard geometry of SAR. In this configuration, the radar platform travels in the azimuth or along-track direction, while the slant range refers to the direction perpendicular to the radar's flight path. The swath width indicates the ground-range coverage of the radar scene, and its length is

determined by the duration of the data acquisition, which corresponds to the period the radar is active (Moreira et al., 2013).

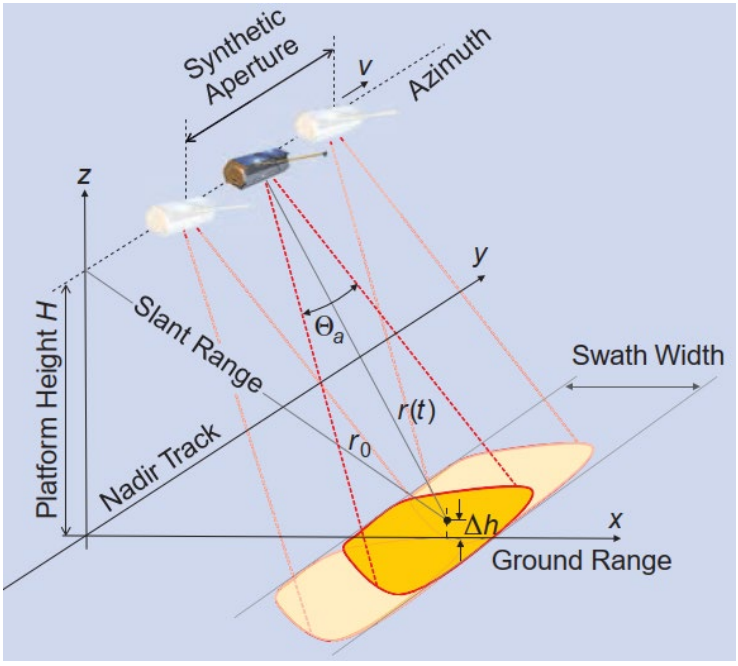

Figure 1: SAR imaging geometry. r_0 stands for the shortest approach distance, θ_a for the azimuth beam width and v for the sensor velocity (Moreira et al., 2013)

By identifying variations between the emitted and received wave phases, it is possible to obtain digital elevation models in the order of meters and deformation measurements in the order of millimeters (Ferretti et al., 2011).

Although using the spectral range corresponding to microwaves, the satellites (or constellations) may exhibit variations in the applied band. Table 1, adapted from Moreira et al. (2013), shows the relationship between wavelength, frequency, and the corresponding band, characteristics directly associated with monitoring precision. The radar used in this work is COSMO-SkyMed (X-band). For this work the radar used is COSMO-SkyMed (band X).

Table 1: Commonly used frequency bands for SAR systems and the corresponding frequency and wavelength ranges (Moreira et al., 2013)

Frequency Band	Ka	Ku	X	C	S	L	P
Frequency (GHz)	40-25	17.6 –12	12–7.5	7.5–3.75	3.75–2	2–1	0.5 – 0.25
Wavelength (cm)	0.75-1.2	1.7–2.5	2.5–4	4–8	8–15	15–30	60–120

GBR (ground-based radar)

The GBR is an instrument that allows the monitoring of mine slopes, hillsides, and dams. It has been designed to remotely scan a rock slope to continuously monitor the spatial deformation of the surface. Similar to the satellite-based technique, using differential radar interferometry the system can detect deformation movements of a rough wall with sub-millimeter accuracy and with high spatial and temporal resolution (Noon et al., 2001).

According to Atzeni et al. (2014), the first application of ground-based synthetic aperture radar interferometry for measuring surface tilt movements was carried out in the Italian Alps in the year 2000. Over time, due to the development of specific radar sensors and dedicated processing techniques, the technology evolved from an early prototype, which consisted of laboratory instrumentation temporarily used in the field, to an industrial product with the highest quality standards (Atzeni et al., 2014).

In summary, as shown in Figure 2, the system works (Sharon and Eberhardt, 2020):

- The system operates by generating a sinusoidal waveform with a precise frequency. This waveform is transmitted through an antenna as a narrow beam of electromagnetic waves.
- The beam is directed towards the monitored pit slope, where a small portion of the energy is reflected back to the radar (also known as backscattering). The backscattered wave, or echo, is intercepted by the antenna and converted into a signal.
- This signal is then processed and analyzed using interferometry to detect differences in the phase values of backscattered waves between consecutive measurements. If a phase change is detected, it indicates movement of the target between the two acquisitions.

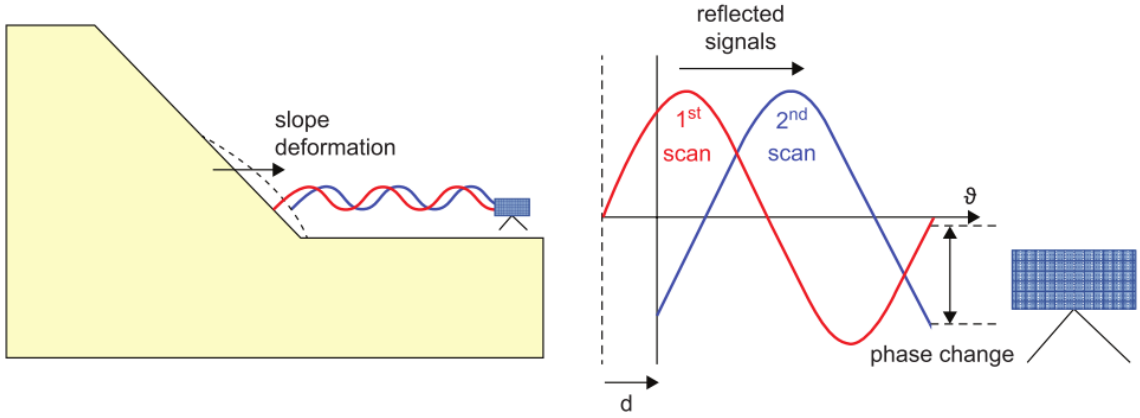

Figure 2: Measurement of displacement using radar interferometry calculated by comparing changes in phase of the reflected signals between two consecutive radar measurements (Sharon and Eberhardt, 2020)

Currently, there are two types of interferometric radars commonly used for slope monitoring: real aperture radar (RAR) and SAR (Figure 3). For this work, IDS's SAR IBIS-FM ground-based radar was used. The systems use a small moving antenna along a guide to simulate a larger aperture, enabling wide-area coverage without significantly varying scan times relative to the monitored area, unlike RAR systems (Sharon and Eberhardt, 2020).

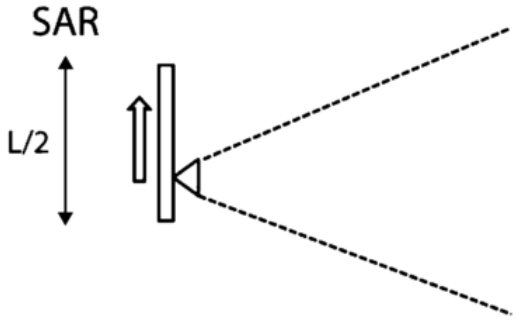

Figure 3: Synthetic-aperture radar (SAR) (adapted from Atzeni et al., 2014)

RTS (robotic total station)

The total station (TS) is an instrument that integrates an electronic theodolite with an electronic distance meter (electronic distance measurement – EDM). Modern robotic total stations (RTSs) are multi-sensor systems that combine distance and angle measurements and automatic aiming data to obtain three-dimensional coordinates.

There are some ways to measure distances by electronic means, among them, pulse method and phase difference method.

Pulse Method (Rueger, 1996)

A short, intensive signal is transmitted by an instrument. It travels to a target point and back, covering twice the distance d. By measuring the flight time between transmission and reception of the same pulse, the distance can be calculated.

$$2d = c\,\Delta t'$$

d = distance between instrument and target

c = velocity of light in the medium

$\Delta t'$= flight time of pulse

Phase Difference Method (Ghilani and Wolf, 2010):

The EDM device is positioned over station A using a plumb line or optical alignment device (Figure 4). The instrument emits a carrier signal of electromagnetic energy to station B. A reference frequency with a precisely regulated wavelength is superimposed or modulated onto the carrier. A reflector at B returns the

signal to the receiver, resulting in a travel path that is double the slope distance AB. In the Figure, the modulated electromagnetic energy is represented by a series of sine waves, each with a wavelength λ. The unit at A determines the number of wavelengths in the double path, multiplied by the wavelength in feet or meters, and divided by 2 to obtain distance AB.

$$L = (n\lambda + p)\frac{1}{2}$$

λ = wavelength;

n = number of full wavelengths;

p = length of the fractional part (some fractional part of a wavelength would in general be expected

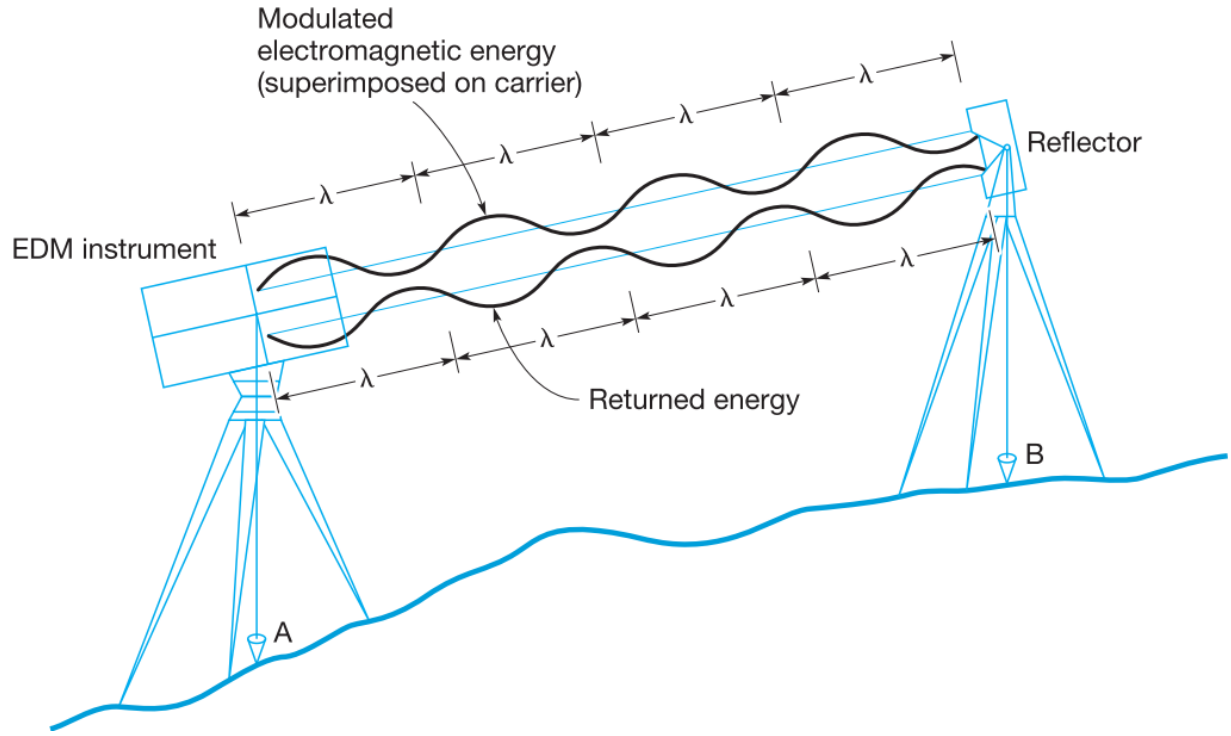

Figure 4: Generalized EDM procedure (Ghilani and Wolf, 2010)

Thus, based on the principles of EDM (Electronic Distance Measurement) and electronic theodolites capable of measuring horizontal and vertical angles (or zeniths), the RTS performs measurements automatically. To locate the prisms (targets), RTSs are equipped with an Automatic Target Recognition (ATR) device, which allows for identification, and a servomechanism that enables tracking of the target (Stiros and Psimoulis, 2012). After measuring distances and angles, it is geometrically possible to obtain the coordinates of the target.

Methodology

To assess the behavior of the surface displacement of the dam, the acquisition and analysis of monitoring data were divided into two main stages. The first stage involved the individual collection and analysis of surface displacement monitoring using the three technologies over a period of three months: InSAR, RTS and GBR subsequently, the monitoring data were integrated and jointly analyzed, which was essential to identify trends and standards of displacements and to better correlate the characteristics of the movements with the appropriate use of surface displacement monitoring tools.

InSAR data were derived from SAR images acquired by the CSK satellite constellation in ascending (ASC) and descending (DSC) orbits. This dual geometry approach allowed for vector decomposition of the line of sight (LoS) movement and analysis in the vertical and east-west directions, as shown in Figure 5. The data sample was obtained with an acquisition frequency of eight days.

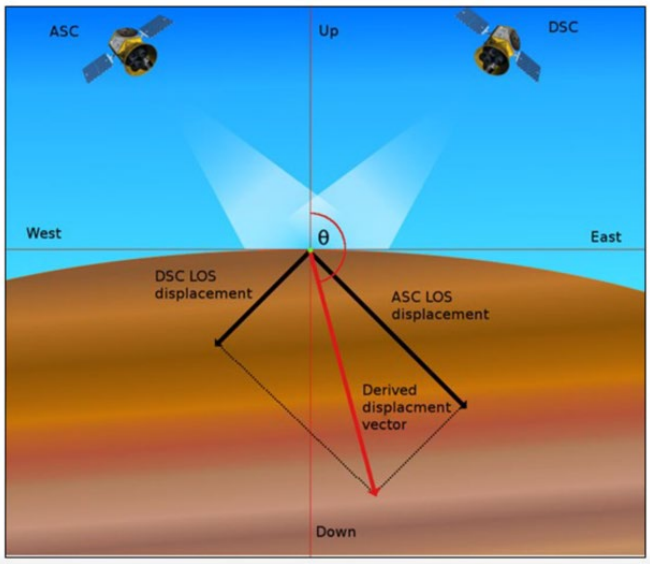

Figure 5: CSK acquisition geometry and LoS vector decomposition (modified from Leighton, 2020)

The use of RTS and monitoring through prisms installed on the surface allowed continuous monitoring of the downstream slope of the tailings dam. The reading cycle for each monitoring prism was approximately 15 minutes. Temperature and pressure data were collected through a weather station and processed using an algorithm to correct noise from atmospheric variations (humidity, temperature, and pressure), as recommended by the manufacturer. The RTS Leica TM-50 was used for this purpose.

GBR monitoring was conducted using the IBIS-FM equipment, configured for continuous monitoring with an approximate acquisition frequency of 2 minutes per cycle on the downstream slope surface of the dam. The GBR was installed as frontally as possible to the structure for better radar signal return. Since the radar measures displacements in the Line of Sight (LoS), the more frontal to the structure, the closer the

movement trends will be to the actual movement. Vegetation on the slopes can generate noise in the data, complicating the detection of slow movements. To mitigate this limitation, subsampling of the data was performed for the analysis of very slow movement, allowing for the analysis of slow deformations in the structures.

Data and discussion

InSAR data were analyzed using velocity maps on a GIS platform (Figure 6) using displacement rate time series, showing a pattern of slow displacement trends in a specific region near the left abutment of the upper portion of the dam. Consequently, this region where the pixels with the highest displacement ranges are concentrated, as indicated in Figure 6, was selected for integrated data analysis. The sample period considered for this analysis was from December 2019 to February 2020.

The data of the time series evaluation during this period demonstrated a very slow vertical displacement downward trend in this region of the structure, with maximum velocity on the order of 3 mm/month.

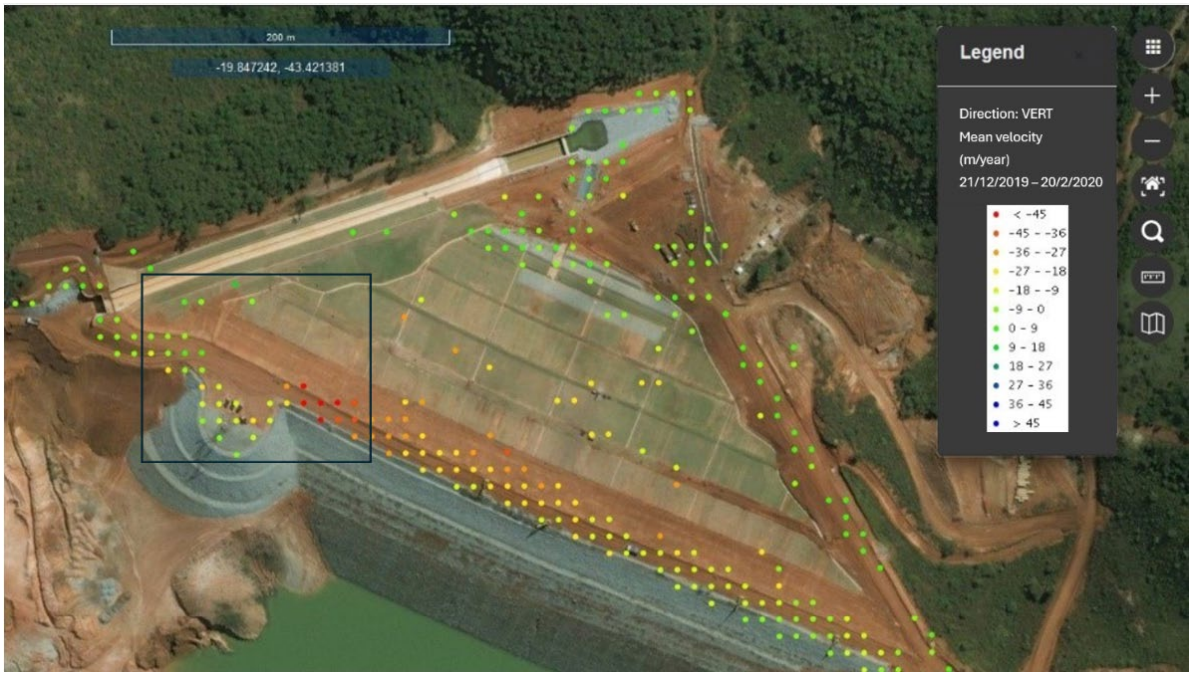

Figure 6: InSAR monitoring displacement rate data

In the region where the InSAR monitoring data showed pixels with the highest displacement ranges are concentrated, RTS-monitored prism data were evaluated (Figure 7). The monitoring prisms, through vertical and horizontal vector time series, showed vertical displacements on the order of 9 mm in 3 months downward. No trends of horizontal movement were observed in the monitoring data in the east-west direction.

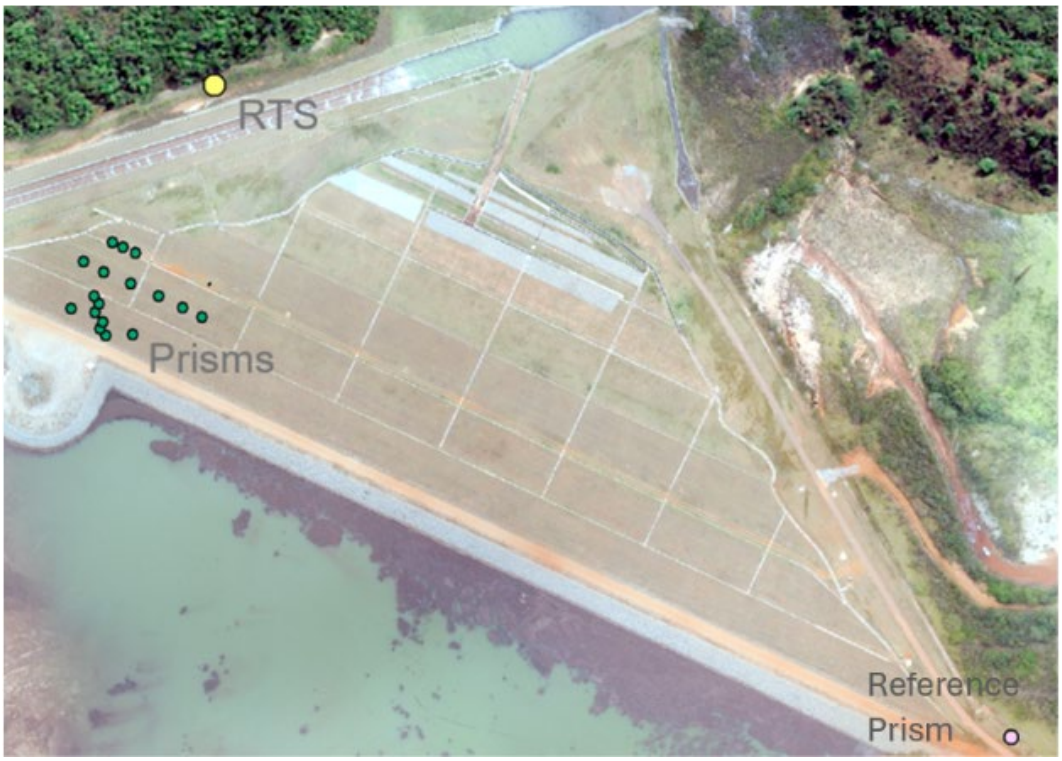

Figure 7: Prisms installed on the downstream slope of the dam for RTS monitoring

GBR data processing was used to detect slow displacement (Figure 8). This technique, called subsampling, processes data sampled over a longer period to reduce noise from the dam's vegetation cover, atmospheric noise, and other sources. These noises can mask slow displacements. For this subsampling process, data were sampled every 16 hours to reduce noise.

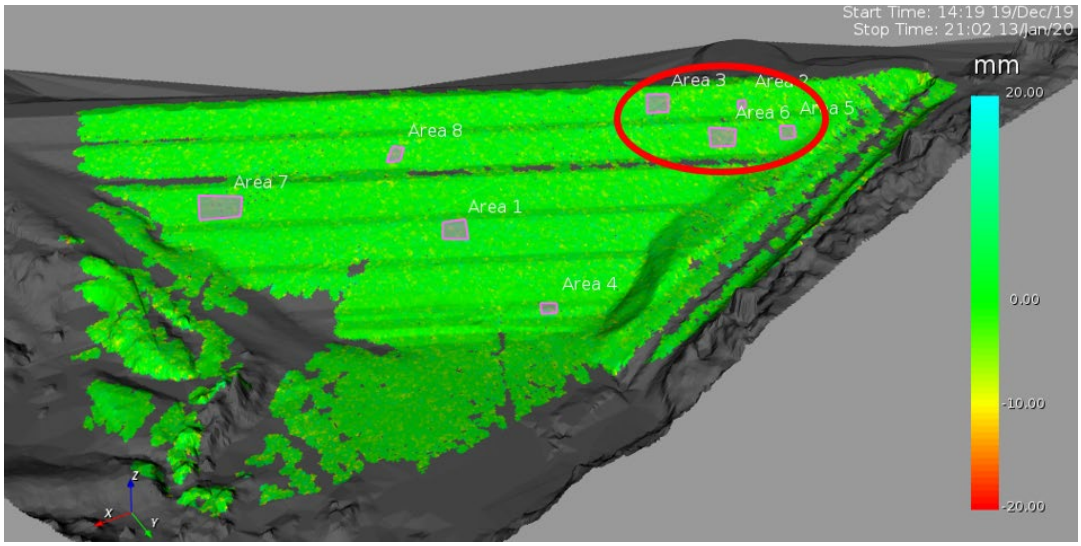

Figure 8: Radar displacement map in subsampling processing. The areas of interest in this study were 2, 3, 5, and 6

Results

Through the integrated evaluation of the monitoring data over the period analyzed in this study, the same patterns of vertical displacements downward were observed in both InSAR and RTS technologies. Both technologies detected slow settlement movements on the order of 3 mm/month (Figures 9 and 10).

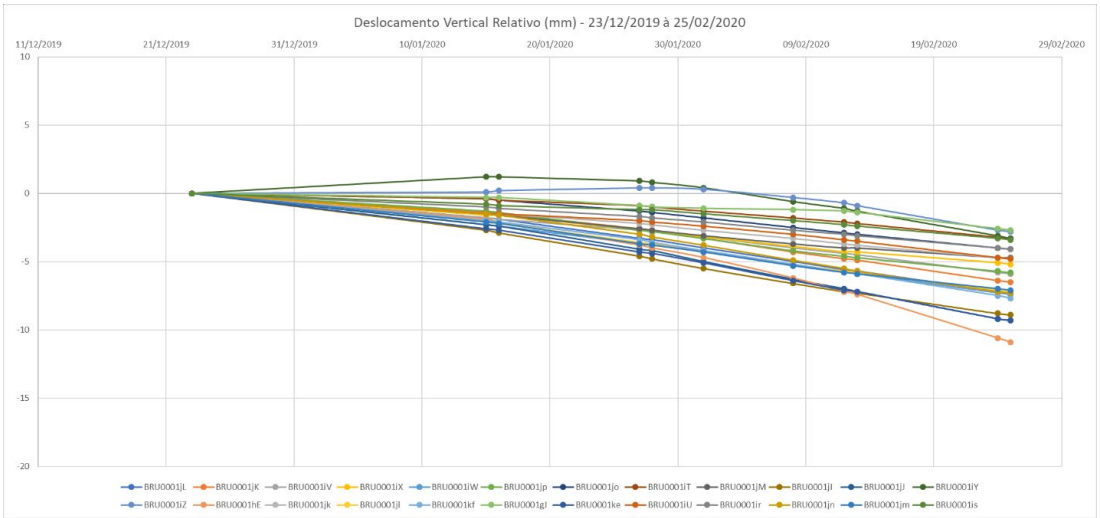

Figure 9: InSAR vertical displacement downward rate data

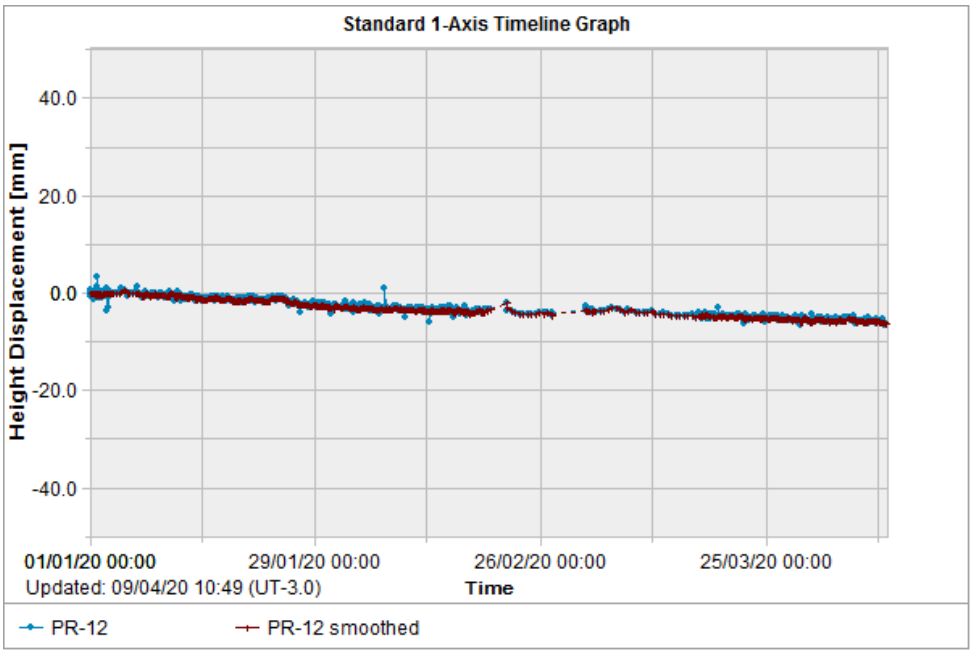

Figure 10: RTS vertical displacement downward data

In the GBR and RTS monitoring, no LoS movements were detected (Figure 11, 12). Since the LoS component is more horizontal than vertical, this is consistent with the other methodologies, as they did not show trends of horizontal movement either.

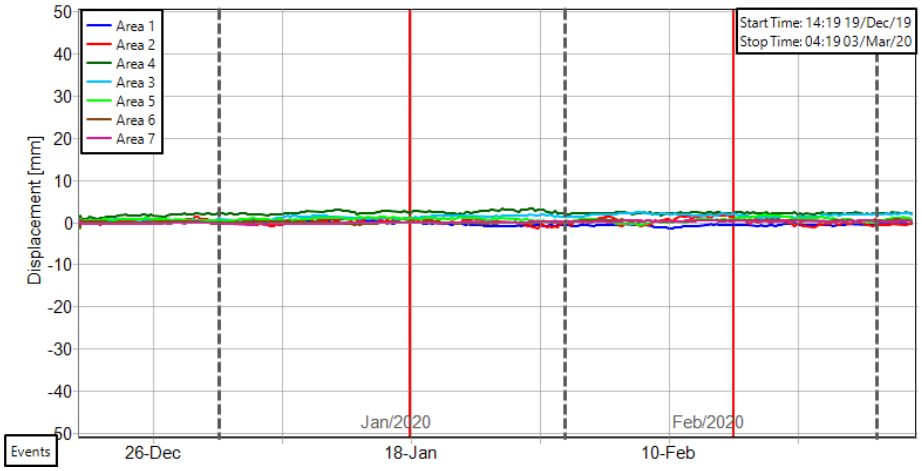

Figure 11: GBR line-of-sight displacement data. The areas of interest in this study were 2, 3, 5, and 6

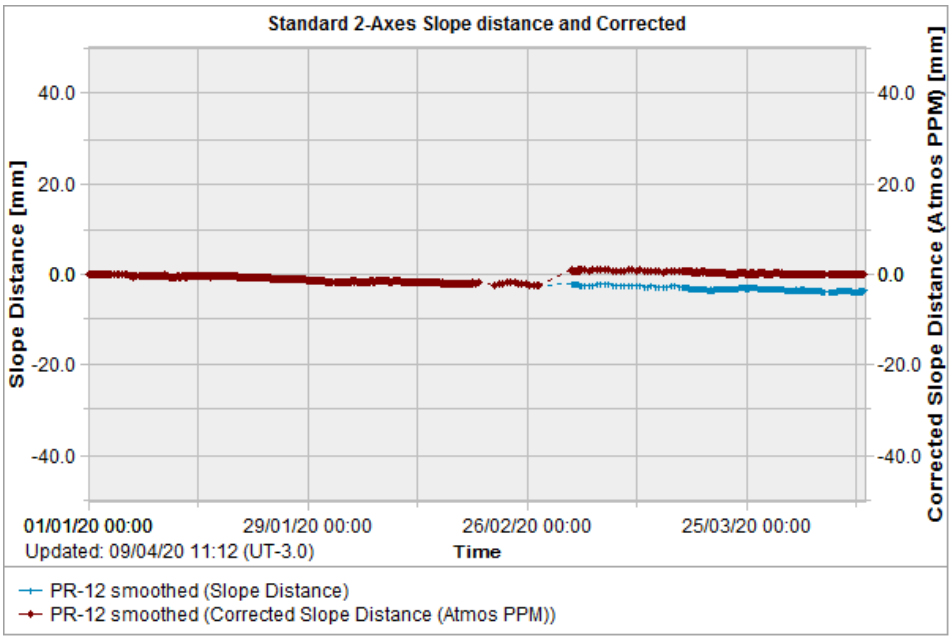

Figure 12: RTS slope displacement (LoS) data

Conclusion

This study showcased how the three displacement monitoring methodologies are applicable to tailings dams, provided their response objectives are well-understood, including the accuracies and limitations of each methodology and understanding what and where to monitor. In this study, a good correlation was observed between the vertical displacement monitoring data of the InSAR and RTS methodologies. Both methodologies, despite being different, showed the same trends and order of displacement in the time series over the same period. In the GBR monitoring data, no displacement trends were observed, likely because

the main movement was vertical, which could not be detected by the GBR, even with the subsampling processing.

Additionally, the methodologies were found to be complementary due to their limitations. Radar has the potential to detect fast movements in the structure, complemented by the robotic total station. However, InSAR is effective in detecting slower, more regional movements that can define regions for refinement and complementation by RTS monitoring. For slow horizontal movements, RTS is the best detection system in this case study and can be complemented by GBR slow movement monitoring using subsampling processing. No horizontal displacements were identified by any of the three technologies in this study.

Abstract

The mining industry continually seeks advancements in technology to enhance operational safety and minimize environmental impact. This paper presents the development of a state-of-the-art Remote Robotic Hybrid Diesel-Electric Cone Penetration Testing Track Rig (Robotic Rig), designed to address the critical need for conducting geotechnical investigations in hazardous mine waste environments while ensuring the safety of personnel and reducing carbon emissions.

The innovation of remote robotic capabilities enables high quality geotechnical testing without the risks associated with personnel working in a hazardous environment. This functionality is crucial for investigating unstable or high-risk areas. The hybrid diesel-electric power system represents a significant step forward in reducing the carbon intensity of geotechnical investigations.

The paper will detail the objectives of the Robotic Rig, discuss its technical features including comparison against conventional ConeTec Penetration Testing (CPT) track rigs, and present the measurable health and safety and environmental impact. The paper will also present findings from field trials demonstrating the rig's operational effectiveness. Through this development, we propose a novel solution that addresses the dual challenges of safety and sustainability in mine waste management, offering a model for future innovations in the mining sector.

Introduction and motivation

The mining industry continuously seeks innovation in response to increasing demands to improve safety, environmental performance, and operational efficiency. Geotechnical investigation plays a key role in this by providing essential data and improving the understanding of the ground conditions, which permits the optimization of design for stability and sustainability. All work areas have inherent risks; however, the risk

in some mine tailings environments exceeds the tolerance under which it is acceptable for personnel to perform their work (Baker et al., 2018). In these cases, it is essential to reduce the risk to personnel by keeping them out of the hazardous environment. This paper discusses the development of robotic capabilities to allow for geotechnical testing from safer and remote work areas by remotely maneuvering the rig into the high-risk area and remotely operating the rig robotics to perform Seismic Cone Penetration Testing (SCPTu), piston sampling, or piezometer installations.

Conducting any ground investigation incurs a carbon cost. Life cycle analysis of geotechnical site investigations demonstrates that while direct push investigations such as Cone Penetration Testing (CPT) have substantially lower environmental impacts than drill-type investigation methods, by a factor of 3–5 (Purdy et al., 2022), there is still a significant emission of carbon dioxide and greenhouse gases. The Robotic Rig development aims to address this environmental issue through implementation of technologies that further reduce the carbon intensity of direct push investigations. Thus, the objectives are twofold:

1. Protect field personnel through remote robotic functionality of the rig, which allows for critical data collection on high-risk sites with a significant reduction in risk to personnel.
2. Reduce the environmental impact of direct push testing by optimizing the use of electric energy conversion, usage, and storage.

Background and standard diesel operation

Conventional CPT rigs are powered by diesel engines such as a Caterpillar C7.1 (Cat C7.1), which powers both rig locomotion and testing operations. The maximum theoretical brake-horsepower efficiency, defined as the efficiency at the output shaft of the engine and before any powertrain losses, of a Cat C7.1 is 41% (Caterpillar, 2024). Once powertrain and energy conversion losses are accounted for the efficiency of converting the chemical energy stored in diesel fuel into work is much lower. To derive the maximum efficiency of conversion of chemical energy into work, the diesel engine should be sized appropriately for the load. This is the case when a conventional CPT track rig is moving, especially in soft ground or on an incline where a significant portion of the 432 hp, the maximum power of the Cat C7.1, is needed. However, the peak power demand for CPT testing is typically between 13–67 hp depending on pushing conditions including tip resistance, friction on the rods, and penetration depth. This means that for CPT and direct push applications an engine such as the Cat C7.1 is greatly oversized and even at a low idle the engine will be producing excess power which is not needed and thus will be converted into heat rather than work. During CPT and direct push operations only around 20% of the power output is utilized, as shown in Figure 1.

In addition to the diesel engine in a conventional CPT track rig being oversized for advancing the cone, there is also significant time during a CPT test where no hydraulic power is needed such as during

pore pressure dissipations, seismic tests, or when adding and removing rods. The diesel engines in conventional CPT rigs are not designed to shut off during these periods when no hydraulic power is needed thus during these operations, all of the engine power output is converted to heat. The total idle time for the push presented in Figure 1 is 27 minutes (68%) where fuel is being consumed unnecessarily, resulting in higher operational costs and excess greenhouse gas emissions.

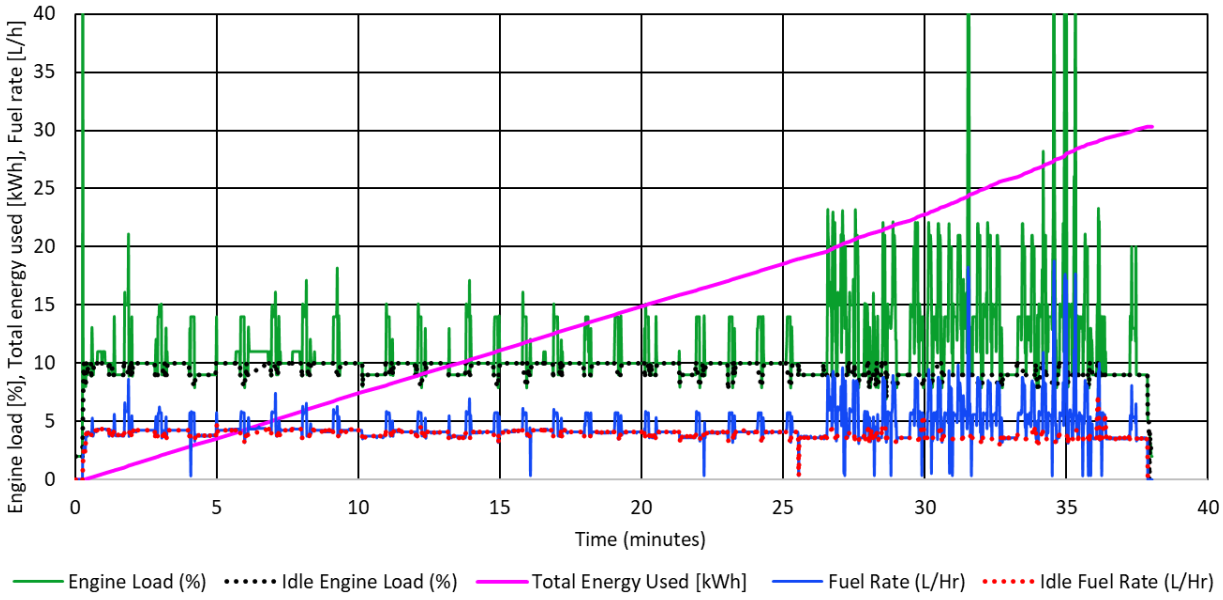

Figure 1: Example fuel usage rate (l/hr) and engine load for standard diesel operations at 1,200 RPM during a 20 m CPT push

Development of features and capabilities

Hybrid diesel electric system

Development of the hybrid diesel-electric system focused on decreasing fuel usage and lifecycle environmental impact while maintaining productivity. A key strategy to realize these objectives was to design a diesel electric system that would capture the excess power produced during idling as electrical energy which would be stored in an onboard battery. This power was optimized for CPT and direct push functions and allows for CPT operations to be powered either by the diesel engine or by the onboard battery system. When the CPT operations are powered by the diesel engine, excess power which is not needed for these operations is captured by the integrated generator and converted into electrical energy and stored in the battery. When CPT and direct push operations are powered by the electrical system, the diesel engine does not run and the electrical system only outputs power when there is a demand. This means that during the operations when hydraulic power is not needed such as pore pressure dissipations, seismic testing, and adding and removing rods, the batteries do not output any energy to the hydraulic system. This greatly reduces the energy wasted as compared to a conventional CPT track rig.

The electric batteries in the Robotic Rig are designed to charge anytime excess power is being output by the diesel engine including during locomotion and during testing when running off the diesel engine. The batteries can also be charged from the grid. When conducting CPT on battery power, as shown in Figure 2, the diesel engines are off and no fuel is being consumed.

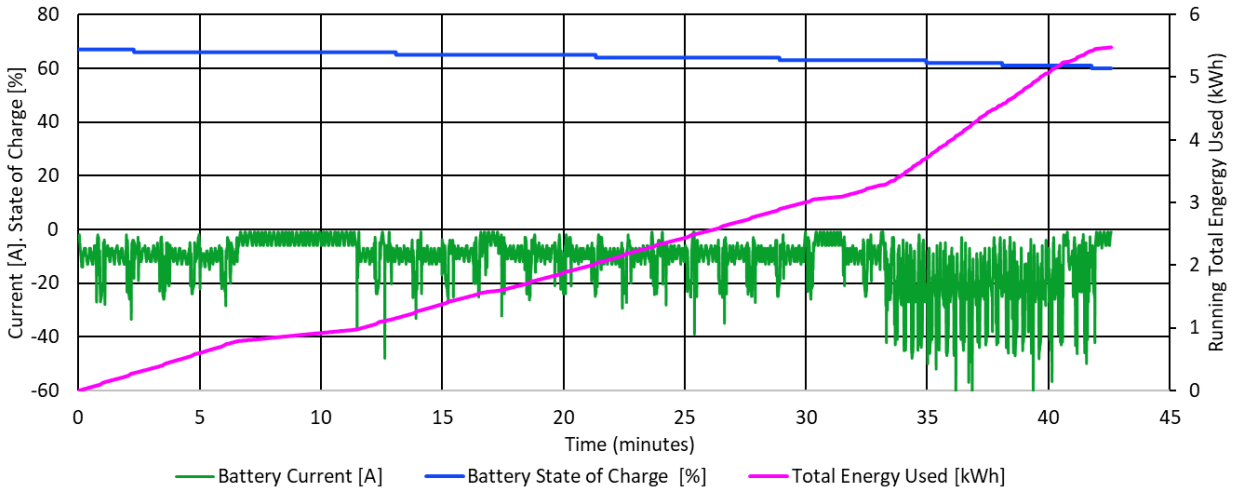

Figure 2: Example fully electric 20 m CPT push comparing work to energy usage. Push was conducted with no diesel usage

The total energy used by the diesel and electric systems for a 20 m CPT can be compared. Based on the data presented in Figures 1 and 2, the electric system when powering the CPT pump only is about five times more efficient than the conventional diesel system and requires only 20% of the energy to conduct a comparable amount of work.

Remote robotic functionality

The primary goal of the remote robotic function is to eliminate the need for operator presence within hazardous sites. This necessitates the ability to track the rig remotely to the testing location and conduct the CPT or other direct push operations remotely through the onboard robotics. The key operations of the robotic system of the Robotic Rig are:

- Add and remove a cone penetrometer, direct push sampler, or piezometer through the push clamp.
- Add and remove a 1-meter-long cone rod on to the end of a direct push tool or another cone rod.
- Tighten and loosen the cone rods from each other.
- Move the thrust cylinders with speed precision.
- Operate the seismic hammer.

The primary robotic equipment in the Robotic Rig is a commercially available industrial 6 degree of freedom robot. While this robot is highly versatile and allow for a great amount of flexibility in the system, some custom robotics apparatuses were also required. The custom robotics and apparatuses implemented for the Robotic Rig include a vertical rod rack, a hydraulically powered seismic beam, a rod tightening and loosening device and a cone rod that does not rely on a continuous cable from the cone to the data acquisition system (DAS). Commercially available cableless rod solutions, such as acoustic and fiber optic technologies, were evaluated and did not meet the geotechnical data requirements established for this project which included the requirement for shear and compression wave seismic testing a penetration depth up to 100 meters. Therefore, a new cableless rod system was developed to support low-latency seismic triggering, allowing the transmission of both standard CPT and seismic data. This system permits the sustained transfer rates of 100 Mb/s while allowing for seismic triggering.

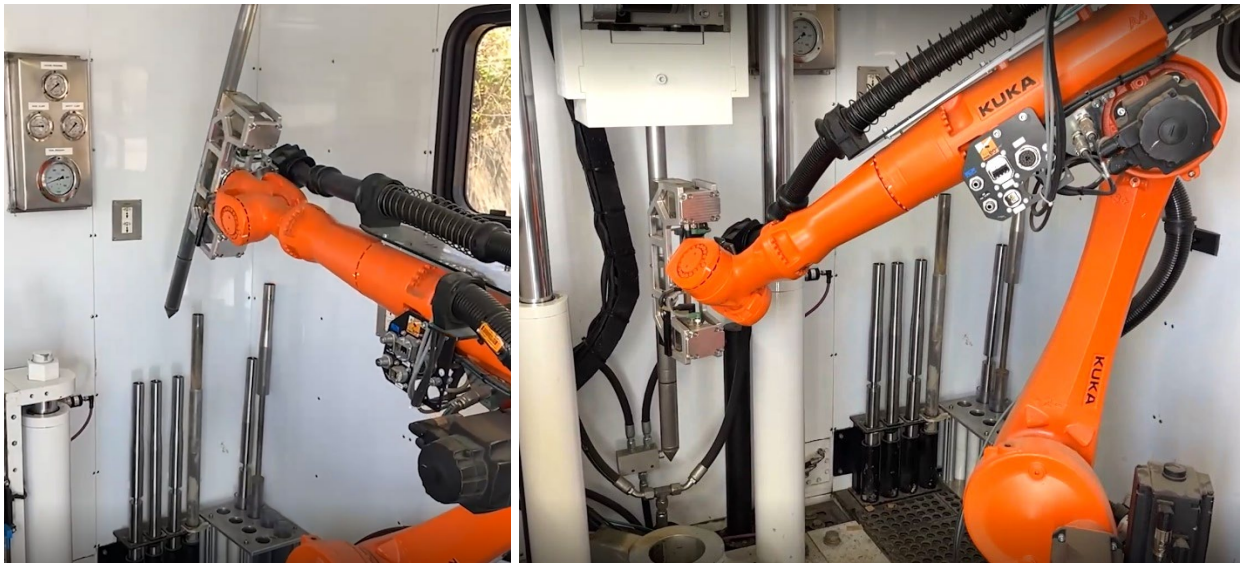

Figure 3: Robotic installation of cone penetrometer through the push clamp

To optimize efficiency, the Robotic Rig is designed to be able to perform a full day of testing in the field without operator intervention. This includes up to four seismic cone tests and the recovery of eight samples, but these limitations are only practical based on the space available in the rig and could be expanded if it became important. The operator intervention involves loading prepared piezocones and sample tubes into the rig before the rig leaves the safe area.

Data geotechnical quality checks

Ensuring the accuracy and reliability of geotechnical data obtained from site characterization is vital when any changes are made to an established technique. Throughout the development of the Robotic Rig, there

was an objective to use as much standard equipment as possible through the data transmission chain. In a conventional push, data would be transmitted from the piezocone, through the cone cable to the DAS. In the Robotic Rig, the data is transmitted from the piezocone through the cableless cone rod system and into the DAS where the data is saved and also re-transmitted to the cloud. It was essential to perform control testing to validate the performance of the cableless cone rod system. Figure 4 shows a comparison between CPT pushes deployed with the cableless rod system and neighboring CPT pushes with a standard cabled rod system. The data presented shows that though spatial variability exists on the test site, cableless rod system obtains comparable geotechnical data, matching the standard of conventional methods.

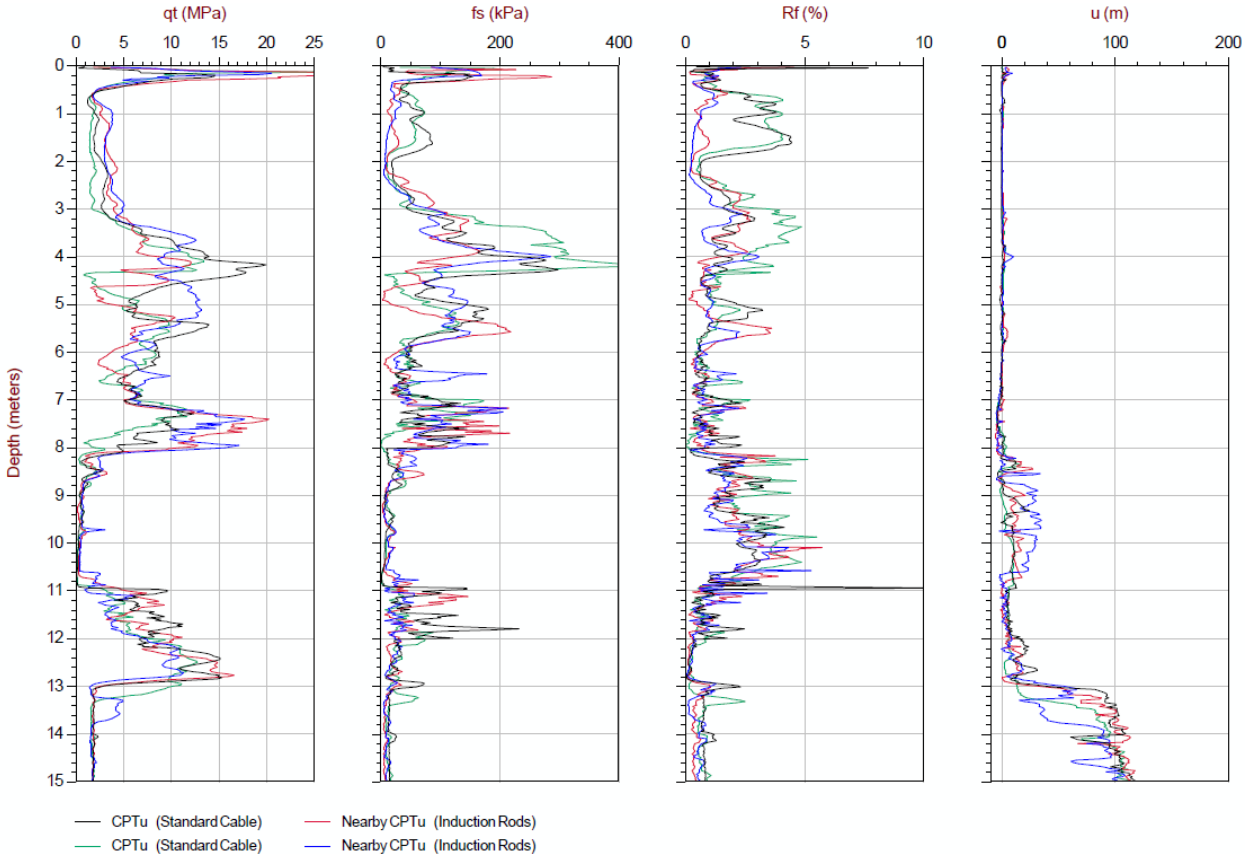

Figure 4: Example CPT pushes comparing in the cableless rod system with standard data

It was observed that when the Robotic Rig performed testing in electric mode, rig vibrations were reduced as the diesel engine was not running. This reduction in vibration has potential safety implications and could also lead to improved surface seismic responses.

Productivity and charging efficiency

There is no discernible difference in productivity between diesel and electric operations, both can provide sufficient power for CPT and direct push testing. Additionally, the system is designed to always fall back

to diesel in case of any issue with the electric system. In most cases, grid power has a lower carbon intensity than a diesel engine so charging the Robotic Rig through the grid would have a lower environmental impact, however in most of the identified use cases today this is not practical. Therefore, a key design element of the electric system is the ability to charge the batteries from the diesel engine. Charging the batteries does add an additional load on the system however it can be optimized to reduce the energy lost through idling. By capturing this otherwise wasted energy the system can charge the batteries for later use, reducing overall fuel consumption. As shown in Figure 2, the energy required for a 20 m CPT push is 5.8 kWh. Traction for 20–30 minutes (moving the rig across site for example) should generate enough electricity to conduct a 20 m push with zero fuel usage during the CPT.

To understand the system efficiency during charging the fuel usage for the Hybrid Diesel-Electric System during regen has been compared against a conventional diesel operation, as presented in Table 1. Though this data was collected during idling in order to minimize the variables on engine load, regen is targeted to occur during traction, while using start-stop functionality to reduce fuel usage when idling. Of the differential energy available 63% (at 1200 RPM) was successfully converted into stored energy for electrical operation.

Table 1: Comparison of fuel usage and efficiency considering regen mode when idling

	Conventional diesel operation			Hybrid operation with regen		
Engine Speed (rpm)	800	1200	1800	800	1,200	1,800
Total Diesel Used (L)	1.64	2.85	5.07	2.32	4.41	5.80
Total Time (Mins)	30.04	33.16	31.52	24.02	28.29	21.12
Average Fuel Rate (L/Hr)	3.27	5.15	9.66	5.80	9.37	16.47
Total Energy Gained (kWh)				1.69	5.49	6.37
Maximum Diesel engine efficiency (%)	41	41	41	41	41	41
Diesel Needed for Energy Gained (1L = 10.56kWh) (L/Hr)				0.97	2.68	4.14
Efficiency of Regen (Diesel Need / Diesel Used) (%)				38.34	63.43	60.75
Torque Load (%)	15.56	15.97	22.14	24.19	26.00	33.05
Torque Load (Nm)	221.14	226.95	314.60	343.72	369.47	469.57
L/hr per SoC%				0.24	0.36	0.50

Operational rates

The current operational rates of the Robotic Rig are comparable to standard non-automated operations, however there is a reduction in productivity when associated activities such as rod handling are considered. The capacity for faster operation exists with further development. Increasing autonomy and reducing

operator interaction is expected to lead to increased standardization of the CPT test, enhancing overall productivity. This is expected to be achieved through improving sensor capabilities, making the robotics system faster and simpler to control. The robotic system is specifically designed for safety-critical sites, where the priority is to make testing possible.

Health and safety impact

Conventional geotechnical testing in mine tailings environments poses many hazards to personnel. It is critical that the risks associated with these hazards are minimized through a robust health and safety program which incorporates the philosophy of a hierarchy of controls, a step-by-step approach to eliminating or reducing workplace hazards (CCOHS, 2024). This approach ranks controls from the most effective to the least effective levels of protection, ranking elimination as the most effective control and PPE as the least effective. According to a 2021 report from International Council on Mining and Metals (ICMM), fatality, except for 2019, and injury incidents are generally following a downward trend for member companies (ICMM, 2021) with a Fatality Frequency Rate (FFR) of 0.033 and a Total Recordable Injury Rate of 5.07 in 2012 compared with 0.018 and 2.94 in 2020. While the rate for fatalities and incidents is on the decline, the total number of fatalities and recordable incidents in 2020 was 44 and 6,977 respectively. Thus, despite the robust health and safety controls in place reducing the risk of working in mine tailings environments, significant risks still exist.

The development of the remote robotic functionality for CPT offers the opportunity to eliminate the need for personnel to work in hazardous environments, by moving the working environment from directly on a mine tailings structure to a safe location nearby. This allows for the elimination or substitution of many of the risks to which personnel are exposed when using conventional equipment, especially those that are typically not managed or are managed through administrative or PPE controls. This approach aligns with the hierarchy of controls, prioritizing elimination and substitution of hazards, and demonstrates a proactive commitment to improving safety and efficiency within the mining industry.

This advancement is most apparent when a job safety analysis (JSA) is applied, and a risk level is determined. In a JSA, risk levels are determined by evaluating the consequence and probability of potential hazards. First, hazards for each job step are identified. The consequence (severity of harm or damage) and probability (likelihood of occurrence) are assessed and combined using a risk matrix to quantify the risk by assigning a rating to both the consequence (1–5) and the probability (A–E). Safety controls are then applied to mitigate the identified risks resulting in an acceptable residual risk. Table 2 presents a selection of typical hazards associated with Cone Penetration Testing. In total, 35 typical hazards were identified and evaluated to calculate the risk before controls, with conventional controls, and with remote robotic controls.

Table 2: Example hazards found in a job safety analysis for cone penetration testing with related controls for both conventional and remote robotic equipment

Item	Step	Hazard
1.1	Inspect Work Area	Personnel encounter hostile wildlife
2.1	Position Equipment	Slips, trip, falls due to ground conditions
2.2	Position Equipment	Local traffic, pedestrians, or other workers in the area
2.3	Position Equipment	Overhead hazard with potential contact
2.4	Position Equipment	Soft or uneven terrain causing immobility or damage
3.1	Deploy Stabilizers and Pads	Crush hazard to body with ground contact
3.2	Deploy Stabilizers and Pads	Pinch points between jack pads, ground, and swivel points
3.3	Deploy Stabilizers and Pads	Property damage from pressure of stabilizers
4.1	Setup CPT probe and software	Moisture damage to equipment
4.2	Setup CPT probe and software	Small cuts on hand from equipment
5.1	Lower seismic beam	Pinch/crush points on ground.
5.2	Lower seismic beam	Heavy lifting causing back injury
6.1	Place cone in pushing system	Pinch point in chuck and rams causing hand injuries
7.1	Add first rod	Small cuts on hand from equipment
8.1	Push cone into ground	Pinch points on ground and around moon-pool area
8.2	Push cone into ground	Utility contact causing injury or damage

Consequence and probability do not increase linearly (Bao et al., 2022). To determine risk, a logarithmic scale has been applied to consequences and probabilities to appropriately represent the wide range of potential outcomes and their impacts, and the vast differences in the frequency of potential events. The approach reflects the exponential difference in impact from minor injuries to catastrophic events and that both high-probability, low-consequence events and low-probability, high-consequence events are appropriately quantified and managed as supported by research (Bao et al., 2022).

The consequence and probability rankings and scores are illustrated in Figures 5 and 6. The risk level is then calculated by: $Risk\ Level = \log_{10}(Consequence\ Score \times Probability\ Score)$

			Probability				
Consequence	Ranking		A	B	C	D	E
		Description	Improbable	Unlikely	Possible	Likely	Certain
	1	Slight Injury	L	L	L	L	L
	2	Minor Injury	L	L	L	M	M
	3	Severe Injury	L	L	M	M	H
	4	Death	L	M	M	H	H
	5	Multiple Deaths	M	M	H	H	H

Figure 5: Typical risk ranking table

			Probability				
Consequence	Score		1	10	100	1000	10000
		Description	Improbable	Unlikely	Possible	Likely	Certain
	1	Slight Injury	0	1	2	3	4
	10	Minor Injury	1	2	3	4	5
	100	Severe Injury	2	3	4	5	6
	1000	Death	3	4	5	6	7
	10000	Multiple Deaths	4	5	6	7	8

Figure 6: Risk score table

By comparing the risk scores associated with tasks identified in the hazard assessment, a risk score reduction can be calculated, before and after the application of safety controls, including both conventional and remote robotic controls (Figure 7). Initially, the cumulative risk score across all tasks identified was 149 before any controls were applied. This score was reduced to 94 after implementing conventional safety controls. The introduction of remote robotic controls further lowered the cumulative risk score to 54, showcasing the enhanced effectiveness of these advanced technologies in minimizing hazards and ensuring a safer working environment. This progression clearly illustrates the impact of employing innovative safety measures in high-risk operations.

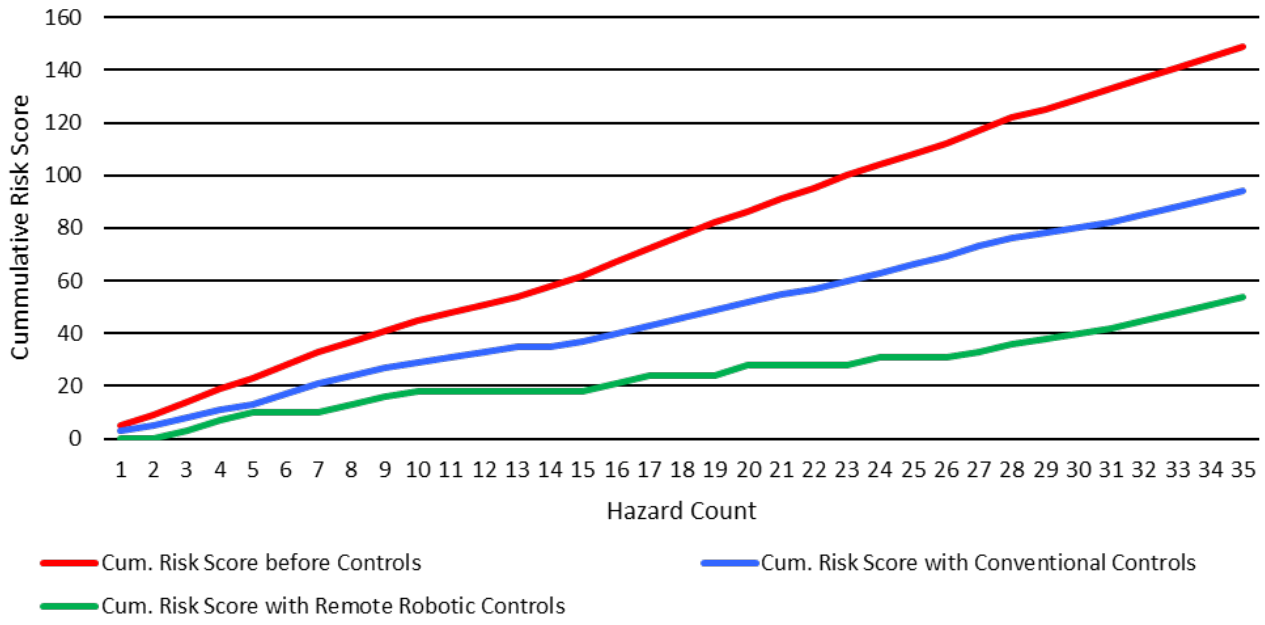

Figure 7: Cumulative risk scores without controls, with conventional controls, and with remote robotic controls

Life cycle assessment

Life cycle assessment (LCA) is a framework used to characterize, quantify, and interpret environmental impacts associated with a product or a system over its entire life cycle. In this study, LCA is used to evaluate the impacts of three site investigation programs that capture possible configurations of the CPT Hybrid Diesel-Electric System. The scope of this study includes impacts associated with raw material extraction, materials and energy processing, mobilization of vehicles and equipment to site, site maneuvering and idling, and penetration (i.e., CPT pushes) for a site in British Columbia, Canada. The methodology used for the LCA calculations, including the calculations in the life cycle inventory (LCI), transportation modeling, and life cycle impact assessment (LCIA), follows the procedure detailed in Purdy et al. (2022). Table 3 below shows the details of Scenarios 1 and 2. Scenario 3 adopts a traditional, fully diesel-powered program. For each scenario, the fuel usage is calculated based on the value during hybrid operation with regeneration at an engine speed of 1,200 RPM, as listed in Table 2 (9.37 L/hr). The roundtrip mobilization from yard to mine site is assumed to be 100 km.

Table 3: Specifications for each modeled scenario

Scenario	Activities	Pushes	Electricity consumption (kWh)	Diesel consumption (kg)
Scenario 1 - Arrive to Site Fully Charged	Charge battery to 100% from grid (from hydro power source)	–	+84	–
	Electric CPT	12	-69.8	–
	Diesel CPT	3	+22	15.62
	Site Maneuver/Idle (1 hr)	–	+20	7.81
	Electric CPT	7	-40.6	–
	Diesel CPT	3	+22	15.62
	Electric CPT	3	-17.4	–
Scenario 2 – Arrive to Site with Zero Charge	Diesel CPT	7	+51.3	36.4
	Electric CPT	8	-46.4	–
	Site Maneuver/Idle (1 hr)	–	+20	7.81
	Diesel CPT	6	+44	31.2
	Electric CPT	9	-52.2	–

The results are presented in a range of formats to provide normalized environmental impacts and representative impacts for each scenario. The normalized results for primary energy (PE) and global warming potential (GWP) can be seen in Table 4 for each life cycle phase, and associated functional unit. The total GWP for each scenario is shown in Figure 8. There is a 44.75% increase in total GWP from Scenario 1 to Scenario 2, and a 67.9% increase from Scenario 2 to Scenario 3.

Table 4: Normalized impacts of primary energy (PE) and global warming potential (GWP)

Life Cycle Phase	Mobilization	Fuel for Pushes	Site Maneuver/Idling	Electricity from Grid
Functional Unit	per 1 km	per 1 m	per 1 hr	per 1 kWh
PE (MJ)	1.28E+01	1.50E+01	2.25E+01	1.24E+00
GWP (kg CO_2-eq)	4.55E-01	2.96E-01	4.44E-01	4.44E-03

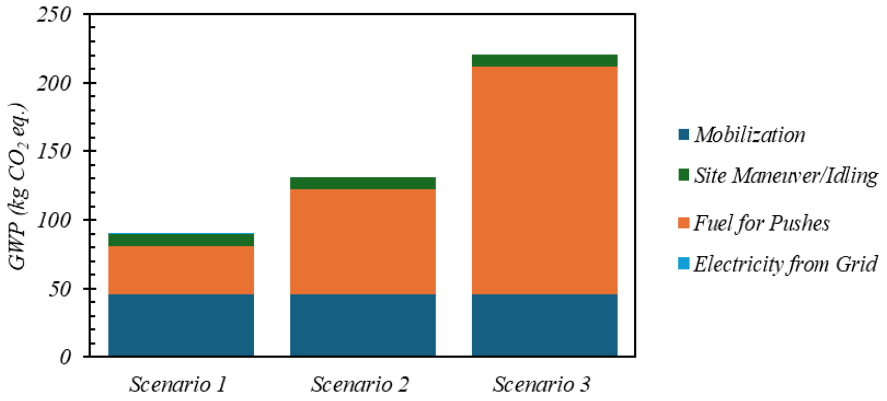

Figure 8: Total GWP (kg CO_2-eq) for each life cycle phase for each scenario

Fuel production and consumption for CPT pushes accounted for 39.3%, 58.6%, and 75.3% of impacts for Scenarios 1, 2, and 3, respectively. However, an opposite trend is observed for site maneuvering and idling. These activities account for 9.8%, 6.76%, and 4.03% of GWP for Scenarios 1, 2, and 3, respectively. This is because the total impacts of this life cycle phase remain the same across scenarios, thus constituting a larger percentage of Scenario 1, which has lower overall impacts compared to the others. A similar trend is observed for mobilization, which also remains constant across scenarios. The only scenario which has impacts from electricity from the grid is Scenario 1. Because the grid pulls electricity from renewable sources, namely hydropower, the impacts associated with this stage are proportionally minimal, making up only 0.55% of total impacts.

Conclusion

The development of the Remote Robotic Hybrid Diesel-Electric Cone Penetration Testing (CPT) Track Rig offers positive environmental and health and safety impacts, helping address the need for safer and more environmentally sustainable operations. The hybrid system, which combines diesel and electric power, offers the flexibility to switch modes based on operational demands, thereby optimizing efficiency and minimizing carbon emissions while maintaining the versatility necessary to cope with testing in rugged environments. Field trials have validated the rig's capability to perform precise geotechnical testing, using energy of the same quality as conventional testing, remotely and from stored electrical. These trials have

shown that the hybrid system has the potential to generate enough stored energy during typical traction operations over 20 to 30 minutes to conduct a 20 m CPT push, though charging through mains power from renewable energy is preferable.

The robotics developed now allow for ground investigation in safety critical tailings storage facilities where traditional methods may endanger human lives and are not considered permissible. By allowing for a deeper understanding of ground conditions, more informed design decisions can be made.

Tailings Facility Surveying Leveraging Complementary Technologies

Veronique Nell, PhotoSat, Canada
Andrea Krupa, PhotoSat, Canada

Abstract

Ensuring the safety, compliance, and efficient management of tailings storage facilities (TSFs) demands robust surveying techniques. In this context, the integration of complementary technologies and data sources offers a holistic approach to TSF surveying. This paper explores the synergies between imagery and surveys from drones, high-resolution optical satellites, rapid revisit optical satellites, bathymetric sensors, and LiDAR for comprehensive TSF surveying.

While LiDAR excels at capturing elevation data, it faces constraints related to accessibility, expense, and revisit intervals. Drones, in comparison, can offer excellent flexibility and accessibility for capturing detailed video, imagery, and topography of TSFs. However, their limited collection area can lead to challenges in the merging of data from multiple flights, as well as the time to acquire and process data over an entire TSF.

High-resolution and rapid revisit optical satellites provide complementary data to drones and LiDAR by capturing a whole TSF in a single acquisition at revisit rates ranging from days to weeks. They offer a supplementary, cost-effective solution with rapid delivery times. In addition to on-going surveying, archived satellite imagery can retroactively provide time-stamped data to determine the deposition history of a TSF when as-built records are unavailable.

Finally, bathymetric surveys provide essential information about underwater topography. By combining bathymetric data with surface topography, operators can gain a comprehensive understanding of TSF geometry, construction, and deposition plan advancement.

Integrating data from these complementary sources allows the TSF operator to overcome the limitations of each technology and enhances the overall accuracy and completeness of TSF surveying.

This paper highlights the collaborative potential of diverse technologies, emphasizing their collective impact on TSF survey quality and accuracy. The integration of these complementary technologies provides operators with the data for safer and more efficient management of tailings facilities, aligning with industry standards and sustainability goals.

Introduction

Ensuring the safety, compliance, and efficient management of tailings storage facilities (TSFs) demands robust surveying techniques. In this context, the integration of complementary technologies and data sources offers a robust approach to TSF surveying.

No two sites are identical. Each location presents unique challenges, influenced by factors such as size, ease of access, operating requirements, and reporting requirements. TSF operators often face recurring challenges that affect the overall design and implementation of the survey program.

Frequency of data acquisition: different data is needed at different frequencies and for different tasks. Month end reporting, weekly operational updates, and integration with multiple sensors such as bathymetry collections, all require data collections at different frequencies, resolutions, accuracies, and over different areas. Another consideration in this category is how quickly data can be collected and how fast the topography can be delivered post collection, so that a site has the data they need when they need it.

Offset errors and data integration: once the data from multiple sources and sensors is collected, it is important to ensure that all the data sets are coherent for all teams to be working from the same baseline. Correcting any offset errors is a key step in achieving effective data integration.

Lack of data continuity: with many TSFs having been in operation for years, if not decades, changing regulations, staff turnover, and changes of ownership can lead to incomplete records and lack of topographic data continuity. With the implementation of new global standards for TSF management, these data gaps can hinder current operators managing their TSFs within the GISTM requirements and in accordance with the "As Low as Reasonably Possible" (ALARP) principles.

In this paper, we will look at the strengths and weaknesses of four surveying methods, or tools: ground surveyors, manned airborne LiDAR, drones, and satellites (high resolution optical and rapid revisit optical). We will compare their performance in six main categories:

1. Area coverage: how large of an area can this tool survey in a single pickup?
2. Accuracy: what is the absolute vertical accuracy of the survey?
3. Repeatability: how repeatable are the results from one survey to the next?
4. Flexibility: how quickly can data be captured from request?
5. Cost: what is the cost of the survey?
6. Processing time: how quickly after the raw data is captured can the survey be delivered?

The following sections will detail how these different tools can be used to address different surveying needs and how, by leveraging their complementary characteristics, their individual weaknesses can be offset.

Different tools for different needs

Ground surveying

Ground surveying is the original surveying method and ground surveyors provide unmatched accuracy on discrete areas of change – sub-centimeter horizontal and vertical accuracy in some cases. The cost of these surveyed points can also be low if work is being performed by existing site survey teams.

The presence of personnel on-site can present challenges, as the surveying work needs to be conducted in a way that does not interfere with operation, while ensuring the safety of all personnel. Also, with a limited number of on-site surveyors, the demands of multiple groups can lead to scheduling issues. When scheduling challenges can be avoided, ground surveyors provide a very flexible way to collect data points over small areas.

Survey points from ground surveyors provide valuable and accurate survey points. Their value can be increased exponentially when paired and merged with the other survey methods described below, where they can be used as ground control or to get a small number of highly accurate survey points over a critical area.

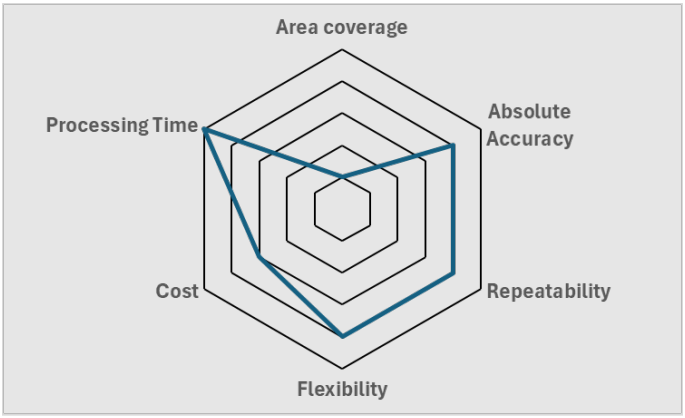

Figure 1: Strengths and weaknesses of ground surveying

Manned airborne LiDAR

Manned airborne LiDAR is the traditional benchmark for high accuracy surveys over mine site scale areas. With vertical accuracies as low as 5 cm with ground control and the ability to capture an entire TSF in a single flight, LiDAR surveys can be a great option for a baseline survey that all subsequent surveys are matched to. LiDAR's ability to penetrate vegetation means that the resulting surface is a bare ground surface – also referred to as a DTM, Digital Terrain Model – another key feature of a baseline survey.

LiDAR surveys are large data sets with very high data density. These can take a long time to process and they can be hard to manipulate. The need to dispatch a manned aircraft means this is a relatively high-

cost option and can also present challenges for more remote sites, or in parts of the world where this type of service may not be readily available.

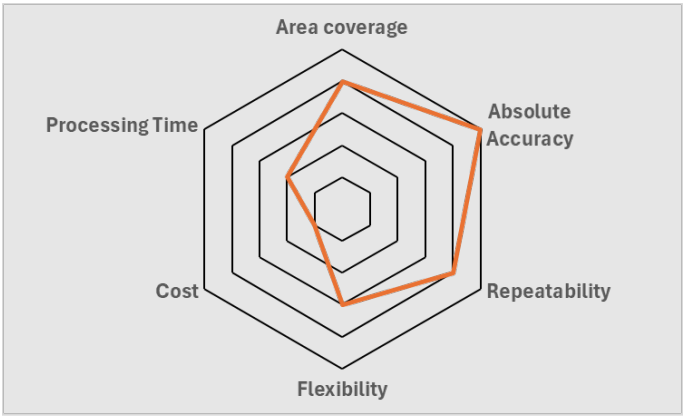

Figure 2: Strengths and weaknesses of manned airborne LiDAR

Drones

Drones have come a long way in the last five years, significantly increasing their payload capacity and autonomy. In the context of topography, the key sensors are optical (including multispectral) and LiDAR. Despite the improvements, the payload capacity is still limited, so high-end LiDAR and multispectral sensors may require larger, more expensive drones.

Since they fly at a lower elevation than traditional manned aircraft, drones can avoid some atmospheric conditions and capture clear data even when clouds are present. The lower flight altitude can also lead to higher resolution imagery and topography with vertical accuracy down to the centimeter level. They are nevertheless sensitive to weather conditions such as high winds, rain, fog, or extreme temperatures that can affect flight stability and data quality. Adverse weather may limit the operational window for surveys.

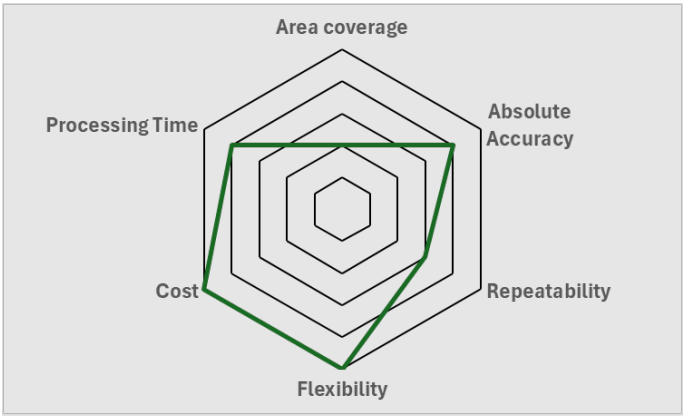

Figure 3: Strengths and weaknesses of drones

In-house drone programs provide incredible flexibility for regular pickups if scheduling requests from multiple teams on a site can be managed.

Limited flight times mean that one TSF can often not be captured in a single flight, which can lead to offsets between different pickups. Also, surfaces derived from drone data are typically Digital Surface Models (DSM), which still include features such as vegetation and buildings. These surfaces need to be post processed to remove these features and produce a bare ground survey.

Satellites

High-resolution satellites

Data from high resolution optical satellites has been commercially available since the early 2000s. Their ability to collect high resolution (30 cm to 50 cm pixel) imagery over very large areas (hundreds of square kilometers) in one shot is unparalleled. By collecting stereo imagery of an area of interest, that is two images of the same area at different angles, taken only seconds to minutes apart, topography can be derived from these stereo pairs. By using previous bare ground surveys, either from LiDAR or previous satellite surveys, as ground control, and tying into areas where no change occurred, this type of surveying can achieve absolute vertical accuracies better than 15 cm RMSE.

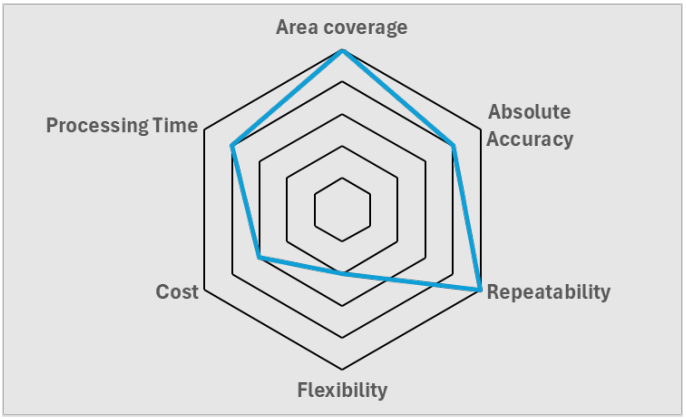

Figure 4: Strengths and weaknesses of high-resolution satellites

When applied to TSFs, this means a whole TSF, even a whole mine site, can be collected in a single, instantaneous snapshot. Since the topography is derived from a single acquisition, the consistency of the data over the whole area of interest is excellent. The challenges of correction for errors and offsets that can come when multiple collections need to be stitched together are avoided. The data is self-consistent, which leads to high precision topography. As subsequent collections are coming from the same sensor and going through the same processing systems, there is excellent repeatability between surveys over the same area and the results from surveys over different areas are easily comparable.

Rapid-revisit satellites

Rapid Revisit Satellite constellation, and specifically ones from which topography can be derived, are a new development in surveying. These growing constellation of 10 or more satellites can provide collection opportunities weekly or even daily anywhere in the world, with collection occurring as little as three hours after tasking.

Their collection area offers larger coverage than a single drone pickup but smaller than high-resolution satellites and manned airborne LiDAR. The imagery resolution and survey accuracy from these satellites is currently lower than what is achieved with the other tools described above, but the sensor technology and processing is rapidly improving.

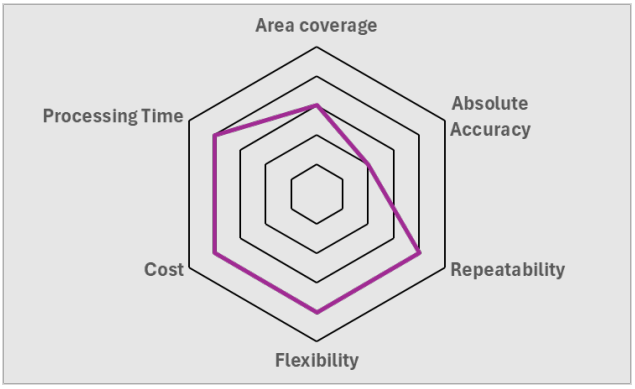

Figure 5: Strengths and weaknesses of rapid revisit satellites

Archived satellite imagery

There is a continuous archive of commercially available data dating back to the 1960s. Figure 6 gives a non-exhaustive list of satellites from which archive data is commercially available. Topography can be generated from most of the sensors on this list.

Accessing archived imagery means that current operators can fill potential data gaps created by change of ownership, personnel, and regulations, to better understand how a site was operated in the past, in order to plan for safer and more efficient operations moving forward.

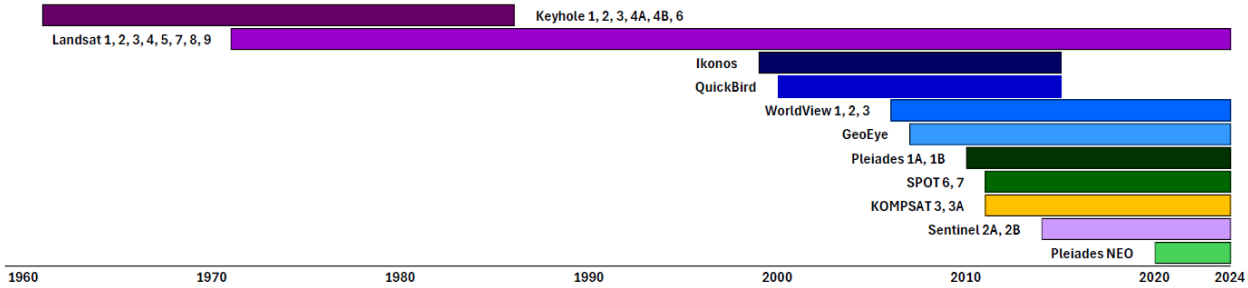

Figure 6: A timeline of satellite imagery

Leveraging synergies

Integrating data from multiple sources

The surveys derived from all the acquisition tools described above are valuable on their own, but to fully leverage their synergies, the various surfaces can be integrated with one another to provide a single, up-to-date surface for teams to work with. This is also true for other sensors such as bathymetric sensors, whose data can be integrated with the above water surface.

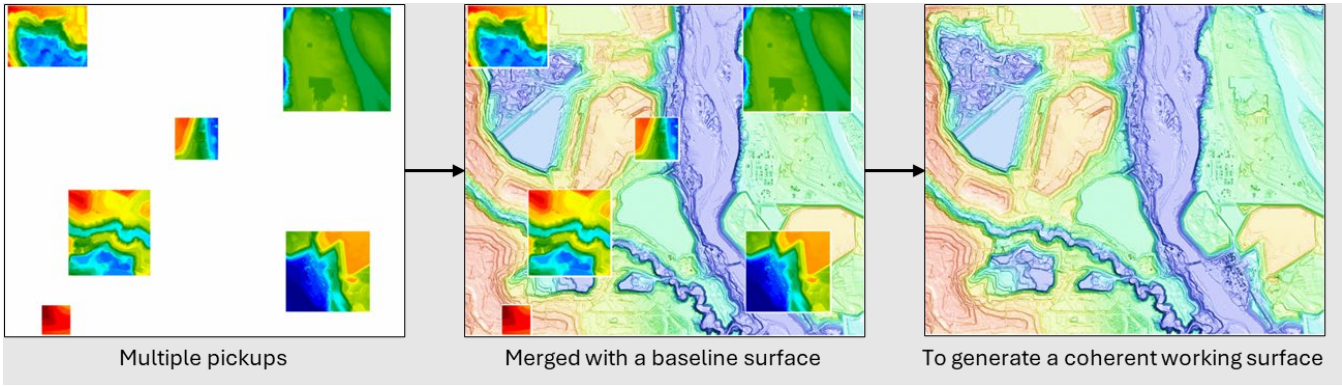

Figure 7: Merging data from multiple sources

A common challenge in integrating surfaces from multiple sources is handling offsets in data and, in some cases, managing surveys in different mine grids. Figure 8 shows how using a baseline surface of a whole TSF can help shed light on offsets between different drone pickups and thereby help to correct them. Comparing newly acquired surfaces to a baseline surface will help avoid any propagation of error over time and ensure teams are working with precise and reliable data.

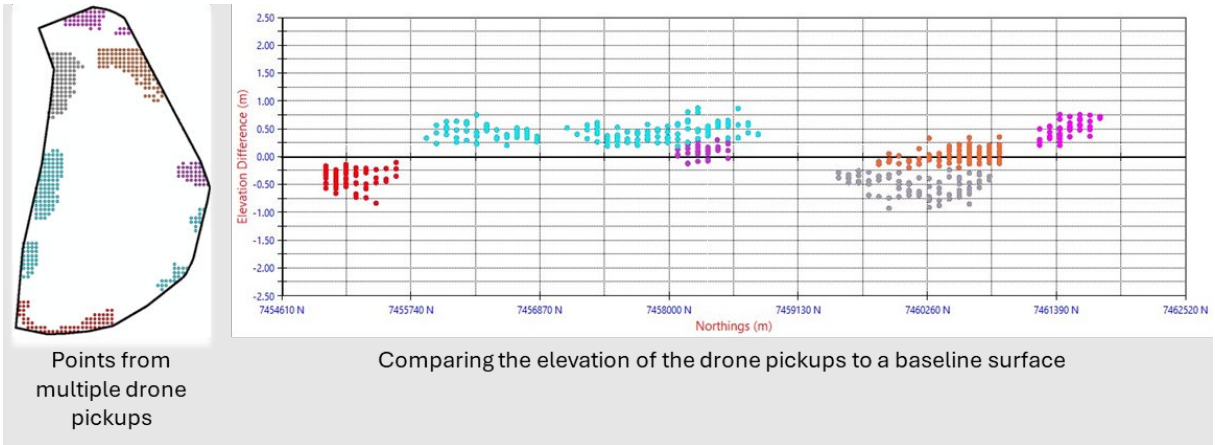

Figure 8: Correcting offsets with a baseline survey

Leveraging strengths to offset weaknesses

When comparing the strengths and weaknesses of all the tools discussed above, we see that by using a combination of them, we can offset the weaknesses of one with the strengths of another.

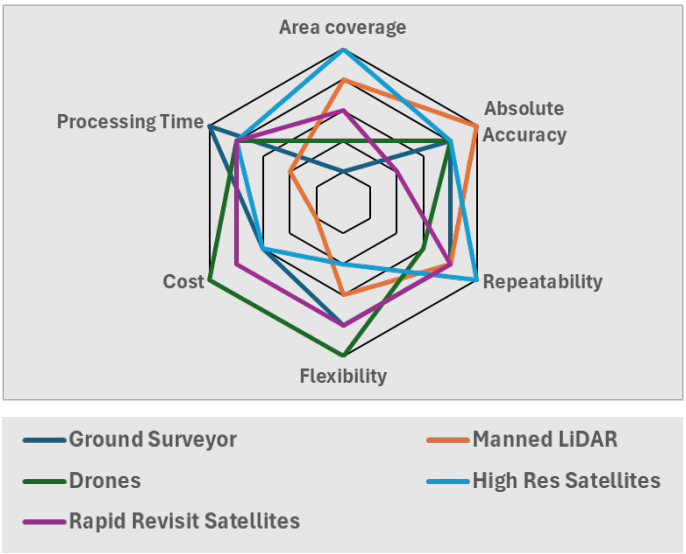

Figure 9: Leveraging strengths to offset weaknesses

Using multiple tools supporting each other can increase the value of each of those tools on their own. For example:

- Using a baseline high-resolution satellite or LiDAR survey as a baseline to QC drone data and correct any offsets makes the survey from drone data more precise and reliable.
- Using highly accurate points surveyed by a ground surveyor to tie any other kind of survey to, will greatly improve the absolute accuracy of that survey.
- By integrating an above water surface survey with a bathymetric survey, operators can generate a single TSF survey to work from, improving overall understanding of the TSF surface and supporting efficient operations.

The right data at the right frequency

Each tool described above is better suited to a different frequency of acquisition. By leaning into the strengths of each tool, TSF operators can ensure they have the right, reliable data when they need it. The cycle shown in Figure 10 is an example of a possible acquisition frequency for each tool.

Figure 10: The right data at the right frequency

Conclusion

Designing and implementing a complete survey program is less about getting more data and more about getting the right data at the right time and efficiently integrating survey data from multiple sources.

Trade-offs will always need to be made around safety of personnel onsite, collection logistics, cost over time, and accuracy. However, by optimizing collection frequency to capitalize on the strength of the tools at their disposal, TSF managers will be able to acquire the survey data necessary to make informed decisions for optimized operations.

Potential of X-ray Micro-CT Imaging for Mine Tailings Deposit Characterization

Dharma Wijewickreme, University of British Columbia, Canada
Ana Valverde, WSP, Canada

Abstract

Characterizing mine tailings from a geotechnical engineering perspective is critical to maintaining the stability and safety of mining facilities. The engineering parameters derived from these characterizations provide the keys to evaluate risks associated with slope stability, liquefaction, and seepage, as well as to develop mitigation measures against potential dam failures. Laboratory studies on tailings have indicated complex behavior patterns during shear. For example, direct simple shear testing carried out on reconstituted specimens of sand and silt tailings have shown that the behavior of the tailings is governed not only by the stress and density state, but also by the soil particle arrangement (fabric) attained during specimen preparation. The commonly used slurry-deposition method for preparing reconstituted specimens for laboratory testing, while arguably it should represent field deposition mechanisms, has not been very successful in enabling the reproduction of in-situ loose densities, and may explain some abrupt flow-failure-type responses observed in the field. Greater attention needs to be paid to details such as particle breakage and particle fabric rearrangement, etc., within the soil skeleton. X-ray Micro-Computed Tomography (X-ray micro-CT) is a non-destructive technique that enables imaging of internal structures in complex solid matrices, and the technique can be used to characterize and examine the soil particle fabric when coupled with advanced image processing. In this paper, building on the experience gained from the study of silt particle matrices at the University of British Columbia, Canada, the potential use of X-ray micro-CT in the characterization of mine tailings is demonstrated, focusing especially on its ability to reveal particle size distributions and internal structure.

Introduction

The stability and safety of mining facilities are paramount in geotechnical engineering, and accurate characterization of mine tailings plays a key role in this regard. Observations from past tailings dam failures have indicated that the mechanical behavior of tailings is influenced by more than just the confining stress and density. The fabric of the soil, or the spatial arrangement of particles, also plays a critical role. Research

conducted at the University of British Columbia (UBC), Canada, has demonstrated the significant impact of soil particle fabric on the mechanical response of silts. This research work has highlighted the differences in behavior between reconstituted and field specimens, young and aged conditions, and uniform and gap-graded particle matrices. These findings underscore the necessity of accounting for particle fabric alongside traditional factors such as void ratio and confining stress to fully describe soil behavior.

One significant challenge in laboratory testing is replicating the in-situ stress, density, and particle fabric states of tailings in test specimens. Commonly used methods, such as slurry deposition, often fail to reproduce the densities and fabrics observed in situ, leading to discrepancies between laboratory results and field behavior. This gap underscores the need for advanced techniques that can provide more accurate understanding of soil internal structure and properties. X-ray Micro-Computed Tomography (X-ray micro-CT) offers a potential approach to this challenge. As a non-destructive imaging technique, X-ray micro-CT enables detailed visualization of internal structures within complex solid matrices. By coupling this technique with advanced image processing, it is possible to characterize the soil particle fabric and obtain precise particle size distributions. Previous studies have primarily focused on the fabric of sandy materials (Al Mahbub and Haque, 2016; Hight and Leroueil, 2003; Fonseca et al., 2012). However, recent advancements have made it possible to investigate finer (silt size) particles (Wesolowski, 2020; Valverde et al., 2020; Valverde and Wijewickreme, 2021a; Valverde and Wijewickreme, 2021b; Valverde and Wijewickreme, 2024).

This study presents the application of X-ray micro-CT to three different gradations of mine tailings – fine, medium, and coarse grain sizes. While preliminary, the results demonstrate the potential of the technique to enhance our understanding of internal structures present in tailings. In particular, the details on the materials tested, specimen preparation methods, and equipment used, as well as how the X-ray micro-CT can reveal particle size distributions, are provided. Overall, the paper aims to contribute to the ongoing efforts to improve the characterization of mine tailings, providing a foundation for further research.

Experimental program

Material description

Three tailings were used for this research. The properties and index parameters of the materials are given in Table 1. PSD testing using hydrometer analysis and mechanical sieving (ASTM (2017) D7928-21 and ASTM (2021) D6913/D6913M-17), was performed on the tailings for comparisons with those from X-ray micro-CT.

Table 1: Soil properties and index parameters of tested tailings

Parameter/Material	Tailings 1	Tailings 2	Tailings 3
Specific gravity, G_s	2.81	3.50	2.74
Plasticity index, PI	CI (Silty Clay)	–	–
Sand	–	52%	96%
Fines (Silt and Clay)	100%	48%	4%

Specimen preparation

Loose tailings in dry form were deposited into 5-mm plastic tubes. A small funnel was employed to carefully pour the dry tailings into the tube. The arrival at a very specific arrangement of particles in these specimens was not considered a significant concern herein, as the current scope and purpose was mainly to determine particle sizes and shapes. After placing the tailings, the tubes were sealed using small rubber plugs at the ends to keep the tailings intact during transit to the X-ray micro-CT scanning facility and also during the imaging process.

Image acquisition, processing, and analysis

The X-ray micro-CT scanner available at the Pulp and Paper Research Center at the Vancouver campus of UBC was used to obtain 3-dimensional high-resolution non-destructive images of the specimens. The scanner available at this facility is a ZEISS Xradia 520 Versa manufactured by Zeiss International, Oberkochen, Germany, as shown in Figure 1. This scanner restricts the movement of the source and detector allowing for greater control and more precise scanning at higher resolutions (Ketcham and Carlson, 2001; Helliwell et al., 2013).

Figure 1: ZEISS Xradia 520 Versa by Zeiss International

The X-ray μ-CT scans essentially produce 2D images of the specimen (as a sequence of thin 2D slices of the 3D specimen) that record the variation of X-ray attenuation within objects, which is a parameter that relates closely to the density of material penetrated by the X-ray (see Figure 2). The 2D images are later stacked and reconstructed into a 3D image. The steadiness of the specimen during the scan is key to

achieving high-resolution images. A specimen holder was specifically designed and fabricated to provide a well-secured specimen during the scan (Valverde, 2023). Several parameters need to be controlled to achieve scans providing images with a satisfactory resolution. For example, the field of view (FoV) – which is one of the key parameters to obtain a minimum achievable voxel size. A FoV of ~1000 µm was used for these scans and resulted in 1 µm resolution.

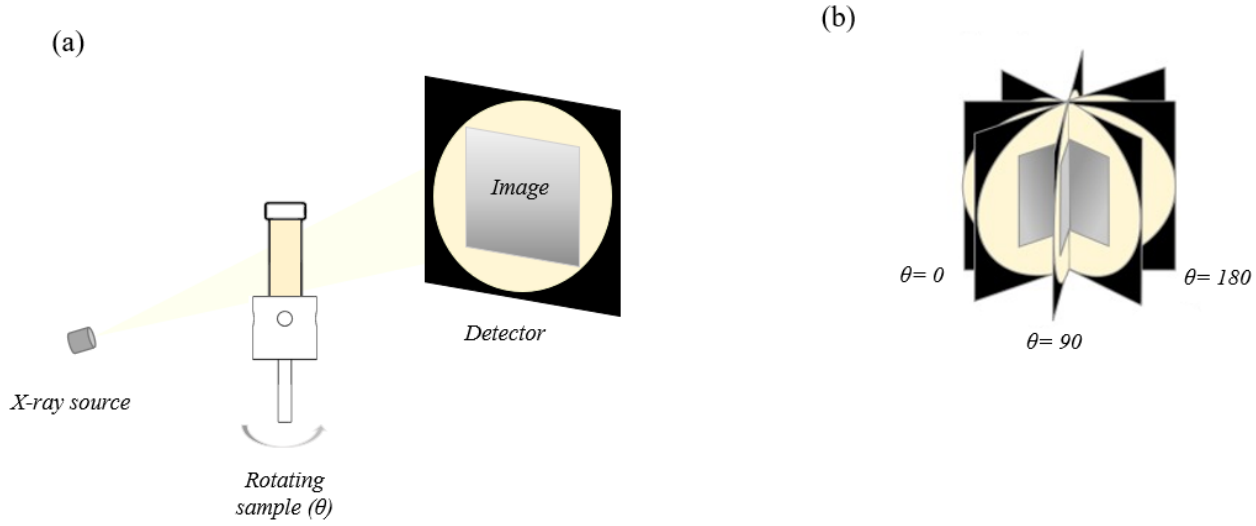

Figure 2: Image acquisition process in X-ray micro-CT scanning (a) image acquisition (b) 2D projections of a sample

The reconstruction and analysis of the digital images yielded was performed using the commercially available Avizo 9.7 software (Thermo Fisher Scientific, 2019). This software has been used by various researchers to successfully study particulate geomaterials (Fonseca, 2011; Markussen et al., 2019). Image processing and analysis were completed by already established workflows at UBC (Valverde, 2023), and they broadly consisted of two phases. First, the images were filtered and segmented to partition the individual grains; herein, the "watershed" algorithm was used to segment the particles. Second, quantitative measurements were obtained from the resulting image. The label analysis tool was used to retrieve the data required for establishing grain size distributions. The feasibility of this technique was calibrated using glass beads (Wesolowski, 2020) and silica powder (Valverde, 2023).

Initial findings

Visual assessment

The raw and processed images for a specific slice of each tailings particle size range (i.e., fine, medium, coarse) are presented in Figure 3 (top to bottom row, respectively) to illustrate typical images generated from micro-CT technology.

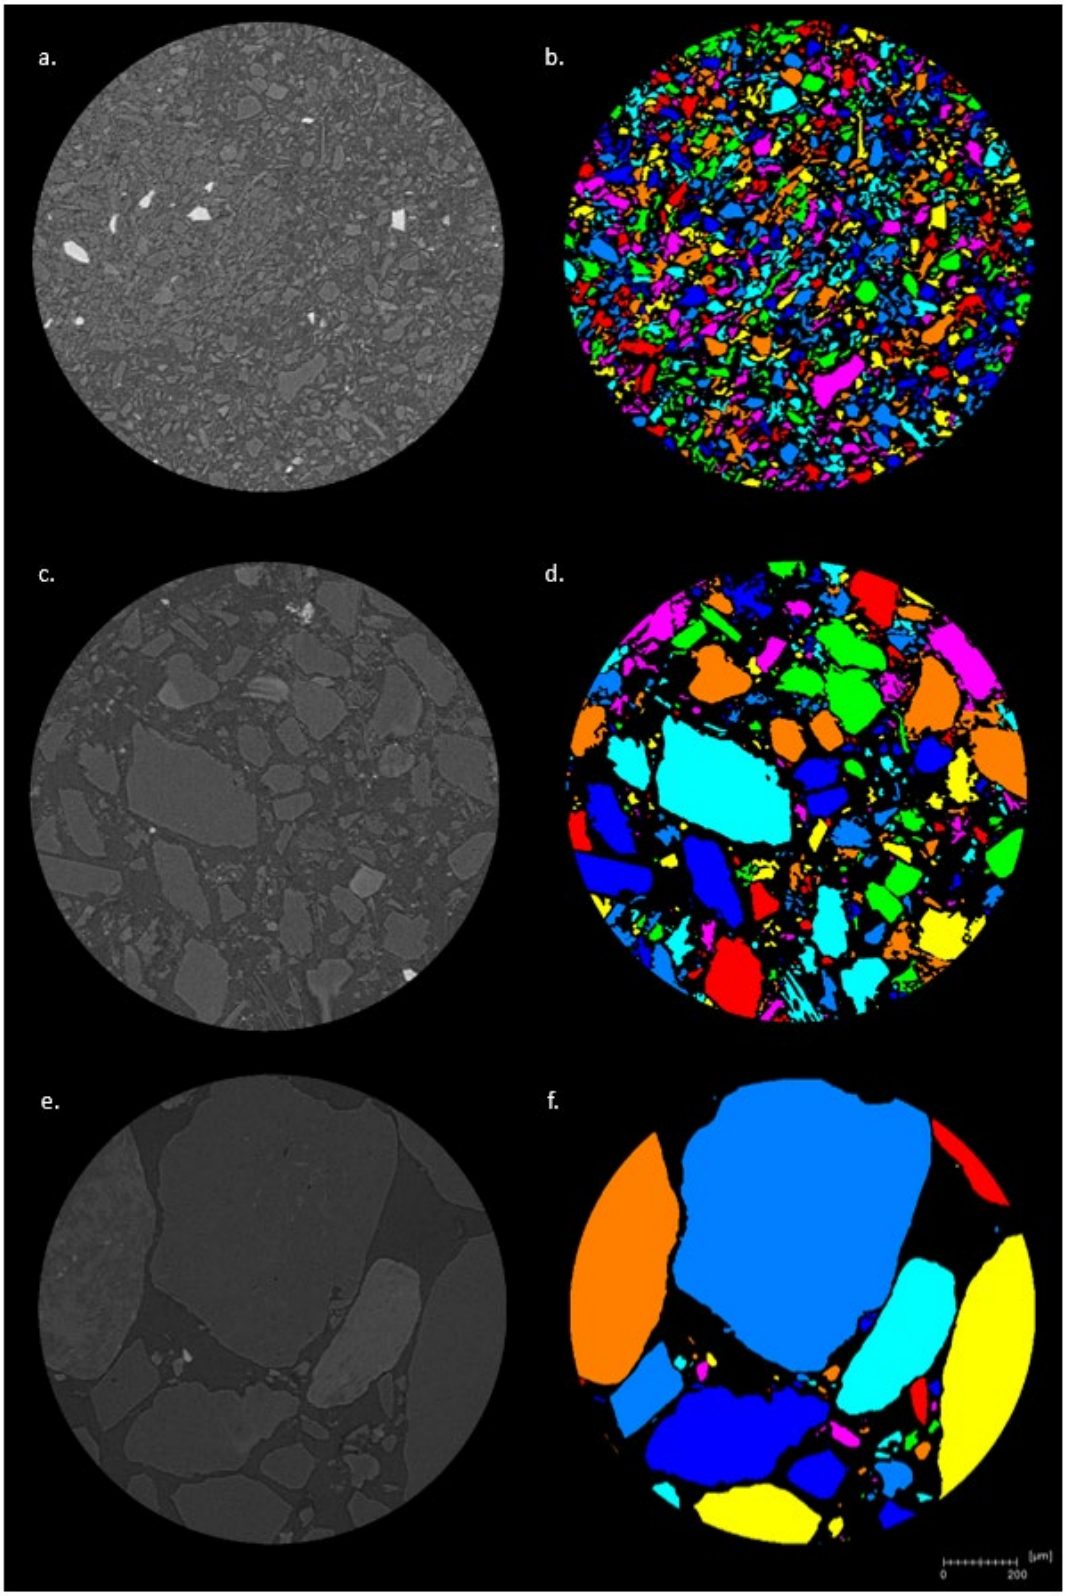

Figure 3: Raw and processed images for the samples used for this study.
Note: top level – fine tailings; second level – medium tailings; third level – coarse tailings

Approximately a thousand 2D images were stacked to reconstruct a given 3D image – as shown by the example in Figure 4 for the coarser tailings.

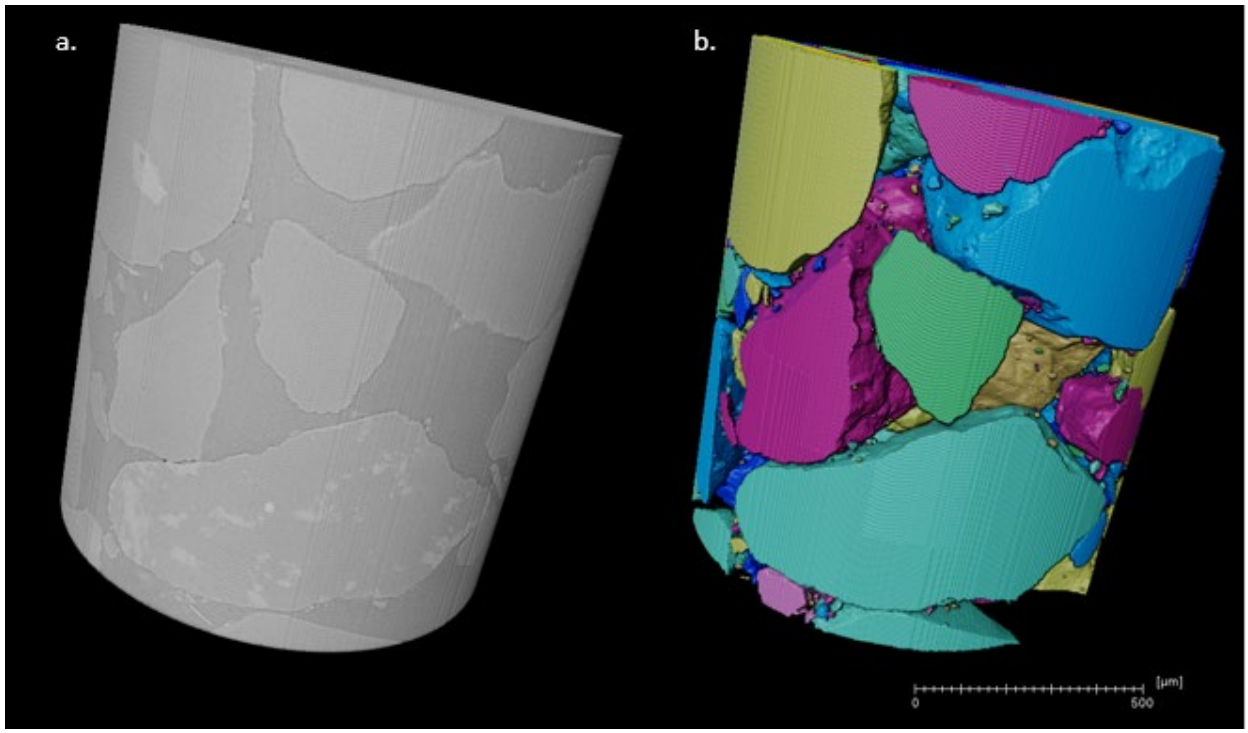

Figure 4: 3D view of a coarse tailings sample (Tailings 3)

In the raw images, it is possible to distinguish a wide variety of soil particles in different tones of grey color. This greyscale intensity reflects the density detected by the imaging device at a given location, and these values, form the key input data for the segmentation process (i.e., pure white = void and solid black = very dense material). The particles that have been segmented for each of the raw images in the left column of Figure 3, using Avizo software, are presented in the respective, counterpart right column. The purpose of segmentation is to individually identify/separate a given particle from the adjoining others.

After the segmentation process, the software allows retrieving the information related to a given individual particle (i.e., length, area, volume, orientation, etc.). If subsequent quantitative analyses were to be undertaken, this data would serve as the main input for all such work. The success of the segmentation process depends on several variable factors including the scanning process and the image processing. From visual inspection, it can be seen that the raw image of the coarser particle matrix (Figure 3.e) is more readily segmented (Figure 3.f.) compared to that for finer particles (see Figures 3.a and 3.b).

It is also of relevance to highlight some of the challenges in interpreting image data, as indicated below. Firstly, it is important to recognize that the imaging resolution controls the smallest particle size that could be meaningfully segmented. For example, some of the black gaps that can be seen between the

colored particles may be a direct result of the resolution. Secondly, it was found that the computer image processing approach tends to treat the smaller particles immediately adjacent to a bigger particle as part of the latter bigger particle. This effect, in turn, could cause the digital particle to have larger dimensions compared to the real particle. Thirdly, it was noted that some bigger particles could be segmented by the software as two smaller particles (i.e., "digital particle breakage"). From visual inspection of the outputs, this does not seem to become a persistent factor with respect to the images of medium and coarse tailings in comparison to those for fine tailings.

Particle size distribution

Knowledge of the particle size distribution (PSD) for a given soil (a plot of percentage weight passing a given particle size versus that grain size) is one of the key metrics used in classifying and characterizing soils (ASTM (2017) D7928-21 and ASTM (2021) D6913/D6913M-17). The information on individual particle information -including length, width, breath, thickness, volume, etc. – from Avizo image processing provided a direct basis to determine digital particle size distributions from a given 3D micro-CT scan. In this effort, for a given particle, the particle size for the x-axis of the PSD plot was assumed to be the smallest dimension derived from the image segmentation process. Since the y-axis of the PSD plot is based on the weight passing a given particle size, it was considered reasonable to assume a constant specific gravity and thereby use the volume of a given particle as the proxy for weight. On this basis, the volume "retained" on digital particle sizes corresponding to each sieve size, as per ASTM (2017) D7928-21, was calculated; afterward, the cumulative volume for each sieve size was divided by the total volume retained over all sieves leading to the percent passing by mass equivalent volume.

The PSD curves obtained for the different tailings from laboratory testing are overlain in Figure 5 for comparison with those obtained from the present analysis of digital data. It can be noted that, while there is a relatively good agreement for the coarser and medium tailings, the results from laboratory tests indicated a coarser fraction larger than that from the analysis of digital imaging data in both cases. On the other hand, for the finer tailings, the laboratory tests indicate a finer fraction than that from the analysis of the digital images.

This difference can be attributed to several factors, as per below. As per the visual observations discussed in the previous section, the resolution is a limiting factor for segmenting the smallest particles. In the present work, the scan resolution was 1 μm, therefore the particles smaller than 0.003 mm would not be considered in the digital grain size analysis. Furthermore, it was seen during visual inspection that the smaller particles immediately adjacent of the bigger particles were treated as part of the bigger particle during segmentation, and this would contribute to the digital curves being of a coarser grain size compared to the laboratory PSD.

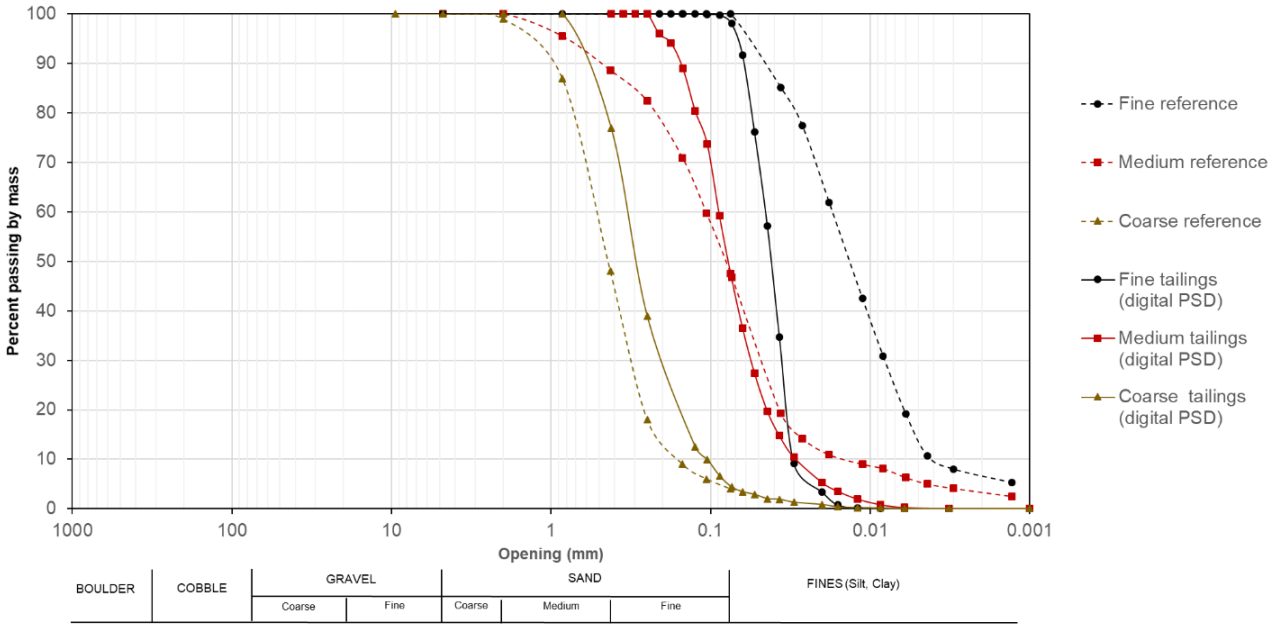

Figure 5: Comparison of digital and laboratory-obtained PSD for tailings

Another factor that affects digital segmentation is that some bigger particles could be segmented by the software as two smaller particles (i.e., "digital particle breakage" which results in a finer gradation compared to the laboratory PSD). It is also important to recognize that grain size distributions for fine-grained materials, obtained from mechanical/hydrometer sedimentation analysis methods could also have limitations, especially if the tailings contain platy fine soil particles. Overall, it is considered that the comparisons between the laboratory and digital PSD would benefit from improvements in the image processing steps.

It is of value to assess the PSDs in relation to their D_{10}, D_{50}, and D_{90} values. Note: D_n value is defined as the grain diameter that corresponds with the point where n% of the particles are finer by weight on a given PSD. For medium tailings the digital PSD has a D_{10} of 0.03 mm, while the reference PSD has a slightly smaller D_{10} of 0.017 mm. This indicates that the digital PSD predicts a slightly coarser material at the 10% finer mark compared to the reference PSD. Moreover, both the digital and reference PSDs have very similar D_{50} values (0.078 mm and 0.08 mm, respectively), suggesting that the median particle size is well approximated by the digital PSD. There is a significant difference in D_{90} values, with the digital PSD at 0.15 mm and the reference PSD at 0.5 mm. The C_u (Coefficient of uniformity = D_{60} / D_{10}) values are 3 for the digital PSD and 5.5 for the reference PSD. A higher C_u value in the reference PSD suggests a wider range of particle sizes, indicating that the digital PSD did not effectively capture the full variability of the particle sizes.

With respect to the coarse tailings, the digital PSD has a D_{10} of 0.105 mm, while the reference PSD has a D_{10} of 0.16 mm. This shows that the digital PSD estimates finer particles at the 10% finer mark compared to the reference PSD. The D_{50} values are 0.3 mm for the digital PSD and 0.45 mm for the reference PSD, indicating that the digital PSD predicts a finer median particle size. The D90 values are 0.58 mm for the digital PSD and 0.95 mm for the reference PSD, again showing that the digital PSD predicts finer particles at the 90% finer mark. The C_u values are close, with 3.3 for the digital PSD and 3.5 for the reference PSD, suggesting that the digital PSD provides a reasonable approximation of the range of particle sizes for this case with coarse tailings.

Conclusion

This paper presents some initial observations from an investigation undertaken to demonstrate the ability of micro-CT imaging to study the particle fabric of mine tailings. Three types of mine tailings were examined using images obtained from high-resolution 3D non-destructive micro-CT scanning. In spite of the limited scope of the study, the initial results from this imaging work illustrated the potential of X-ray micro-CT for the visualization of fabric and microstructure of tailings. Moreover, the importance of the analysis technique selected to process the images, the difficulties and constraints in arriving at reliable outcomes, and the need for further studies and improvements on this subject were highlighted.

In particular, the difficulties in imaging tailings containing both silt and sand size particles was revealed. The need for future work to refine and improve the image analysis process to better account for the true 3D volume of individual particles, and in turn, improvements in particle segmentation, was highlighted. It is recognized that the exploration of scalar and directional parameters (i.e., including particle orientation) will be the end goal in arriving at a complete description of fabric in tailings materials.

Acknowledgments

The authors would like to acknowledge the financial support of the Natural Science and Engineering Research Council of Canada (NSERC). Enthusiastic collaborative support provided by Dr Mark Martinez and James Drummond at the Pulp and Paper Centre at UBC Vancouver is appreciated. Thanks are due to Dr Mavi Sanin of WSP for facilitating the provision of the tailing materials for imaging work.

Influence of Density on Predicting Saturation in Filtered Tailings using an Electromagnetic Sensor

Garret M. Martin, NewFields Mining Design and Technical Services, USA
Christopher A. Bareither, Colorado State University, USA
Joseph Scalia IV, Colorado State University, USA

Abstract

Filtered tailings stacks can experience changes in degree of saturation over time due to compression from subsequent tailings placement, climate interactions, and seepage. Understanding spatial and temporal changes in saturation within a filtered tailings stack is important when evaluating geotechnical and geochemical stability. The main objectives of this study were to characterize the effects of density on sensor output and create a density correction procedure that improves saturation and volumetric water content predictions. Laboratory-scale compression tests were conducted on filtered, hardrock mine tailings with an electromagnetic sensor embedded in the tailings specimens to measure volumetric water content and degree of saturation. Results indicate the predicted volumetric water content was generally within 8% of the measured value, and saturation was generally within 5% of the measured value during testing when the effects of density were not considered. However, correcting for density can improve the volumetric water content and saturation predictions to within 1% to 3% of measured values. A density correction method is outlined in this paper and is accompanied by discussions on field-scale implementation for measuring the volumetric water content and degree of saturation in filtered tailings stacks.

Introduction

Filtered tailings offer the benefits of water conservation as well as enhanced geotechnical stability via stacking tailings in an unsaturated state. However, filtered tailings stacks are not immune to risks associated with other tailings management strategies (e.g., slurry tailings). The degree of saturation in filtered tailings can increase due to compression induced by the growing height of the tailings stack. Additionally, during the lifetime of the facility the degree of saturation in filtered tailings can change due to desiccation and/or infiltration. Filtered tailings stacks must be properly designed, constructed, and managed throughout the facility lifecycle to minimize risk to people and the environment (Morrison, 2022).

The degree of saturation of filtered tailings plays an important role in the geotechnical and geochemical stability of filtered tailings facilities. Rodriguez et al. (2021) reported that maintaining saturation below 80% is the most influential factor to enhance geotechnical stability in tailings facilities. Opposingly, Aachib et al. (2004) report that the oxygen diffusion into unsaturated porous media (e.g., tailings) decreases exponentially at saturation above 85%, which implies that mitigation of acid generation in sulfide-containing tailings requires a high degree of saturation. However, geochemical stability also may be enhanced via low saturations and low unsaturated hydraulic conductivities, and thus low fluxes of percolating water. Regardless of the tailings management strategy, there is a need to reliably determine in-situ tailings saturation to assess stability.

Electromagnetic sensors have been implemented and researched within the agricultural community for many years (e.g., Topp et al., 1980; Noborio, 2001). These sensors are relatively inexpensive and can be designed to be durable, corrosion resistant, and compatible with different data loggers. Woyshner (1992) predicted the volumetric water content of a sulfide ore tailings facility with an average error of +1.1%, standard deviation of 2.2%, and a maximum error of 5.5%. However, Landim et al. (2023) identified substantial error (≈ 20%) when predicting volumetric water content in iron mine tailings using the manufacturer calibration, and indicated that sensor output was affected by tailings dry density. The test results and discussion included herein provide further insight into the effects of tailings dry density on sensor output.

Mine tailings within a tailings facility can experience spatial and temporal variation in dry density. Although the attributes of electromagnetic sensors support monitoring spatial and temporal variations in degree of saturation throughout a filtered tailings stack, the impacts of dry density on sensor performance must be considered during sensor implementation. The objectives of this study were to characterize the effects of density on sensor output and to create density correction procedures that improve volumetric water content and saturation predictions.

Materials and methods

Experimental program overview

The experimental scope of the project involved sensor calibration, measurement of sensor response to compression and infiltration, and characterization of density affects. All testing was conducted on a single hardrock mine tailings. Calibration testing was first completed to relate raw electromagnetic sensor output to measured values of volumetric water content and degree of saturation. The calibration equations were used in a simulated filtered tailings stack scenario to assess the timeliness and accuracy of sensor response to changes in volumetric water content and degree of saturation due to specimen compression and water infiltration. Moist-tamped specimens were used to characterize changes in sensor output as tailings dry

density varied, and the test results were used to develop an approach to correct sensor output for density affects.

Mine tailings

Hardrock mine tailings from a precious metal mine were used in this study. Particle size analysis yielded 14% fine sand and 86% fine-grained particles (i.e., silt and clay that pass the No. 200 sieve), by mass. The tailings had low plasticity with a liquid limit of 30 and a plasticity index of 9. The specific gravity of the tailings was 2.72. Standard Proctor compaction testing (ASTM D698) yielded a maximum dry density of 1.69 Mg/m^3 and optimum gravimetric water content of 15.8%. Particle size, plasticity, and compaction test results were extracted from Aghazamani (2022), and the specific gravity was determined as part of this study.

Teros 10 soil moisture sensor

The Teros 10 is an electromagnetic soil moisture sensor (METER Group, Inc., Pullman, WA, USA) that is sensitive to the dielectric permittivity of the surrounding medium. The raw sensor output in millivolts (mV) can be calibrated to volumetric water content and degree of saturation. Additional information regarding dielectric permittivity and soil moisture sensor principals of operation are discussed in previous studies (Topp et al., 1980; Peddinti et al., 2020).

An ESP32 Adafruit Feather micro-controller was used to operate Teros 10 sensors and record output values. The ESP32 was programmed using Arduino IDE software. The micro-controller was programmed to report the average of a specified number of measurements as a single output value to smooth noise in the raw sensor output.

Tailings specimens prepared to a target water content and dry density yielded a single, averaged millivolt sensor output, which was coupled with physical measurements of volumetric water content, degree of saturation, and dry density. All sensor output as a function of time was recoded for compression and infiltration tests. Additional details on sensor operation and data processing are in Martin (2023).

Test molds

Customized test molds were fabricated to accommodate the sensor volume of influence. Two test molds were used in this study: small-mold = 100-mm diameter; and large-mold = 300-mm diameter. Both molds were fabricated from PVC pipe and enclosed at one end with PVC end caps.

Specimen preparation and testing methodology

Specimen preparation methods were similar across the various tests performed. Tailings were oven-dried for ≥ 24 hours, manually broken up, and passed through a No. 40 sieve (0.425 mm). Subsequently, tailings were hydrated to target water contents.

The small mold was used to conduct calibration and characterization of density affects testing, and the large mold was used to conduct specimen compression and infiltration proof-of-concept tests. For moist-tamped specimens, moisture conditioned tailings were compacted in uniform lifts to achieve a desired volumetric water content and dry density. Several slurry-deposited specimens were prepared in the small mold during sensor calibration by pouring slurry into the mold to a target total volume. Mass-volume measurements were taken from the constructed specimens before and after testing to determine the actual volumetric water content, degree of saturation, and dry density of the specimen to the nearest 0.1% or 0.01 g/cm^3. Further discussion and details regarding specimen preparation are in Martin (2023).

Following specimen preparation in the small mold, sensor output was recorded for a desired period, and the data was processed as described in Martin (2023). After specimen preparation in the large mold, the specimen was prepared for compression testing. Vertical load was applied to the surface of the test specimen incrementally via an air-cylinder. Applied load and vertical deformation were recorded during testing. Output from an embedded Teros 10 sensor was continuously recorded. After completing Compression Test 2, water was added incrementally to the top of the specimen while under the final applied load to observe the sensor response as the wetting front infiltrated through the specimen. Specimen deformation was recorded throughout the water infiltration period to correct volumetric water content and saturation calculations for comparison with predictions made via the Teros 10 sensor. Further discussion and details on the laboratory testing procedures are in Martin (2023).

Sensor calibration and accuracy

Calibration testing of the Teros 10 was conducted by relating raw sensor output to physical measurements. Three Teros 10 sensors, each inserted into a unique tailings specimen, were used to account for potential variations between sensors. Relationships between volumetric water content and degree of saturation versus sensor output are shown in Figure 1. Calibration equations for volumetric water content and degree of saturation were fit to each data set and are included in Figure 1. A third-order polynomial was used for the volumetric water content calibration curve, which is consistent with the calibration curve developed by METER Group (i.e., the Teros 10 manufacturer) and other studies on electromagnetic sensors (Topp et al., 1980; Bhuyan et al., 2020; Narayanan and Sathian, 2021). The degree of saturation calibration is a linear relationship.

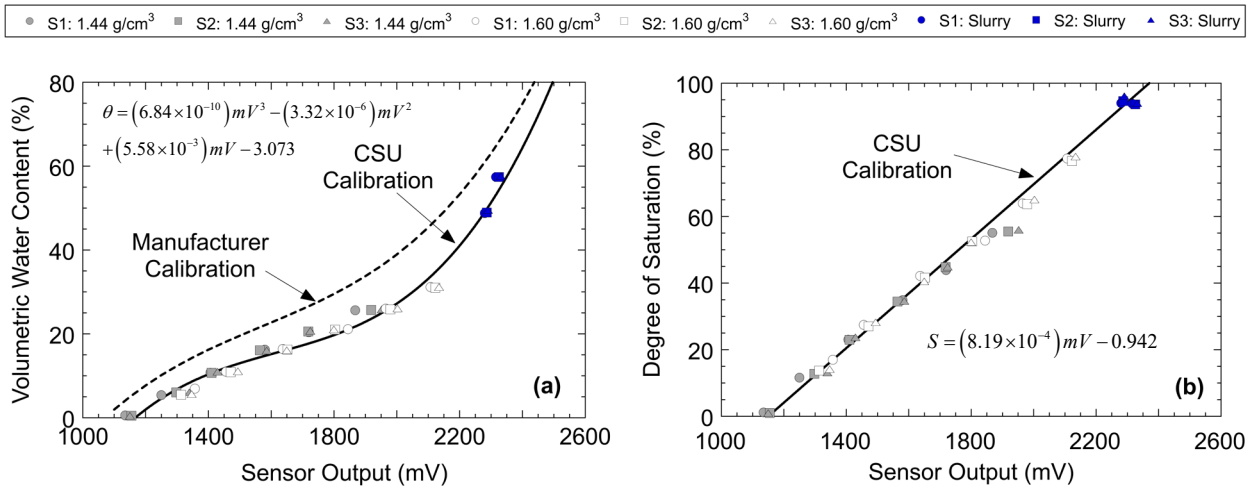

Figure 1: Results from calibration testing of (a) volumetric water content and (b) degree of saturation versus sensor output in millivolts (mV)

Compression and infiltration testing

Two compression experiments were conducted on moist-tamped specimens prepared in the large mold to a target dry density of 1.36 g/cm^3 (approximately 80% Standard Proctor maximum dry density) and target volumetric water content of 15%. A total of 10 uniform load increments were applied to the specimens and the final vertical stress was 668 kPa. Each applied load was maintained for approximately 5 to 7 minutes to allow for immediate deformation to reach apparent completion before the subsequent load was applied. The volumetric water content and degree of saturation predicted by the Teros 10 sensor via the calibration equations presented in Figure 1 (i.e., Predicted) were compared to actual values (i.e., Measured) determined from direct measurement of specimen volume based on continuously recorded deformation.

At the conclusion of Compression Test 2, water was poured on the specimen surface in four daily 600-mL increments; the specimen remained under the final applied stress during infiltration. Sensor output was recorded throughout the wetting process and the test concluded when the signal showed negligible change for 24 hours, which occurred about 4 days after the final water application. Due to uncertainty in the amount of water that infiltrated into the specimen, the accuracy of the sensor response to specimen infiltration was only evaluated by comparing sensor predictions to the measurements at the beginning and conclusion of the infiltration test.

Results and discussion

Characterization of density affects

Mine tailings within a tailings facility can experience spatial and temporal variation in dry density. Landim et al. (2023) noted an increase in raw sensor output for specimens prepared at higher dry densities, and

Narayanan and Sathian (2021) concluded that sensor accuracy when predicting volumetric water content is affected by dry density of the surrounding medium. A general understanding of the dielectric permittivity of porous media and sensor function can help explain the sensor behavior.

Porous media, such as filtered tailings, can generally be separated into air, water, and solid phases, whereby each has a unique dielectric permittivity. The Teros 10 sensor output is representative of the weighted average dielectric permittivity of the three phases occupying the total volume of influence of the sensor. Therefore, the sensor output is unique to a specific combination of air, water, and solid particles present within the sensor volume of influence. If the volumetric proportions of the three phases change, the weighted average dielectric permittivity will also change and yield a different sensor output. Thus, two specimens of tailings can have the same volumetric water content or degree of saturation, but variations in dry density between the two specimens would yield different sensor outputs.

The effect of varying dry density on sensor output was evaluated using moist-tamped specimens prepared in the small mold to a range of volumetric water contents and degrees of saturation for several dry densities. Relationships between sensor output and specimen dry density for target volumetric water contents of 15%, 20%, and 25% and degrees of saturation of 30%, 45%, and 60% are shown in Figure 2. For a given volumetric water content or degree of saturation, a linear response in sensor output was observed with variations in dry density. The slope between sensor output and dry density (shown as *"m"*) was generally consistent for the three volumetric water contents evaluated. However, as the degree of saturation increased, the slope of the linear relationship between sensor output and dry density, *m*, became increasingly negative.

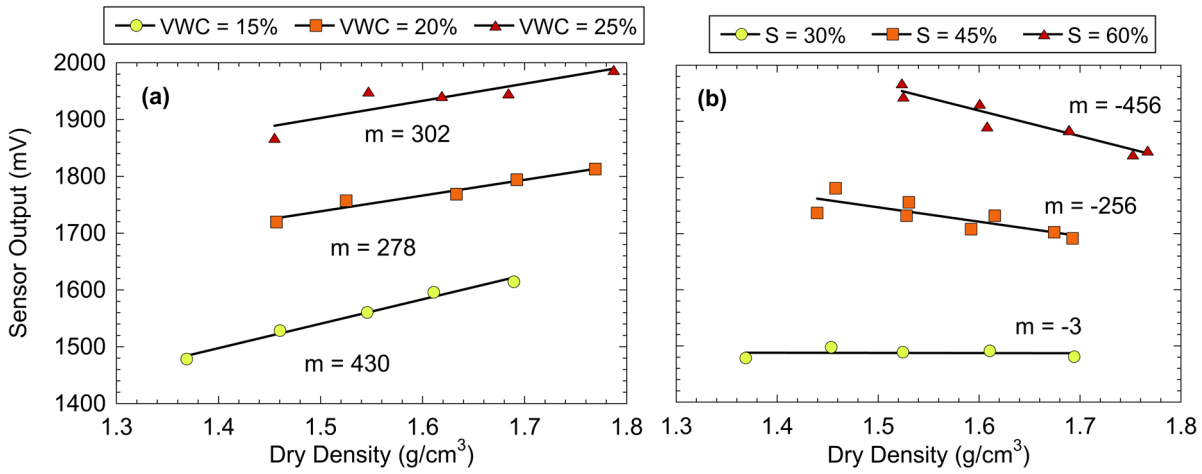

Figure 2: Relationships between sensor output and specimen dry density for (a) constant values of volumetric water content (VWC) and (b) constant values of degree of saturation (S). The parameter m is the slope of the linear regression

The results in Figure 2a suggest that *m* is generally constant and independent of volumetric water content. Therefore, the sensor-predicted volumetric water content should exhibit relatively consistent

sensitivity to dry density regardless of actual volumetric water content. The results in Figure 2b suggest that m is dependent on the degree of saturation. Specimens prepared at a degree of saturation of 30% exhibited negligible change in sensor output for the range of dry density. However, at higher degrees of saturation, variations in dry density had a more pronounced effect on sensor output, thus making sensor prediction of saturation more sensitive to changes in dry density at elevated saturation levels.

An approach for density correction

A correction for density effects was applied to the compression and infiltration test results to reduce the error in predicted volumetric water content and saturation (described subsequently). The following sections discuss the framework and process used to correct the compression and infiltration test data for density effects. Results of the correction process are presented accordingly.

Correction framework

Equation 1 serves as the core framework of the density correction process discussed herein:

$$mV_{corrected} = mV_{raw} - m(\rho_i - \rho_{ref}) \quad \text{(Equation 1)}$$

where $mV_{corrected}$ = sensor output corrected for dry density, mV_{raw} = raw (uncorrected) sensor output, m = relationship between sensor output and dry density, ρ_i = measured specimen dry density during testing, and ρ_{ref} = reference density deemed representative of sensor calibration. The corrected sensor output ($mV_{corrected}$) was then used to predict the volumetric water content and saturation based on the calibration equations developed during this study (Figure 1). If the specimen dry density at a given point in time during sensor operation is known, the specimen density relative to the reference density can be determined. The relationship between the change in specimen dry density and resulting change in sensor output, *m*, can be used in conjunction with the density of the specimen to approximate an increase or decrease in sensor millivolt output due to variations in dry density.

Selecting an "*m*" value

Results in Figure 2a suggest *m* is consistent regardless of volumetric water content, provided the specimen remains unsaturated. Therefore, the average value of *m* for the three volumetric water contents shown in Figure 2a was used when correcting sensor output for volumetric water content predictions (m_{vwc} = 336.5). In contrast, *m* varies depending on degree of saturation. A linear relationship was created between the slope *m* and degree of saturation data from Figure 2b to yield m = -1523.3(*S*) + 466.23. Thus, the slope *m* decreases linearly as the degree of saturation increases.

Determining an appropriate *m* value for density correction of sensor-predicted saturation required an iterative process. The iterative process developed to determine m_{sat} is shown in Figure 3. The iterative process was repeated until no appreciable change in predicted saturation was observed.

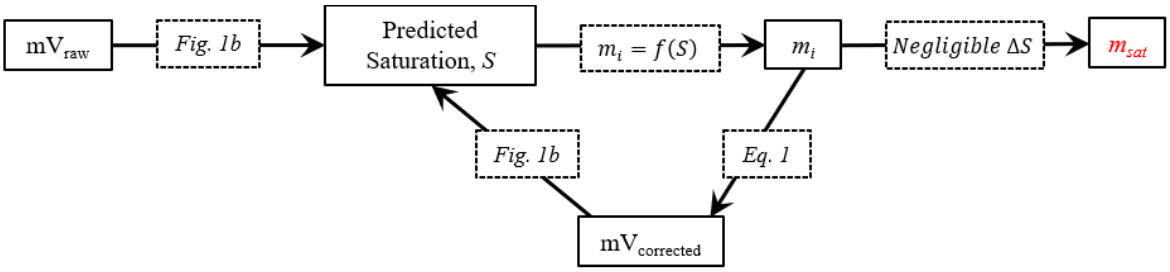

Figure 3: Depiction of iterative correction process saturation calibration

Data processing indicated the number of iterations required to reach a consistent saturation value was dependent on the magnitude of the $(\rho_i - \rho_{ref})$ term. Values of 0.36 g/cm^3 required at least 5 iterations while values of 0.59 g/cm^3 required as many as 14 iterations to reach a consistent saturation value. Care should be taken during the density correction process for predicted saturation to ensure sufficient iterations are performed to reach a stable m_{sat} value.

Selecting a reference density (ρ_{ref})

Determining an appropriate reference density (ρ_{ref}) representative of the sensor calibration is critical to the density correction process. Three different approaches for determining ρ_{ref} were considered for density correction. The first, and simplest, approach assumed the average dry density of moist-tamped specimens prepared during sensor calibration was generally representative of the calibration equations. Therefore, the average dry density of moist-tamped calibration specimens was considered for density correction ($\rho_{ref} = 1.55\ g/cm\text{^}3$). However, the results of the correction process indicate mixed success when assuming an average value for ρ_{ref}, and alternative approaches were considered.

The second and third approach for determining ρ_{ref} both sought to optimize the ρ_{ref} value based on available data sets obtained from directly measured specimens. A laboratory optimized reference density was determined based on moist-tamped specimen data from the Characterization of Density Affects testing. The density correction framework was applied to the laboratory data, and the value of ρ_{ref} was then adjusted using MS Excel's solver application to minimize the calculated mean squared error (MSE) between the corrected sensor prediction and the known volumetric water content or saturation. The same optimization approach was also performed using two discrete data points extracted from the compression and infiltration testing data sets. This approach essentially simulates the act of obtaining undisturbed samples at two discrete points in time during the field operation of a sensor network. Data points near the onset and midpoint of the compression tests were used for optimization. For the infiltration test, only the two measured data points at the start and end of the test were available for optimization. Table 1 summarizes the ρ_{ref} values determined from the three approaches tested.

Table 1: Reference density (ρ_{ref}) values determined for volumetric water content (VWC) and saturation (S) density correction procedures based three different approaches

Test Scenario	Calculated Reference Density, ρ_{ref} (g/cm^3)		
	Average Moist-Tamped Specimen Density	Laboratory Optimization	Field Optimization
Compression Test 1 (VWC)	1.55	1.71	1.62
Compression Test 1 (S)		1.66	1.70
Compression Test 2 (VWC)		1.71	1.49
Compression Test 2 (S)		1.66	1.98
Infiltration Test (VWC)		1.71	1.39
Infiltration Test (S)		1.66	1.80

Density correction results

The uncorrected temporal trends of the predicted volumetric water content and degree of saturation during compression and infiltration testing are shown in Figure 4 through Figure 8, along with the density-corrected predictions that incorporate the three approaches for determining ρ_{ref} discussed in the preceding section. Also included with the compression test results (Figures 4 to 7) are residual plots presenting the difference between the sensor-predicted and measured values throughout each test. In general, the sensors responded in a timely way to changes in volumetric water content and degree of saturation induced by compression and infiltration of the surrounding tailings. In the absence of a density correction, the volumetric water content and degree of saturation predicted by the sensor during compression generally remained within about 1.5% and 5% of the measured value, respectively. Results from infiltration testing indicate that, in the absence of a density correction, saturation predicted by the sensor remained within about 5%, whereas volumetric water content was over-predicted by about 8% at the completion of infiltration.

Table 2 summarizes the average error and maximum error for each test based on the density correction approach applied. The use of an average dry density value for ρ_{ref} generally yielded mixed success at improving sensor accuracy. Optimizing ρ_{ref} based on available laboratory data generally showed improved sensor accuracy across most scenarios, but still displayed some inconsistency. The use of a field optimized ρ_{ref} generally yielded improved sensor accuracy across all scenarios except for predicted volumetric water content during Compression Test 2. However, the field optimized ρ_{ref} consistently resulted in sensor predictions of volumetric water content within about 1% of the measured value, and predicted saturation remained within about 3% of the measured value.

Table 2: Summary of average error and maximum error of uncorrected and corrected compression and infiltration test results

Test Scenario	Correction Approach							
	Uncorrected		Average		Lab. Optimized		Field Optimized	
	Avg. Error	Max. Error	Avg. Error	Max. Error	Avg. Error	Max. Error	Avg. Error	Max. Error
Compression Test 1 (VWC)	-1.0%	-1.4%	-0.8%	-1.0%	0.3%	1.1%	-0.4%	0.5%
Compression Test 2 (VWC)	-0.3%	-0.5%	-0.2%	1.1%	1.0%	2.2%	-0.7%	-1.0%
Compression Test 1 (S)	1.6%	2.2%	1.7%	3.4%	0.4%	1.4%	-0.1%	1.3%
Compression Test 2 (S)	4.3%	6.5%	4.4%	5.5%	2.7%	4.5%	-0.6%	3.3%
Infiltration Test (VWC)	4.3%	8.4%	1.8%	3.8%	4.3%	7.4%	-0.4%	-1.4%
Infiltration Test (S)	3.9%	4.9%	12.7%	19.2%	6.6%	9.4%	0.4%	1.2%

Practical implications of density correction approach

When deploying a network of electromagnetic sensors within a tailings facility, the sensor output and the accuracy of the sensor will be affected by variations in dry density. The potential error in predicted volumetric water content and degree of saturation due to variations in tailings dry density will depend, in part, on the range of dry density the sensor will be subjected to in a field application. The simulated filtered tailings scenario tested during this study indicates that the sensor was reasonably accurate when predicting saturation despite the variations in dry density imposed. Should greater accuracy be desired, a method to correct sensor output for the effects of dry density is described herein. The proposed correction process infers the following practical implications.

- The relationship between dry density and sensor output for a given tailings (i.e. m value) is related to the composition of the tailings and pore fluid being tested because the composition impacts the dielectric permittivity of the material. As such, a material-specific characterization of density affects will need to be performed to use the correction process. This would include a series of laboratory tests of remolded specimens similar to those used in this study. See Martin (2023) for additional details on laboratory testing.
- The success of the density correction process is directly impacted by the ability to successfully estimate the dry density of the tailings at any given point in time during sensor operation. Laboratory testing, modeling, and/or field monitoring to provide insight into volumetric strains within a filtered tailings stack over time could be used to aid in predicting in-situ dry density within the facility.
- The correction process provides a framework that can be used to "tune" the sensor calibration by adjusting the ρ_{ref} value based on available datasets of directly measured values.

Performing a field optimization of the ρ_{ref}, as described above, would require direct measurements of in-situ volumetric water content or saturation near an operating sensor (i.e., undisturbed samples). The results from this study suggest confidence in the sensor-predicted value can generally be improved with as few as two discrete field data points. A greater number of data points would allow for further improvement in confidence and/or accuracy. The benefit of improved accuracy/confidence should be weighed against the cost of performing the correction process as well as the odds of achieving success in a field environment.

Conclusion

The results of this study suggest that an electromagnetic soil moisture sensor can be used to predict variations in volumetric water content and degree of saturation within a filtered tailings stack with anticipated compression and surface water infiltration. Sensor output is affected by variation in dry density, and the effects of compression on sensor performance should be considered when evaluating the accuracy of sensor-predicted volumetric water content and saturation. Understanding of the effects of variations in dry density on sensor performance can be utilized to correct sensor output for density affects and to reduce potential error.

During specimen compression and infiltration, error in predicted volumetric water content varied from less than 1.5% to 8%, and error in predicted saturation was predominantly less than 5% when no correction for density affects was applied. A possible framework for correcting the effects of dry density on sensor output was presented in this study and could be considered if greater accuracy or confidence in sensor-predicted volumetric water content or saturation is desired. Several variants of the density correction approach were evaluated and produced varying degrees of success in improving sensor accuracy. The method of using in-situ field measurements of volumetric water content and saturation to "tune" the sensor calibration via an optimized reference density (ρ_{ref}) consistently yielded an error of less than 1% and 3% in predicted volumetric water content and saturation, respectively. The effects of dry density on sensor performance and possible approach for correcting density affects should be further explored and studied.

Abstract

Nowadays tailings thickening is monitored on the basis of underflow density. But with greater demands placed on minerals processing, the thickening is expected to be better controlled by continuous monitoring of underflow rheology. Responding to an industry request, an online pipe viscometer was developed for monitoring the underflow of tailings thickening for the industry's largest mines. The paper reports on recent testing of the autonomous apparatus. It consists of a multiple pipe viscometer unit housed in a transportable shipping container. By vertically orienting, the design safeguards against settling solids in the measuring section. In our application of a pressure differential membrane system, a temperature drift problem was encountered, adding to earlier experienced persistent problems with the downward pipes. Without such problems the unit also measures tailings density, but now an additional independent density meter is necessary. In the processing of data only the upward pipe is now utilized, and the strategy to convert from raw data to rheological Bingham parameter values was upgraded. Similar issues are emerging in wastewater transport and treatment. The paper concludes on the technological readiness level of the instrument.

Introduction

Royal IHC and Deltares co-created an Autonomous Rheometer (ARM) which continuously measures the rheology and density of tailings (Boomsma et al., 2022). The ARM was primarily developed for the mining industry but can be used in other sectors too. The mining industry, while delivering great value to our society and civilization, inadvertently produces waste, e.g., tailings. These tailings contain a significant amount of water and demand a huge amount of storage volume. Today, there are about 217 billion m^3 of tailings

accumulated in the world; this amount is enough to fill up a pipeline with a 30 m diameter connecting the Earth to the Moon. Roughly speaking, half of this volume is water. The irony is that about 50% of mines are located in arid and semi-arid areas, suffering severely from water scarcity (Meshkati et al., 2021).

The main question is: how can we ensure that less watery tailings end up in storage facilities? Without converting the processing chain to deliver thicker paste, mine industries use thickener units to achieve this goal, by adding and mixing flocculants and coagulants and allowing time for tailings to consolidate. Nonetheless, very watery tailings end up in storage facilities. The performance of a thickener unit can be optimized by rheological feedback (Chryss et al., 2019; Wang et al., 2020) from downstream of the thickener, e.g., improving the quality of its underflow tailings, as shown in Figure 1. The ARM was developed to serve that purpose, providing continuous measurement of rheology and density to the thickening operation.

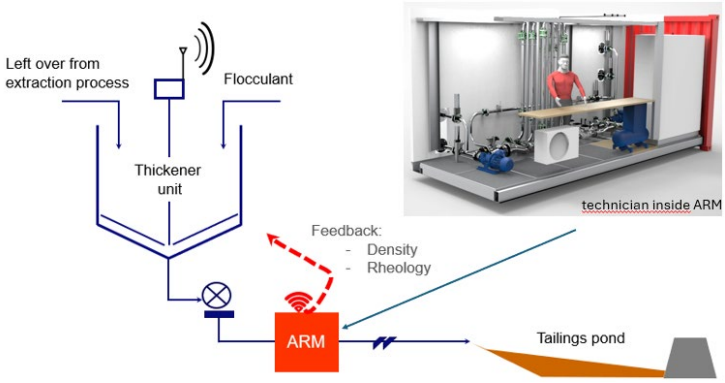

Figure 1: ARM in the underflow of the thickener providing feedback on rheology and density

The ARM is installed in an airconditioned container with a 6 m length, about 2.5 m wide and about 2.5 m high (e.g., a 20' high cubical standard shipping container). It is designed to output, 24/7, Bingham yield stress and dynamic viscosity plus density. It has 3 parallel simultaneously operating measuring units: three inverted U-loops (see Figure 2) for redundancy and for eventual compensation for wall slip of the tailings. The automatic measuring cycle is governed by a control valve in each pipe steering the discharge. It also contains a water flushing circuit for cleaning and verification of the instruments' performance. It is designed for large discharges (diverging a slip stream through the ARM), high solids content slurries and tailings with sand. The ARM may potentially help save up to 10 to 20% of water in thickeners.

In the initial phase (TRL1-3) it was decided to rely on known physical principles and combining experiences in manufacturing and hydraulic transport at IHC and experiences in non-Newtonian rheology and its hydraulic transport fundamentals at Deltares. Testing went through a couple of phases: prototype single U-loop testing and pump type testing (in the year 2019, TRL 4). Integral testing of the manufactured containerized ARM (in the year 2020), where it appeared sometimes difficult to obtain reliable results from

the largest descending pipe, specific testing for wall-slip and density measurement (in the year 2022), component testing (in the year 2023), and integral testing with an additional independent density meter, in the year 2024.

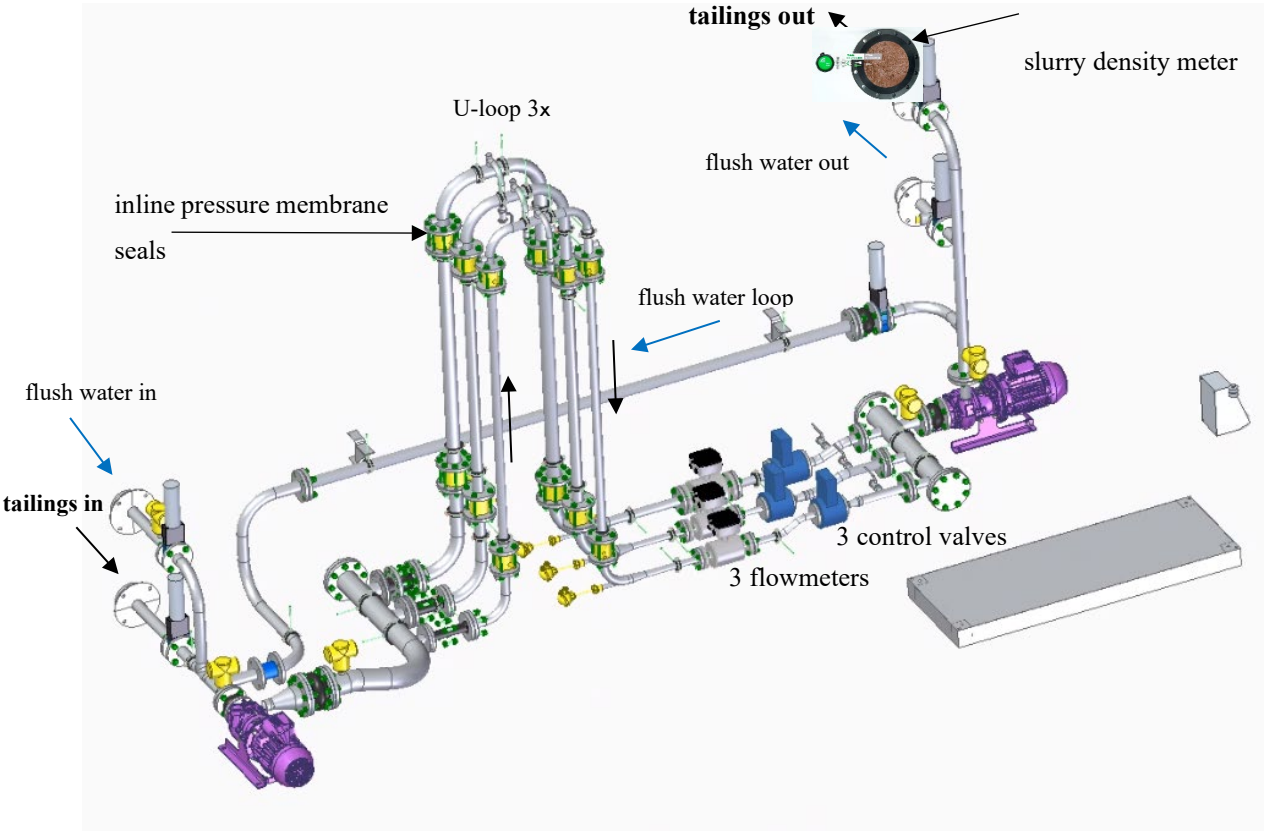

Figure 2: Internal view of an ARM and an external densitometer situated at an outlet

The TKI Water Technology research component (a Public-Private Partnership), which commenced in the year 2022, studies densitometering and wall slip. Wall slip may occur with mixtures at a high solids concentration. The 3 U-loops in the ARM are a provision to detect wall slip and are designed to provide information to correct for wall slip. As a spin-off of its vertical design, the ARM in principle also outputs density, enabling a verification of performance, and if differences occur between pipes, it is necessary to have an independent density measurement to assist in determining the hydraulic resistance from the U-loop measurements for rheological characterization.

The first measuring campaign in the TKI measured density and investigated wall slip using U-loop pipes only. Using clay-based model tailings without coarse material, the ARM produced data autonomously. While it was doing so, it associated rotoviscometry on these model tailings, but with added coarse plastic 1 mm spheres; this was done to investigate whether such a mixture could be used in a next phase to test wall slipping with the ARM. The results appear positive. More importantly, it was concluded

that the ARM gave unworkable results, and it was decided to commence investigating the performance of several components individually (which was done in 2023). It turned out that there was a temperature sensitivity problem, despite the air-conditioning of the ARM housing. The temperature of the circulated water varied, the testing fluid, which had consequences that we will discuss in this paper. The need for independent density metering hence appeared even stronger. The 2024 measuring campaign planned to include Rhosonics slurry density metering (SDM). Note that these temperature differences are less likely to occur when tailings are handled, since these come from a large thickener, which does not heat up very quickly, as compared to our model tailings, which circulate.

Pressure measuring system

The ARM is purposely equipped with pressure sensor membrane technology (Siemens SITRANS inline seals in a sandwich design), contrary to the usual pressure taps. This is done to prevent clogging of such pressure taps and associated impulse tubes leading to the differential pressure sensor. A sketch of the differential pressure measurement system utilizing membrane seals is shown in Figure 3. The membranes are not aligned entirely flush with the pipe's inside, but rather are recessed a little, to provide shelter from the abrasive influences of the tailings. In the vertical pipes, the distance between the membrane pairs is 1.3 to 1.7 m.

$$\left.\frac{\Delta p}{\Delta z}\right|_{up} = -(\rho - \rho_{oil})\,g - \frac{4\tau_w}{D}$$

$$\left.\frac{\Delta p}{\Delta z}\right|_{down} = -(\rho - \rho_{oil})\,g + \frac{4\tau_w}{D}$$

$$\left.\frac{\Delta p}{\Delta z}\right|_{up} + \left.\frac{\Delta p}{\Delta z}\right|_{down} = -2(\rho - \rho_{oil})\,g$$

$$\left.\frac{\Delta p}{\Delta z}\right|_{up} - \left.\frac{\Delta p}{\Delta z}\right|_{down} = -\frac{8\tau_w}{D}$$

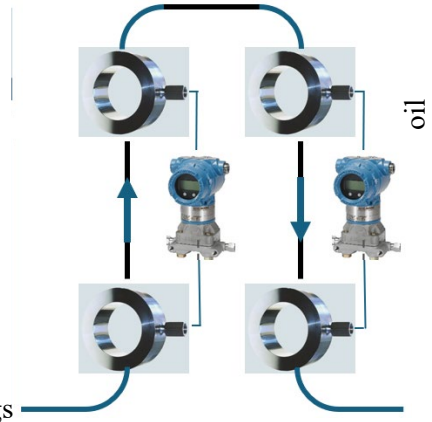

Figure 3: Membrane-based, differential pressure measuring system utilized in ARM's U-tubes

Additional density meter

The Rhosonics additional slurry density meter (SDM) functions on the basis of acoustic impedance (measuring the power of reflected acoustic waves). It measures outputted mixture densities accurately up to +/– 0.5% of the reading (Rhosonics SDM ECO, 2024), e.g. + –7 kg/m^3 for our conditions. In the trial, it is positioned at the outlet of the ARM, Figure 2, such that it can be flushed with water, for reference/validation purposes.

Method

The objective is to characterize the tailings rheology by the Bingham rheological model:

$$\tau = \tau_y + \eta_B \dot{\gamma} \quad (1)$$

where τ is the shear stress [Pa], τ_y is the yield stress [Pa], η_B is the plastic viscosity [Pa s] and $\dot{\gamma}$ is the shear rate [1/s].

To determine rheology, the ARM produces, during its measuring cycle, simultaneous data pairs of flow rate and pressure differences measured in the 3 U-loops, from which the rheological properties τ_y and η_B are determined. The pressure differences are processed, such that wall shear stress due to the flow's friction is calculated (see fourth equation in Figure 3). Basically, the static pressure due to tailings density ρ, principally measured in the U-loop configuration (Clift and Manning-Clift, 1981), is subtracted from the measured DP's (see first two equations in Figure 3), but also an external density meter can be used for ρ. There are two methods applied to determine the rheological properties: 1) The bulk shear rate (=8U/D) is transformed into wall shear rate (Rabinowich-Mooney transformation), and next the rheological parameters of the Bingham model are determined. 2) Fitting of the entire non-linear analytical solution to integral data sets of flow rate, pipe diameter and wall shear stress,(Magnon and Cayeux, 2021).

Previous implementation of determining rheological parameters by ARM

Initially the Rabinowich-Mooney transformation to determine wall-shear rate was utilized (Van Wijk et al. 2023), on the basis of which the Bingham parameters were determined next. The transformation proceeds via a piecewise power-law approach of the raw data (bulk shear rate and wall shear stress). The detection and correction principle for wall slip, based on the availability of 3 pipes, is described in Van Wijk et al. (2023), where the data is evaluated at the same wall shear stress. The transformation results in a limiting resolution, because of the rather flat rheometric flow curves.

Current non-linear implementation (upgrade)

The current implementation is an integral method. The Levenberg-Marquardt (LM) method is used to fit the Buckingham-Reiner equation (Buckingham, 1921), quantifying Bingham laminar flow in a pipe to the data, to find the Bingham yield stress (τ_y) and plastic viscosity (η_B). The Levenberg-Marquardt (LM) method is a non-linear method for fitting data to equations (Magnon and Cayeux, 2021), implemented via the python SciPy toolbox leastsq. The Buckingham-Reiner equation reads:

$$Q = \frac{\pi}{\eta_B} \frac{\left(\tau_w - \tau_y\right)^2}{\left(\frac{\tau_w}{R}\right)^3} \left[\frac{\left(\tau_w - \tau_y\right)^2}{4} + \frac{2\,\tau_y\left(\tau_w - \tau_y\right)}{3} + \frac{\tau_y^2}{2}\right] \quad (2)$$

where Q is flow rate [m^3/s], R is pipe radius [m] and τ_w is wall shear stress [Pa].

Fitting is done for each pipe separately and the average of the thus determined Bingham yield stress and plastic viscosity of the three pipes is given on output.

Measurement

The mixtures were created at IHC's Kinderdijk shipyard by mixing dry kaolinite-based clay powder (FTS1) and tap water. At the beginning of the current test program, the test set-up was filled with existing FTS1 slurry from a 200 liter storage vessel. FTS1 suspensions are thixotropic. For such fluids, only a Bingham characterization of the remolded conditions is meaningful, which is exactly what occurs in the intake and by shearing in the ARM.

Temperature influence

Measurements of the three pipes do not always converge well, like the result shown in Van Wijk et al. (2023). Hence, it was decided to verify the behavior of components, revealing a relevant temperature drift problem of the pressure sensors (see Figure 4). Note that the depicted pressure difference of DP=1,600 [Pa] corresponds to a measurement error of 16 [Pa] wall shear stress in the DN40 pipe. Experience with another U-loop system in a sand-water test set-up, where corrections/calibration were conducted with clear standstill water, led to the conclusion that the same must be done, but with the actual slurry in the pipes.

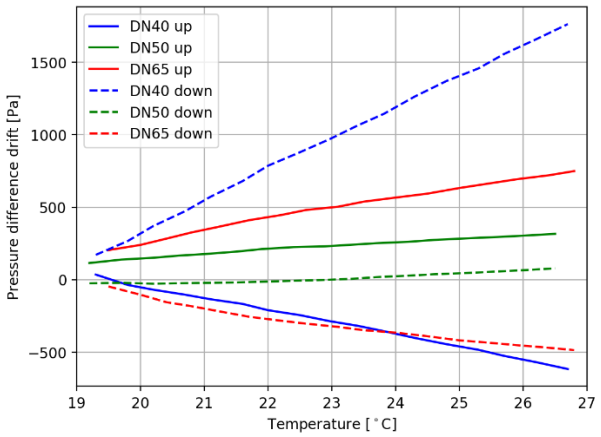

Figure 4: Temperature drift of differential pressure sensors in U-tubes, 8-6-2023, pumping water for 4 hours. The graph shows reference conditions with (almost) zero flow in ARM's normal cycle

Non-linear fitting of the Bingham model to the ARM data

In the days ahead of the next trial, one year later, the SDM was calibrated on water and three FTS1 slurry densities covering the measurement range in the coming trial and, because it revealed a velocity dependency, it was calibrated for the specific velocity range of the ARM's outlet. On the morning of the trial, the pressure sensors were nulled. Temperature variation during the trial is shown in Figure 5, e.g., the

same range as in Figure 4. The slurry's temperature is higher than the ambient air, indicating energy dissipation within the flowing slurry, raising its temperature.

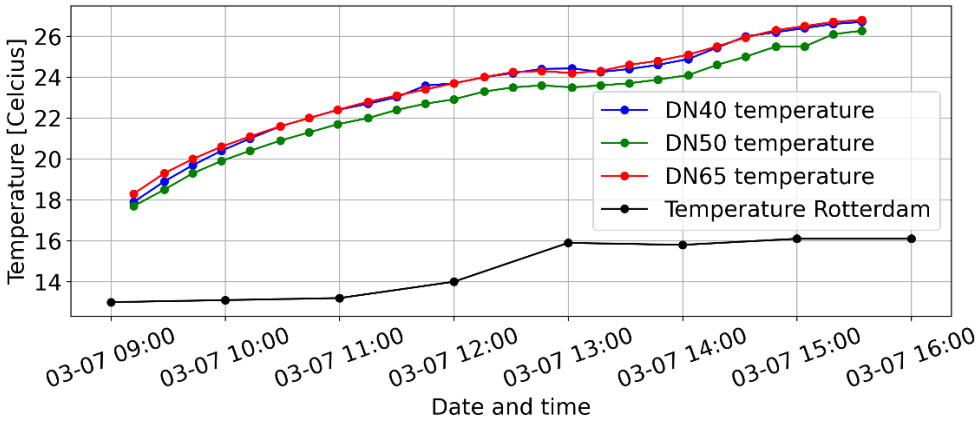

Figure 5: Temperature during the trial

The density outputted by the ARM according to the Uloop principle is shown in Figure 6. We see a lot of strong variation, although the same slurry was pumped around all the time. On the contrary, the SDM outputted a fairly constant density during the day: 1,310 to 1,320 kg/m^3. Sample densities were 1,296, 1,295 and 1,296 kg/m^3. Hence, we base rheological output of the ARM on density by SDM.

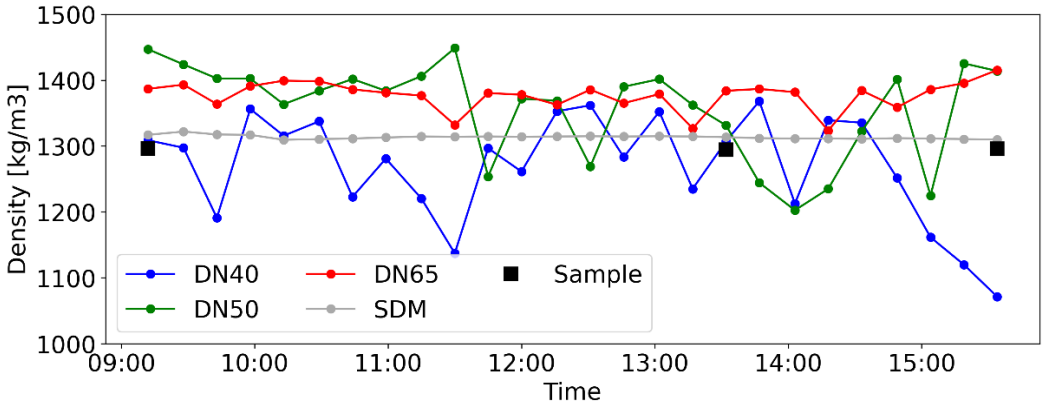

Figure 6: Density according to U-loop principle, SDM and laboratory sample during the trial

Figure 7 shows the synchronously produced data points from the three U-loops. Each data point represents 30 seconds of constant testing conditions recorded at 10 Hz (of which the first 15 seconds are discarded to ensure a steady situation). The displayed data points are 15 second averages. The day-average density of the SDM, used for computing the shear stress, is given in the legend as well as the Bingham parameters according to the LM fit. We see how the steady data of each pipe is fitted by the Bingham based Buckingham-Reiner equation, nicely following the data points. Given the available flow rates, the largest pipe diameter experiences a smaller range of shear stress variation. Naturally, the small diameter pipe

captures the higher shear stresses, while the greater diameter pipes may accentuate lower shear stresses conditions.

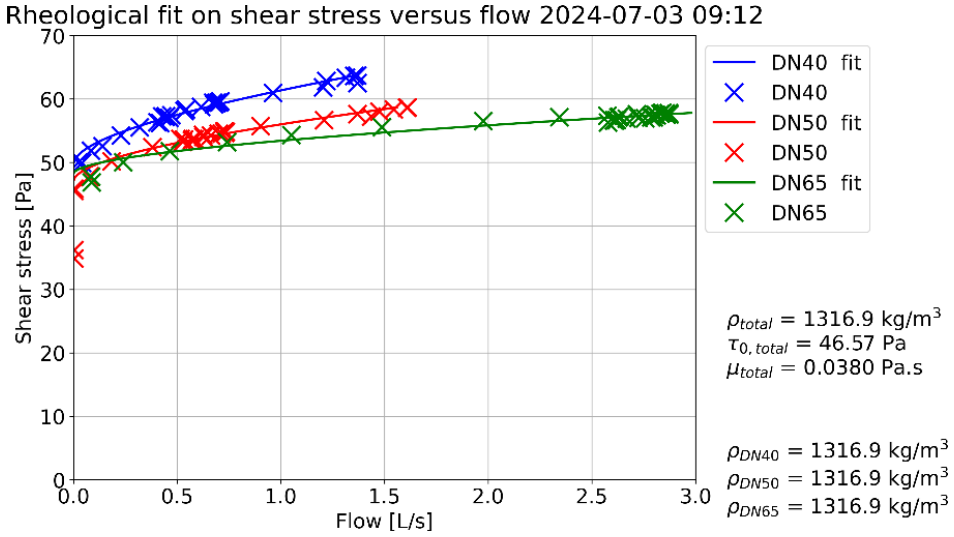

Figure 7: Results of Levenberg-Marquardt fitting of measurements

Figure 8 shows the same data organized as a rheogram, and we see the flow curve according to the ARM data, including the LM fit and the results of rotoviscometric testing (Haake Mars 1 DIN CC 25 coaxial element, remolded conditions) of sampled slurry at the same moment. An interesting paralleling of ARM and rotoviscometric flow curves is observed, with a difference of circa 10 to 15 Pa. This is of the same order as the shear stress at cessation of rotoviscometric measurement (notice the orange data point located on the y-axis at ~16 Pa). Similar readings were experienced in a Fann type rotoviscometer. It is hence likely that in the nulling procedure, the fluid was "hanging" partly in the vertical pipe, leading to this difference.

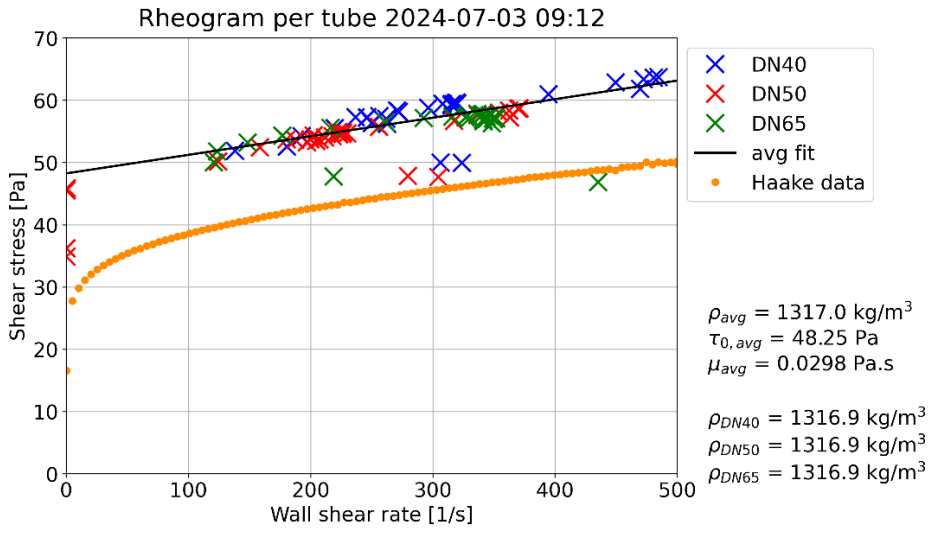

Figure 8: Just after nulling the DP-cells: ARM data processed into flow curve and rotoviscometric measurement; the legend shows ARM's Bingham model parameters and SDM density

Figure 9 shows the rheology six hours later, revealing divergence of data. The yield stress measured by the ARM increases 4.5 Pa and the plastic viscosity increases are similar. The rotoviscometric Haake flow curves increase by 3 Pa (tested at the same temperature as the slurry in the ARM).

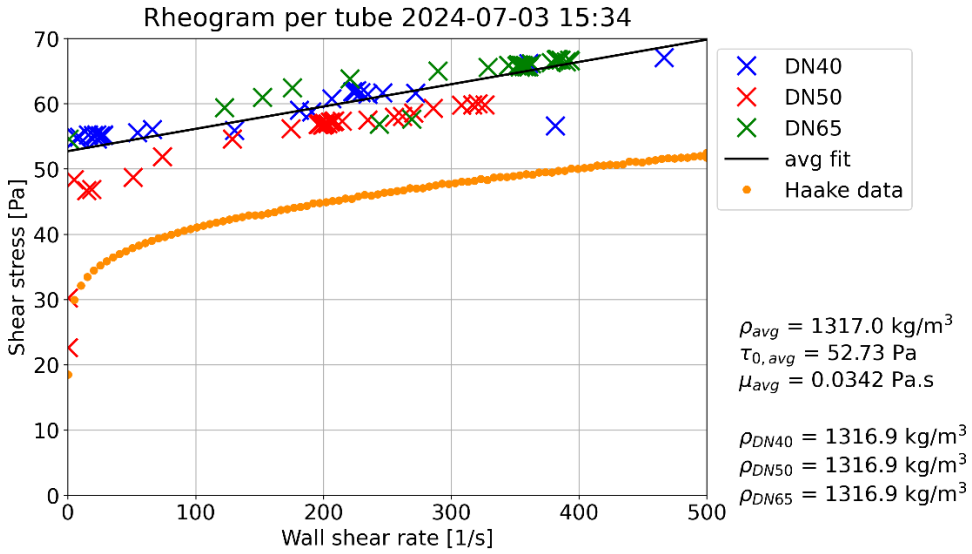

Figure 9: ARM data processed into flow curve and rotoviscometric flow curve

Evaluation

Temperature variation appeared to be a problem under the testing conditions. Under prototype conditions at the underflow of a mine's thickener, temperature variation is expected to be much less because the enormous volume of fluid does not heat up or cool down significantly during the day-night cycle. But since the influence of temperature on pressure measurements was so big, it was deemed better to be able to correct for it. In the prototype a divergence of flow curves or densities between pipes such as in Figure 9 or Figure 6 can be monitored, and when necessary, a flushing procedure can be activated for nulling the DPs, using water that does not exhibit a yield stress.

The cohesive clay slurry must have been partly hanging on the pipe wall during calibration. It is therefore better to calibrate with water from the flushing circuit. It does not need to be clean, since yield stresses decay exponentially with clay concentration decreasing and the actual density can be measured by an SDM.

Wall slip of mixtures is a concern and, if it occurs, it will affect readings. In the course of our research, not described here, we have come up with a formulation of a model tailings that, as expected, will give wall slip for > 30 Pa strength. ARM's identification software and correction software may be tested with this, if the fluid temperature is kept constant.

Rhosonics SDM measures at a distance of micrometers from the wall (Maas and Boerma, 2024). The slurry should therefore be homogeneous. A remaining question is: is this SDM suitable for measuring tailings that have wall slip? In case a thin fluid layer is present at the wall, the SDM might only measure the density of this layer. Rhosonics is aware of this potential risk and has developed a special spool with pockets, to remove the wall effect in front of the sensor (Maas and Boerma, 2024).

The Technological Readiness Levels that the ARM went through are shown in Figure 10: TRL 1 = literature/experience, TRL2 = the proposal, TRL3 = literature and creation of digital twin, TRL 4 = our first testing in the laboratory, TRL5 = tested at industrial yard, TRL 6 = Manufactured ARM is tested in industrial setting, TRL = 7 and 8 and 9 are to be gone through at the mine.

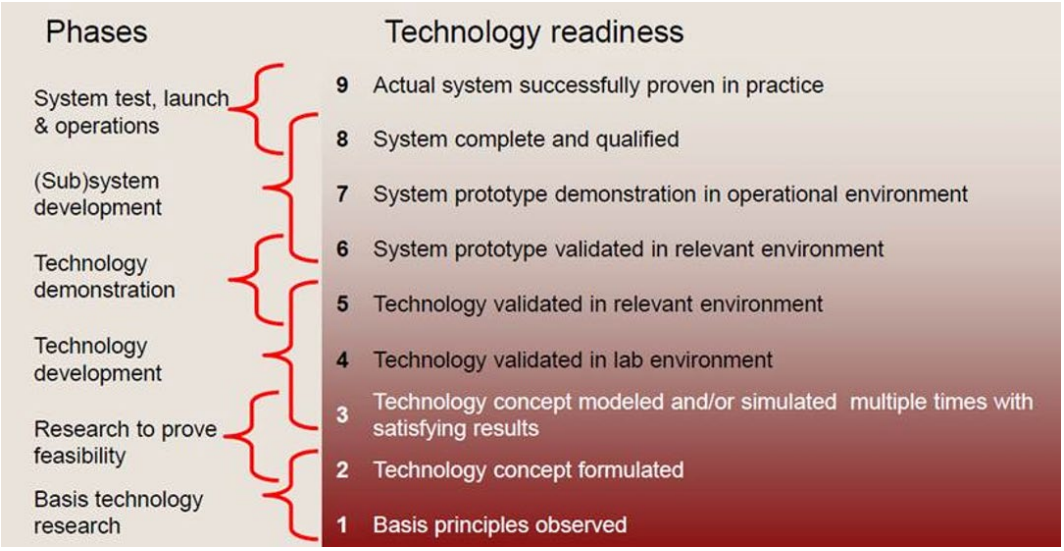

Figure 10: TRL definitions used in the development of the ARM

Waste water industries' transport and treatment may benefit from the current development and it may lead to a reduction of water usage and to innovations in waste water transport. The maximal strengths of Concentrated Domestic Slurries (Thota Radhakrishnan, 2019) can be of the same order as the tailings. In the development of the ARM a digital twin is developed, on the basis of which similar dedicated ARM units for waste water industry can be designed.

Conclusion

As a consequence of temperature drift in the membrane-based DP-measuring system, it is necessary to have an independent and accurate density meter.

The nulling procedure for the off-set of DP-cells needs to be reviewed, the fluid's adhesion probably interfered, and an alternative is necessary and is proposed.

It is recommended to:

- investigate the suitability of a nulling procedure of the DP-sensors based on intermittent flushing, to minimize discrepancies between ARM output and rotoviscometric measurements on drawn samples;
- repeat the described ARM test with model tailings containing coarse settling material to test wall-slip detection and correct for it; and
- transfer the ARM to the mine.

Acknowledgements

The authors would like to thank the concerned mining innovation program for granting Royal IHC and Deltares the principal project. Performance evaluation of the ARM is conducted by Royal IHC, Deltares, Rhosonics Analytical and Sweco Nederland within a Public-Private Partnership: TKI Water Technology, project 2022DEL002. We wish to thank the earlier researchers: J. van Wijk, M. In ‘t Veld, and J. van der Hoeven. We are grateful for the financial and organizational engineering of the TKI by E. Meshkati and C. McLeod, and our partners in initiation of the TKI: F. Vermeulen and V. Braz, and experimenters S. Huisman and M. Busink. Finally, we would like to thank J. Ohalloran for the work on de SDM and E. de Hoog for the final data analysis.
