Plenary Abstracts xxv

Chapter 1: Plenary Session Paper: What Could Tailings Facility Engineering Look Like in 2030? 1

What Could Tailings Facility Engineering Look Like in 2030? | Andy Small, Andrew Witte and Annika Bjelkevik 3

Chapter 2: Analysis 27

Numerical Simulation of Trigger Mechanisms of Static Liquefaction Applied to a Tailings Dam | Miguel A. Villalobos Bravo and Richard Witasse 29

TWIM Framework: A Digital Twin Approach for Strategic Dry Stacking Tailings Management | Cauê Stocchi Somensi, Douglas Deoclécio Tostes Firmo, Gustavo Marçal de Sousa, Alexandre Cristino Correa dos Santos and Lucio Schiavon Yamamoto 45

CPT Calibration Chamber Testing of Tailings Sand at High Confining Pressures | Matthew Haynes, Riccardo Fanni, David Reid and Kyle Smith 57

Interpretation of Pore Pressure Dissipation Test Results in Tailings | E. Rust and M. Rust 69

Estimation of Undrained Shear Strength Parameters from Laboratory Testing for Geotechnical Analysis: tff vs. qf | Masood Kafash, Thomas Barham, Lisa Yenne, Ranjiv Gupta and Georgia Lysay 83

A Critical Review of the Residual Pore Pressure Generation during Cyclic Loading | David Espinoza and Jenny Ramirez 95

Numerical Modeling Comparison of Large-strain Tailings Consolidation | Daniel Pham 107

Enhancing Data Management and Analysis for Mine Waste and Tailings Dam Design through Modern Data-Analytics Dashboards | Ela Talebi, Fariba Yavari and Kris Hojka 127

PLAXIS and CASM: Formulation, Implementation, and Verification │ Erick Rógenes, Ian Paes, Bruno Guimarães Delgado, Alessandra Gomes, Daniel Rocha Lanzieri, Felipe Cruz, Alomir Fávero Neto and Leandro Lima Rasmussen..... 137

A Comparison of Different Methods Used to Estimate the State Parameter to Assess the Static Liquefaction of Tailings │ Fahimeh Mahdavi Naftchali, Mathan V. Manmatharajan, Hamed Behzadipour and Michael Etezad 151

Silty Sand Tailings Saturation and its Influence on Interpreted CPTu Soil Behavior Type │ Andrew Burgin, Richard Dawson, Mauricio Pinheiro and Anelisa Vasconcelos 163

A New Implicit Kinetics Method to Estimate Shear Strength Mobilized in Liquefaction Flow Failures │ Jiarui Chen, Scott M. Olson, Soham Banerjee, Mandar M. Dewoolkar and Yves Dubief 173

Seismic Deformation Analyses of Germano Main Dam Part I: Calibration of PM4Sand Model for Sand Tailings using Field and Advanced Laboratory Test Data │ Pu Yang, Mehdi Qoreishi, Mauricio Pinheiro and Evan Hsiao 185

Seismic Deformation Analyses of Germano Main Dam Part II: Development of 2D FLAC Model and Sensitivity Studies Data │ Pu Yang, Mehdi Qoreishi, Mauricio Pinheiro and Evan Hsiao 197

Particle Size, Hydraulic Transportation, and In-line Mixing, from a Tailings In-Line Flocculation Perspective │ Raymond Guang and Trong Dang-Vu 209

Preliminary Design of the Tailings Cover System Using Numerical Modeling to Perform Sensitivity Analysis │ Bibhuti Panda, Rouzbeh Rasouli, Jason Chen and Anne-Marie Dagenais 223

The Evaluation of Nonlinear Dynamic Numerical Simulations of TSFs │ Michael James 237

Modeling of Embankment Scour Caused by a Tailings Pipeline Break and Potential Risk of Dam Breach │ Angus Rose, Mateus Nogueira and David Accadia 251

A Parameter Calibration Methodology for the Clay and Sand Model (CASM) Constitutive Model │ Alessandra Gomes, Erick Rógenes, Felipe Cruz, Paula Pais and Alomir Fávero Neto 265

Drained Laboratory Vane Shear Testing to Characterize Nonplastic Tailings │ Alvino Bezuidenhout and Luis A. Torres-Cruz 279

Modeling Assumptions and Implications during Closure Assessments on Legacy Tailings Facilities │ Benjamin Kramka, Erin Dunn, Lauren Meyer and Jason Cumbers 293

Enhancing the Safety of Tailings Dams: An Updated Approach in Fault Tree Analysis and Probabilities │ Geinfranco Villalta and Raquel Borja 305

Analysis of the Deformation and Cracking Mechanism of the Itabiruçu Dam – Case Study │ Paulo Cella, Carlos Santos, Felipe Neiva and Laura Rodríguez 323

Enhancing Pseudo 3D Seepage Modeling with Topographic Integration for Heap Leach Facilities │ I.J. Vega, A.G. Terlisky and M. Noël 339

Comparative Analysis of Vane Shear and Fall Cone Tests for Characterizing Oil Sands Tailings in the Sandy-fine Category │ Peter Kaheshi, G. Ward Wilson and Heather Kaminsky 351

Selection of the Seismic Coefficient in Pseudostatic Slope Stability Analyses of Tailings Dams | Jonathan Bray and Jorge Macedo 363

The Critical State Line Parameters of Iron Ore Tailings from Basic Laboratory Tests: Updated Insights with Additional Data | José Ccotohuanca and Daniel Klassen 379

Enhancing Tailings Dam Foundation Assessment: a SHANSEP Approach for a Brazilian Alluvium Soil | Carlos Besso, Sergio Capellão, Marcus Vinicius Lima Dias and Rodrigo Marinaro 393

Interpretation of Cyclic DSS Testing under Static Bias on Underflow Copper Tailings | Alfonso Cerna Diaz, Kevin Ritter and Jason Hilgers 409

Cyclic Response of Mine Tailings at Field and Laboratory Scales – Example Using a Novel Database | Cody Arnold and Jorge Macedo 423

Some Considerations on the Stability of Tailings Dams Subjected to Blasting Vibration | Ezra Coyle and Shayan Hashemi 433

Geotechnical Controls for Piles of Filtered Iron Ore Tailings | Danilo Eloi, Rodney Silva, Miguel Paganin, Letícia Cedro, Gricor Channakian, Felipe Bonucci, Mateus Leite and Adrielle Santos 441

2D and 3D Numerical Analyses of a Trial Embankment Construction over a Tailings Storage Facility | Alfonso Cerna Diaz, Lisa Yenne, Pooya Sheykhloo, Richard Davidson and Theo Gerritsen 453

Fabric Effects on the Onset of Static Liquefaction under Drained Conditions – Implications for Mine Tailings | Srinivas Vivek Bokkisa and Jorge Macedo 473

Numerical Modeling Evaluation of Consolidation Behavior of Saturated/Unsaturated Fluid Fine Tailings Consolidated Using the Applied Suction Method | Bereket Fisseha, G.Ward Wilson and Delwyn G. Fredlund 487

The Use of Waste Rock in Geotechnical Projects: the Challenge to Achieve the Geotechnical Parameters | Danilo Eloi, Miguel Paganin, Letícia Cedro, Rayssa Silva, Marina Ferreira, Gricor Channakian and Rodney Silva 505

Feijão Dam I 3D Numerical Simulation: A Comprehensive Approach, from Triggering to Dam Breach | Alfredo Arenas and Nicolas Pereira 517

The Use of Programming Language in GISTM Compliance for the Holden Mine | Summer Y. Sun and Phillip E. Crouse 531

Chapter 3: Application of GISTM 543

ALARP: Where are We Going and How Do We Get There? | Malcolm Barker, Chris Topham, Nick Glover and Manuel de Membrillera Ortuño 545

Conformance vs. Compliance: Contrasting the Voluntary GISTM to 9 years of Federal CCR Regulations | Lucas P. Carr, Steven F. Fecht and Nguyet Nguyen (Wit Win) 567

A Screening Approach for Preliminary ALARP Assessments of Societal Risks of Existing Tailings Dams | Chao Han and Wade Ludlow 585

Integrating Geometric Deposition and Hydrological Water Balance in Tailings Management: A Semi-Probabilistic Approach │ Paulo Victor S.A. De Castro, Miguel Palape, Roberto Cezar Rego Silva and João Marcus S.A. De Castro 601

Incorporating Lifespan Considerations into ALARP Decision-Making for TSFs: A Practical Methodology │ Ignacio A. Cueto, Osvaldo N. Ledesma and Franco Oboni 609

A Risk-Based Approach for Management of Change of Tailings Storage Facilities │ Bryan Bale, Shawn Gravel and Adam Chiorando 621

Global Climate Change due to Earth Cycles and Implications for GISTM Standards │ Kris Hojka and Fariba Yavari 633

Credible Failure Modes: Considerations for Assessment and Application │ Scott Martens and Angela Kupper 645

Practical Remedies to Improve the Defenses of Tailings Structures │ Jeremy Boswell, Anan Morshed, Thomas Kujawa and Meghan Barton 661

Update on GISTM Implementation at BHP – Lessons Learned on the Journey │ Chad LePoudre, Tenaya Brown, Justin Willis and Chris Sonntag 675

Meteorological Inputs to Tailings Storage Facility Assessments and Risk Assessments – Experience and Lessons Learned │ Bill Kappel, Doug Hultstrand and Andy Small 689

GISTM – Effective Implementation │ Lis Boczek, Richard Zayler and Gideon Steyl 711

A Case Study on ALARP for Safety Management of Tailings Storage Facilities │ Theo Gerritsen and Yi Zhu 721

Importance of Environmental Components in Assessing Risks under GISTM │ Karen Bechard, Heather Townsend and Rachel James 733

Maintaining Continuity – Lessons Learned from a TSF Incident Linked to Engineer Transitions │ George Afriyie, Jeremiah Williams, Rashida Umar and Ankomah Bosomtwi 745

Preventing Potential Consequences of a TSF Failure: Addressing the Other Side of the Risk Equation │ Susan Joyce and Keiran Doyle 753

Surveying the Landscape: Understanding Engineer of Record Challenges and Perceptions in the Brazilian Tailings Industry │ Luciano Souza, Luciana Praça, Matteus Hamade, Mauro dos Santos and Raika Silva 765

The Role of Engineer of Record – a Reflection of the Current State of Practice from an Australian Perspective │ Theo Gerritsen, Laura Fidel, Lis Boczek and Chris Hatton 779

Beyond HR: Embedding GISTM Principle 11 in Leadership for Transformative Tailings Management │ Johan du Toit and Fernando Damasio 791

Global Industry Standard on Tailings Management (GISTM) – Some Aspects of Implementation │ Marcelo Roberto Barbosa, Lucas Samuel Santos Brasil, Flavia Cruz Pereira, Denise Capanema and Marina Borges 803

Risk-based Planning of Monitoring Programs for TARPs │ Richard Sisson and Dirk van Zyl 813

Chapter 4: Breach and Inundation Estimates 827

Application of USACE LifeSim to the Feijão Dam B-1 Tailings Storage Facility Failure of January 25, 2019 | William Johnstone and Jesse Morrill-Winter 829

The Importance of Considering Dilute to Dry Tailings Rheology Formulations in Practical Tailings Dam Break Modeling | Reinaldo Garcia, Jacinto Artigas, Sergio Martinez, Pilar Garcia-Navarro, Javier Murillo, Nick Calero and Adolfo Correa 845

Dam Breach Analysis: A Methodology for Non-Newtonian Hazard Mapping and Fatality Rate Estimates | Mark Walden, Martin Rust, Nick Rocco, Sarah Melberg and Reinaldo Garcia 857

Multi-model Analyses of Tailings Impoundment Failure and Runout: Part III | Armin Saeedi, Mario Martinelli and Paul Simms 873

"Failing Forward" to Secure Oil Sands Tailings Impoundments against Catastrophic Failures: Preliminary Results | Armin Saeedi, Louai Alshafti, Xuexin Xia, Gonzalo Zambrano Narvaez, Nicholas Beier, Mario Martinelli and Paul Simms 885

Probability Distributions of Tailings Dam Breach Volumes by Failure Mode as Part of a Risk Screening-Level Tool | Stephanie Bale, Vincenzo Coia, Brad Russell and Daley Clohan 897

Volumes of Dam Material Mobilized by Erosion During Tailings Dam Failure Events | Daniel Adria, Violeta Martin and Heleman Wong 911

Estimation of Outflow Runout Distance in Tailings Dam Using an Artificial Intelligence Technique | Mohammad Rashidi, Sam Abbaszadeh and Jenisha Chhetri 929

Good Practices for the Elaboration of Hypothetical Dam Break Studies in Brazil | Caique Simões Renna Costa, Fernando Pereira Aguilar, Mônica Torres dos Santos Almeida and Vicente Mello 943

Good Practices for Hydraulic Safety for Mining Dams in Brazil | Fernando Pereira Aguilar, Manuelle Prado Cardoso Pereira and Vicente Mello 955

Chapter 5: Case Histories 965

Agnico Eagle LaRonde Filtered Tailings Project, Concept to Commissioning | Ajit Baruah and Paul de la Duarantaye 967

The Closure of the Germano Pit Tailings Storage Facility | Mauricio Pinheiro, Richard Dawson, Andrew Burgin, Mathieu Wacowich, Rogerio Torres, Jose Bernardo and Anelisa Vasconcelos 977

A Safe Approach to Assess the Trafficability of Tailings Beaches for Operation and Closure Construction Activities | Delakshan Inparajah, Gordon W. Pollock, Ahreum Lee, Anthony Faulder and Jason Chen 991

Long-term Performance of a Coarse-grained Monolayer Cover on a Pre-oxidized Mine Site | Karine Sylvain, Isabelle Demers, Thomas Pabst, Sophie Turcotte and Andréane Samson 1005

Geotechnical Failure of a Waste Rock and Heap Leach Facility at the Bellavista Gold Project | Terry Braun 1019

Tailings Disposal Management in Large Reservoirs – Case Study for Mirim Dam, Salobo Mine, Brazil │ Gustavo Belotto, Carlos Alex Alves Lima, Henrique Tropia Granja Guerzoni, João Paulo Rodrigues Costa, Felipe Campolina, Jefferson Oliveira and José Henrique Coelho Wanderley Costa 1033

Dam Safety Remediation Measures at the Aitik Tailings Management Facility, Northern Sweden │ Romain Girard and Joseph Quinn 1045

Tailings Pond Sedimentation Capacity: A Practical Approach │ Michael Louws, Karina Stapleton, Andrew Witte, Sam Nunoo and Faegheh Niyazi 1061

Key Parameters that Influence the Operation of Tailings Dry Stack Disposal, Considering Various International Practices │ Gino Vizcarra, Kathy Tehrani, Fernando Sgavioli, Thatyane Martins Gonçalves and Frank Pereira 1073

Characterization of Flocculated Fluid Fine Tailings Using On-line Microscopy │ Paul Mikula, Nan Wang, Adeola Bello-Hamilton and Randy Mikula 1083

Reducing Mine Closure Cost Risks by Employing Effective Construction Management Strategies │ Michael Nahir, Marie Rousseau and Geoff Karcher 1095

Proposal for Guidelines on Filtered Tailings Disposal: Detailing the Hypothetical Rupture Studies │ Elaine Soares, Waldemar Felitti, Fernando Aguilar, Alex Castro and Luiz Vilas Bôas 1111

The Use of an O-pile System for Foundation Seepage Control during Tailings Dam Construction: A Case Study │ Rui Couto and Siavash Farhangi 1123

Seismic Imaging Techniques in Mine Closure Planning: Case Studies Across Multiple Abandoned Mines │ Majid Mirzanejad, Zach Spence, Lincoln Steele, Will Levandowski and Dan O'Connell 1135

Tailings Risk Mitigations at Hudbay Flin Flon: Prioritization Approach and Implementation of Multiple Mitigation Measures │ Brad Russell, Trevor Ross, Matt Dugie, Matthew Schafer and Ed Carey 1149

Case Study of Optimizing Design by Performing Field Trials of a Filter Selection for a Rockfill Embankment │ Jason Hilgers, Thomas Barham, Julia Jarriel, Tiffiany Cromey, Robert Snow, Devinne Ramirez and Ranjiv Gupta 1163

Game-changing Technology for Large-scale Filtered Tailings │ Oliver Whatnall, Sam Caldwell, Stuart Wilson, Ricardo Santander and Juan Ccarita 1175

Characterizing Creep Behavior of a Fine-grained Zinc Pressure Leach Tailings │ Jade Chung, Adrian Wightman and Stephanie Alexander 1189

InSAR Study into Pre- and Post -Failure Deformations of the Jagersfontein Tailings Dam │ Divya Sekhar Vaka and Skevi Perdikou 1207

The Barriers to Widespread Adoption of Tailings Dewatering Technologies │ Ljiljana Josic, Ashley Verge and Kasra Majdanishabestari 1217

Monitoring Tailings Saturation at a TSF Using Tensiometers and Laboratory SWCC │ Mahmoud N. Hussien, Soumia El Mansouri, Vu Tran and Eric Cloutier 1231

A Framework to Determine Tailings Liquefaction – GISTM Conformance for the Holden Mine │ Mohammad Rashidi, Phillip E. Crouse and Summer Y. Sun 1241

Challenges and Mitigations to Bring a Historical Tailings Facility into Compliance with Modern Standards | Anthony Zhang and Chris Johns 1255

Chapter 6: Closure Issues 1267

Effect of Temperature on the Generation of Arsenic from Waste Rock from an Arctic Mine – A Laboratory Investigation | Elaura Seutin, Bruno Bussière, Benoît Plante and Vincent Boulanger-Martel 1269

Lessons Learned from Designing a Soil Cover System for a Tailings Storage Facility Exposed to an Arid Climate | Vincent Castonguay, Elissar Ozeir, Miguel Medina and Fannie Lessard 1281

Modeling Cover Systems for Tailings Facilities: Integrating Hydrus-1D and Python for Enhanced Seepage Prediction | Ariel Terlisky, Imanol Vega, Gastón Quaglia, Jonathon Doherty and Michel Noël 1293

The Vibro-consolidation Technique for Tailings Management and Dam Decommissioning Works | Gustavo Marçal de Sousa, Ana Torres, Felipe Moraes Russo and Lucio Schiavon Yamamoto 1307

Design, Construction, Monitoring and Numerical Modeling of Large-scale Field Trials: Assessing Cover Performance for Reclamation Method Selection | Karine Sylvain and Marie-Lin Breard Lanoix 1323

Kidston Hydro Electric Power: Re-purposing an Abandoned Mine | Malcolm Barker, Tony Ford and Peter Gaylard 1337

Enhancement of Tailings Properties by Cement Amendment for their Valorization in Cover Systems to Reclaim Active or Closed Tailings Storage Facilities | Audrey Jalce, Isabelle Demers, Benoît Plante, Thomas Genty, Eric Brouard, Marie-Pier Éthier, Sophie Turcotte and Marie-Andrée Guindon 1353

TRIM4Post-Mining: Geotechnical Input for Transition Information Modeling for Post-mining Landscapes | Gerald Verbeek and Gustavo Hamu 1367

Utilization of Novel Electrokinetic Geosynthetics for Stabilization of Ultra-fine Tailings | Nilan Jayasiri, Andy Fourie and Cristina Vulpe 1377

Enhanced Conceptualization of Reactive Filtered Tailings Oxidation Using a Reactive Transport Model | Katherine Raymond, Jared Robertson, Julie Zettl and Mike O'Kane 1391

Orphaned and Abandoned Mines in Manitoba: From Identifying Hazards to Achieving Closure | Mohammad Ahmeduzzaman, Dami Adedapo and Cory Graham 1407

Decharacterization of Tailings and Sediment Dams in Brazil – Hydrological and Hydraulic Aspects | Manuelle Prado Cardoso Pereira, Mônica Torres dos Santos de Almeida, Caique Simões Renna Costa, Helena Maria Campos Castro, Fernando Pereira Aguilar and Vicente Mello 1419

Checklist for Decharacterization of Mining Dams: Engineering and Environmental Aspects | Rafael Caetano Cardoso Boaventura, Murilo Damato, Gislene F.S.R. Fournier and Manoela C. A. Neves 1429

The Importance of Hydrogeological Models for Closure of Tailings Dams | Ana Carolina Neves and Waldemar Felitti 1439

Tailings Dam Decharacterization Projects: Proposal for Water Monitoring Plan | Ana Carolina Neves, Helen Simone Chiaranda, Bruno Resende Lopes and Rafael Gomes Oliveira 1451

Boodarie Tailings Storage Facility – Our Journey to Closure | Nathalia Revelo Mendez, Daniel Meunier, Darren Springer, Bria Whiter and Simon Harris 1465

Chapter 7: Design 1477

Lessons Learnt by Applying a Risk-based Approach to Tailings Storage Facilities | Peter Chapman, Scott Gover and Jordan Ribbons 1479

Evaluating the Stability of Upstream and Brittle Facilities – Case History Validation of the "Rules" | Michael Davies and John Lupo 1495

How to Design a Tailing's Dam Full Removal? Lessons Learned from a Case Study in Brazil | Benicio Junior, Claudio Rodrigues, Neil Singh and Luciano Souza 1507

Design of a Co-disposal Facility for Thickened Tailings and Potentially Acid-generating Waste Rock | Patrick Williamson and Wilson Muir 1521

A Study on the Possibilities, Constraints, and Motivation for Transitioning a Conventionally Designed TSF into a Full-scale Hydraulically Dewatered Stack Facility for Fine Residue Disposal in South Africa | N.W. Nxumalo, P. Newman and A. López 1533

The Relevance of Particle Crushing for the Design of Compacted Filtered Iron Ore Tailings Storage Facilities | João Paulo de Sousa Silva, Bruno Guimarães Delgado, Alexia Cindy Wagner, João Vítor de Azambuja Carvalho and Nilo Cesar Consoli.....1543

Iron Ore Tailings Dam De-Characterization: Evaluation of Key Parameters for Future Dry Stacking | Hugo Carlos Scheuermann Filho, Thatyane Martins Gonçalves, Nilo Cesar Consoli, Gino Vizcarra, Frank Pereira and Nilthson Noreña 1555

Lessons Learned in Applying the Observational Method to a Tailings Facility Constructed on a Soft Clay Foundation | Bryce Marcotte, Kyle Scale, Calvin Boese, Michael Andree, Travis Pastachak, Brent McFarlane and Jason Bell 1565

Compaction Sensitivity in Tailings Stack Infiltration Modeling: Unsaturated Properties Uncertainty Analysis | Letícia B. L. Garcia, Marcos A. Lemos Júnior and Guilherme J.C. Gomes 1577

Stay and Fight, or Flee? Assessing the Risks of Intervention Leading up to a Catastrophic Failure | Justin Willis 1589

Bayesian Networks Application and Analysis of Failure Mechanism and Triggers in Tailings Dams: A Case Study | Keith Mandisodza, David J. Williams and Chenming Zhang 1603

A Feed Forward Approach to Optimizing Oilsands Tailings Centrifuge Operation | Paul Mikula, Adeola Bello-Hamilton, Nan Wang, Jim Lorentz and Randy Mikula 1621

An Often-Overlooked Approach for Slope Stability of Tailings Dams Built Using Centerline and Downstream Construction | Jed D. Greenwood, Iván A. Contreras and Junhong Li 1633

Buttressing of Tailings Storage Facilities | Raquibul Alam and Ljiljana Josic 1645

Transportable Moisture Limit vs. Conveyability Testing | Christopher Olsen, Kenneth Rahal, Chris Braun and Skyler Pinnick 1661

Learning from Experience – Let's Get Real | Malcolm Barker 1679

Southeast Rock Disposal Site Tailings Co-disposal Facility | Ben Wickland, Don Parsons, Anthony Van Engelen and Scott Coombs 1695

Feasibility of Repurposing Wood Processing Waste as an Industrial Liner Material | Robyn Gaebel, Heidi Cossey, Ali Nasseri-Moghaddam and Kristin Salzsauler 1705

Operational Processes for Stacking Filtered Tailings – Itabira Case Study | Rodney Silva, Felipe Bonucci, Danilo Eloi, Miguel Paganin, Weslley Maciel, Jonas Guedes, Maira Drumond and Mateus Leite 1717

Performance Assessment of a Filtered Tailings Storage Facility Partially Built with Uncompacted Tailings | Edwin Sanchez and Denys Parra 1733

Next-Gen Tailings Waste Management: Transforming Life-Cycle Strategies | Lakshmin Bachu 1749

Chapter 8: Environment and Water 1763

Evaluation of Biogeochemical Processes for Weak Acid Dissociable Cyanide | Larissa Smith, Sandra Dworatzek, Jeff Roberts, Valerie Bertrand and Elizabeth Walsh 1765

Combining Approaches for Environmental Assessment of Tailings Ponds and Waste Piles in the Eastern Amazon | Silvio Ramos, Paula Ribeiro, Cecilio Caldeira, Wendel Pereira, Markus Gastauer and Pedro Souza-Filho 1775

Freeze-thaw Durability of Cemented Paste Backfill Containing Arsenic Trioxide Roaster Waste Dust | Caroline Alexon, Nicholas Beier, Amirhossein Mohammadi and Isabelle Demers 1787

Water Balance and Water Quality Predictions for the Cariboo Gold Project Filtered Tailings Facility | Adrian Moreau, Jiajia Zheng, Michelle Liew and Alex Fitzpatrick 1799

Development of a Calibrated Seepage Model to Predict Pore Pressure Reduction to Inform Tailings Storage Facility Closure Planning | W.E. Rouncivell, R.L.C. James and S. Lorentz 1813

Rapid Water Table Response to Transient Pressure Wave Generation in the Unsaturated Zone of Tailings Dams | Charné Theron and Simon A. Lorentz 1825

Geochemical Investigations toward a Groundwater Compliance Action Plan at the Moab UMTRA Project Site | Lisa Burgess, Keaton Belli, Chelsea Bokman, Jennifer Nyman, Liz Moran and Ken Pill 1837

Critical Seepage Analyses for Stability of Tailings Dams | Dobroslav Znidarcic, Gordan Gjerapic and David Rees Gillette 1849

Assessment of Silicate- and Catecholate-based Surface Treatment Performances to Limit the Mobilization of As from Low Sulfide Filtered Tailings | E. Lagae Capelle, L. Coudert, I. Demers, C. M. Neculita and G. Pépin 1861

The Internal and Interface Shear Strength of Geosynthetic Clay Liners for Mining Application | Andrew Jung and Reza Gorakhki 1873

Prediction of Pore Air and Water Pressure Propagation Induced by Extreme Rainfall in Tailings Dams | Simon A. Lorentz and Charné Theron 1883

Deportments of Magnesium and Silicon in a Two-part HCl-NaOH Leaching of Asbestos Tailings | Terry C. Cheng and Claude L. Morissette 1891

Evaluation of Best Available Technologies and Practices for Tailings Seepage Detection and Monitoring at Cobre Panamá | John H. Fortuna and Carlos Hubner Torres 1903

Standardizing Sediment Porewater Passive Samplers to Measure Metal Availability at Mine Sites | Florent Risacher, Jason Conder, Brent Pautler, Alex Sweett and Andrew Jackson 1925

Preliminary Assessment of the Environmental Impacts of Artisanal Gold Mining: The Case of the Kashozi Mining Site, South Kivu, DRC | Akonkwa Mudekuza Kepler, Alex Kalonji-Kabambi and Bwemere Ciribuka Grâce 1933

Implementation of Saturated and Unsaturated Seepage Analysis in a Polymetallic Tailings Storage Facility: A Case Study | Jose Alfredo Promotor, Sergio Hernández, Osvaldo Flores and Cesar Gallegos 1947

Challenges Faced in Developing Plans for Emergency Drinking Water Supply in the Context of Mining Dam Collapses | Josiani Esteves Cordova, Lucas França Carvalho Silveira, Yuri Abner Rocha Lebron, Gabriela Rodrigues Barroso, Fernanda Luiza Costa Lisboa and Vicente Alimento Júnior 1961

Chapter 9: Geotechnical Issues 1975

Exploration of Passive Desaturation of In-place Tailings Using Wicking Geosynthetics | Kendall Monley and Joseph Scalia IV 1977

Rate Effects in In-situ Testing in Hard Rock Mine Tailings and their Impact on the Estimation of Shear Strength Parameters | Mohammad Zarrabi, Estelle Nkamegue, Michael Demers-Bonin, Mohammad Kermani and Kendell Cator 1991

Geotechnical Challenges of Tailings Storage Facilities in Cold Regions | Morteza Esfehani 2003

Assessment of Flow Liquefaction Susceptibility of a Tailings Dry Stack Pile Using the State Parameter and Yield Stress Ratio Approach | Marcus Vinícius Lima Dias, Dieggo Santos, Mariela Silva, Gustavo Marçal de Sousa and Marília Freire 2015

Enhancing Soil and Tailings Characterization: Integration of Photonics Technology with Cone Penetration Testing | Iman Entezari, Dallas McGowan, Joseph Bindner, Joseph Glavina and Jason DeJong.....2027

Hydraulic Dewatered Stacking Demonstration – Approaching Operational Completion | Phil Newman, Mark Bruton, James Purrington, Alireza Nickman and Andrea López 2039

In-pond Mixing of Fine and Coarse Tailings – Results from a Commercial-scale Pilot in Canada's Oil Sands | Evan Davison, Lucas Hu, Bobby Hutchinson and Peter House 2053

Evaluating Iron Ore Tailings' Variability in an Upstream Dam For Dam Closure │ Thatyane Martins Gonçalves, Alexia Cindy Wagner, João Vítor de Azambuja Carvalho, Frank Pereira and Nilo Cesar Consoli 2067

Solar-Powered Electrokinetic Tailings Dewatering │ Ed Hanna and John Vandersleen 2079

Effect of In-situ Dewatering and Compaction of Copper Tailings Using Accelerated Mechanical Consolidation │ Oscar Santiago, William McAdam and Rafael Menezes ...2093

Influence of In-situ Soil Fabric on the Critical State of a Laminated Glaciolacustrine Silty Soil │ Morteza Mohamadi, Simon Dickinson, Chang-Gyun Jeong, Erinn Raison and Adrian Wightman 2107

Mechanical Behavior of Gold Mine Tailings Dried by Natural Dewatering │ Mayara Ferreira Rodrigues, Paula de Mello Martins and Jaime Pinheiro 2119

Analysis of Video Images Obtained during Cone Penetration Testing │ Gerald Verbeek, Gustavo Hamu and Oksana Khomiak 2131

Predicting Tailings Properties Using Hyperspectral Sensing and Machine Learning │ Joseph Bindner, Joseph Scalia IV, Christopher Bareither, Iman Entezari and Dallas McGowan 2143

Fundamental Properties of Filtered Tailings on Density-Moisture Curves │ Uddav Ghimire, Jackson S. Norbutas and Tejo V. Bheemasetti 2155

Multi-Test Approach to Determining Consolidation Parameters in Flocculated Tailings and Soft Soils │ Ehsan Eidi, Ken Dickson, Arazooben Patel, Louise Whitham, Morgan Tizzotti and Paul Simms 2167

Optimization of Operations Based on Monitoring and Construction Quality Assurance at Minera Peñasquito │ Christian Armstrong, Kenneth Rood, Eduardo Jose Garcia Romero and Patrick Mwamba 2179

How Many Triaxial Tests Do You Actually Need to Get a Critical State Line? │ Marcos Arroyo, Lluis Monforte and Stefano Collico 2191

Holden Mine Post Closure Monitoring – a Statistical Method for Developing Trigger Action Levels │ Summer Y. Sun, Ray Dorow, Paul Pellicer, Mohammad Rashidi and Phillip Crouse 2203

Shear Strength Characteristics and Joint Envelopes of Compacted Unsaturated Fine-grained Bauxite Residue │ Hua Tian, David J. Williams and Keith Mandisodza 2217

Measurement of Bingham Yield Stress and Plastic Viscosity of Tailings Slimes using an In-Situ Viscometer │ Dallas McGowan, Yasmin Byrne, Y. Simon Sun, Heather Kaminsky and Jason DeJong 2237

Mechanical Response of Plastic Fine Tailings under Constant Shear Drained Loading │ Luis Vergaray-Astupina and Jorge Macedo 2253

Development of Tailings-Specific Correlations for Estimating Fines Content from CPT Data Using Artificial Intelligence Method for the Holden Mine │ Mohammad Rashidi, Phillip E. Crouse and Summer Y. Sun 2263

Stacked Deposits of Filtered Fluid Fine Tailings Using Geotextile Tubes – Updates on Enhancing Chemical Stability │ Fernando Da Silva 2275

Spatial Variability Assessment of Mine Tailings | Luis Vergaray-Astupina and Jorge Macedo 2297

Tailings Characterization for Flow Liquefaction Evaluation at a Large Tailings Storage Facility by Advanced Laboratory Testing | Juan Carlos Ayes-Zamudio, Akhter Hossain and Tony Freiman 2309

Chapter 10: Monitoring and Risk Management 2321

Improving Tailings Deposition: A Drone and Satellite Survey Validation Framework for Enhanced Facility Management | John Thuysbaert, Joe Piccolo-Lawrance, Joseph Quinn and Romain Girard 2323

Risk Management for Access to Dams at Emergency Level Control: Control Levels (OMS Manual) and Safety Plan | Virginie Queiroz Rezende Pinto, Daniel Bernardes Raposo, Milena Fernandes Xavier Matos, Elias Silva de Sousa and Alexandre Cristino Correa dos Santos 2335

Passive Seismic and Interferometry Techniques in Dam Decharacterization Monitoring | Camilla Rodrigues, Marc Lambert and Ben Witten 2345

New Wireless Technology for Tailings Monitoring | Leonnardo Probst Simoes, Braulio Rodrigues, Sean Allen, Jake Lloyd, Vitor Almeida, Jhonimar Santos and Denis Rafael Valentim 2357

UPLOAD – ANALYSE – ACT: Artificial Intelligence-assisted Faster, Seamless, and Almost Real-time Tailings Dam Construction Quality Assurance is Knocking at our Doorstep | Anjan Kundu 2367

Vale Base Metals Modernization of Instrumentation Monitoring System for Dam Safety at Canada Tailings Storage Facilities | Wing-Keat (Wayne) Wong, Greg Puro and Lucas Lobato Ribeiro 2373

Assessing SAR, InSAR and Multispectral Optical Data for Mapping Supernatant Pond Evolution | Élyse Gaudreau, Ajinkya Koleshwar, Kenny Yue, Pablo Blanco, Riccardo Tortini and Giacomo Falorni 2383

The Application of a 3D Inclinometer in Monitoring the Performance of a TSF near an Active Mine Pit | Zhen Ran Yung, Qing Zhan, Stephen Darmawan and Rudy Moniaga 2397

Integration of Multi-Sensing Technologies for the Monitoring of Tailing Storage Facilities | Vincent Le Borgne, Adam Dulmage, Josh Sun, Evan Davison, Divya Sekha Vaka and Skevi Perdikou 2407

Integrated Analysis of Dam Surface Displacement Monitoring | Felipe Bolívar Domingos, Alessandra Mazon and Jefferson Barbosa 2419

Chapter 11: Site Investigation 2431

Enhancing Safety and Reducing Environmental Impact through Development of a Robotic Hybrid CPT Rig | David Slack, Roque Obusan, Yasmin Byrne, Dora de Melo and Jason DeJong 2433

Tailings Facility Surveying Leveraging Complementary Technologies | Veronique Nell and Andrea Krupa 2447

Potential of X-ray Micro-CT Imaging for Mine Tailings Deposit Characterization | Dharma Wijewickreme and Ana Valverde 2457

Influence of Density on Predicting Saturation in Filtered Tailings using an Electromagnetic Sensor | Garret M. Martin, Christopher A. Bareither and Joseph Scalia IV 2467

Testing of an Autonomous Rheometer for Optimized Tailings Thickeners Operation | Arno Talmon, Wiebe Boomsma, Bas Nieuwboer, Samir Rustamov, Menno Jaspers, Sven van Asperen and Miguel de Lucas Pardo 2485

Chapter 12: Author Index..... 2497

Author Index 2499

ORGANIZERS

Colorado State University

The Civil & Environmental Engineering Department (CEE) at Colorado State University is internationally recognized for world-class engineering research and education. Our faculty develop global solutions to address environmental issues including tailings and mine waste, wildfires, and other natural hazards compounded by climate change. Our faculty are pioneers in water research, from hydraulic design and stream restoration to stormwater treatment and wastewater monitoring. The department takes pride in over 150 years of history, dating back to the first department head, Elwood Mead, who oversaw the construction of Hoover Dam and was the namesake of Lake Mead. Beyond research, our faculty prioritize the preparation of future engineers and scholars by balancing rigorous coursework with dynamic and supportive instruction. The department hosts the ASCE Excellence in Civil Engineering Education (ExCEEd) workshop, helping engineering faculty across the U.S. and internationally become better teachers. The department offers two ABET-accredited Bachelor of Science degrees in civil engineering and environmental engineering, and a new construction engineering degree beginning fall 2025. CEE offers a Master of Science, a Master of Engineering, and a Ph.D. in civil engineering, as well as several certificates including a graduate certificate in tailings engineering.

C3 Alliance Corp.

At C3 Alliance Corp., our mission is to create stronger communities through innovative and inclusive solutions for resource development. We understand that the sharing of information and ideas is vital to gaining insights and developing relationships and that community members, business, and government representatives can all benefit from meeting to share stories and knowledge. C3's expert team of event planners specialize in providing project management, strategic knowledge and expertise for planning conferences and networking opportunities. We benefit from a vast network of professional contacts to organize exceptional events that connect people and knowledge across resources sectors, communities and government.

For more information, visit the C3 website at http://www.c3alliancecorp.ca/

COMMITTEES

Conference Leadership Committee

Chair – Christopher A. Bareither, Associate Professor, Civil & Environmental Engineering, Colorado State University

Co-Chair – Joseph Scalia IV, Associate Professor, Civil & Environmental Engineering, Colorado State University

Plenary Session Lead – Amanda Adams, Principal Engineer, Stantec

Plenary Session Lead – Jason Andrews, Senior Geotechnical Engineer, Senior Vice President, Engineering Analytics

Plenary Session Lead – Michael Henderson, Principal, Strata-Geo LLC

Plenary Session Lead – Kate Patterson, Tailings and Water Resources Engineer, Principal, Klohn Crippen Berger, Ltd.

Plenary Session Lead – Nicholas Rocco, Geotechnical Engineer, NewFields Mining Design & Technical Services

Plenary Session Lead – Ryan Shedivy, Assistant Vice President, Geological Engineer/ Mine Waste Mountain Team Leader, WSP USA Inc.

Short Course Technical Lead – Jason Hilgers, Associate Vice President, Geotechnical Engineer – Mining Group, AECOM

Social Events Coordinator – Sam Rivet, Senior Solutions Manager, MineBridge Software Inc.

Tradeshow Reception Lead – Shawn Steiner, Manager – USA West, ConeTec

Student Volunteer Coordinator – Emily Jagerhorn, Graduate Research Assistant, Civil & Environmental Engineering, Colorado State University

Organizing Committee

Marie-Josée Banwell, Business Development Manager, TRE Altamira Inc.

Dean B. Durkee, Sr. Consultant & Vice President, Gannett Fleming

Jason Cumbers, Principal Engineer, Stantec

Zach Fox, Senior Geotechnical Engineer, Knight Piésold Consulting

Robyn Gaebel, Senior Geotechnical Engineer, Geosyntec Consultants Inc.

Wes Herweynen, Senior Tailings Engineer, GHD

Ljiljana Josic, Sr. Director Tailings, Water and Geotechnical Engineering, AtkinsRealis

Andy Jung, Technical Manager, CETCO

Jean Kugel, Senior Engineer, BGC Engineering

Daryl Longwell, Principal Civil Engineer, Tetra Tech, Inc.

Linda Lorenzetti, Diemme Filtration

Dave Ludwick, Senior Civil Engineer, SRK Consulting Inc.

Ian McKechnie, Lead Product Manager, Hatch Ltd.

Doug Oliver, Principal Hydrogeologist, FloSolutions

Randal Osicki, Associate | Senior Geotechnical Engineer, Thurber Engineering Ltd.

Fab Pakizehkar, Veolia Water Technologies & Solutions

Omar Rodriguez, Design Engineer, Soletanche Bachy

Kurt J. Schimpke, Senior Geotechnical Engineer, Barr Engineering Co.

Teresa Speigl, Director Tailings, Crushed Leach, & Water, Freeport-McMoRan

Aaron Tomkins, Principal Geoscientist, GBG Group

Maythe Villavicencio, Marketing Manager, PhotoSat

Oliver Whatnall, VP, Americas, Jord International

Todd Wisdom, Director, Paterson & Cooke USA, Ltd.

Zygi Zurakowski, Principal Engineer, Water and Geotechnical Engineering, Newmont

Conference Secretariat

Sarah Weber, C3 Alliance Corp.

Melissa McRitchie, C3 Alliance Corp.

Meryl Nelson, C3 Alliance Corp.

Bronagh Furlong, C3 Alliance Corp.

Michaela Bub, C3 Alliance Corp.

Preface

The first conference in this series was on Uranium Mill Tailings Management in 1978, which was organized by Civil Engineering Department of Colorado State University, Fort Collins, Colorado. The organizing committee consisted of John Nelson, Thomas Shepherd, Steven Abt, Wayne Charlie, and John Welsh. The series of conferences on uranium mill tailings continued through 1985, and in 1984 and 1985, the conference title was expanded to Management of Uranium Mill Tailings, Low-level Waste and Hazardous Waste.

In 1986, the organizing committee, consisting of Steve Abt, John Nelson, Richard Wardwell, and Dirk van Zyl, changed the title and focus to Geotechnical and Geohydrological Aspects of Waste Management. Content informed the design and operation of waste disposal facilities. The same focus was maintained for the 1987 conference.

By 1988 the uranium market had declined, uranium mills had closed, and support for a symposium on uranium mill tailings, hazardous waste, or most any topic associated with mine waste had declined. Thus, the conference was not held from 1988 until 1994. In 1994, Colorado State University, the sponsor of the uranium mill tailings conferences, resuscitated the conference series as Tailings & Mine Waste, the title by which the series remains today. In 2004, attendance reduced leading to a negative financial situation for the conference and reluctance on part of Colorado State University to support the conference series; thus, the conference was not held from 2005 until 2008.

In late 2007 an organizational committee was established in Colorado through the support of several consulting engineering companies: Engineering Analytics, Golder, Knight Piésold, MWH Global, Robertson GeoConsultants, Inc., SRK Consulting, Inc. Tetra Tech, Inc. and URS Corporation. A stable financial basis was established for the conferences in Colorado. A partnership also was established between Colorado State University, University of British Columbia, and University of Alberta. The conference now rotates between the United States and Canada, whereby in even years Colorado State University hosts the conference and in odd years the conference rotates between University of British Columbia and University of Alberta.

Message from the Chairs

The Tailings & Mine Waste Conference is an industry-academia partnership that serves as a platform for professionals to network, share knowledge, debate, discuss lessons learned, and generally advance both the state-of-practice and state-of-art in tailings and mine waste management. Colorado State University is proud of the creation and continued success of this conference series. Over the past few years, the Colorado conference has continued to grow and was relocated to the Denver area to engage more working professionals. We hope that you enjoy this year's Conference at a new venue – the Westin in Westminster. We will be back to Westminster again in 2026, before (hopefully) celebrating the 50th Anniversary of the Conference back where it all began in 2028.

Although hosted by Colorado State University, conference planning and support would not be possible without the support of C3 Alliance, and all the industry sponsors. We would especially like to thank our Patron Sponsor, Freeport-McMoRan for their continued support, as well as ConeTec, Geosyntec, Hatch, Klohn Crippen Berger, SRK, and WSP for stepping forward as Platinum Sponsors. All revenue from the conference is used by Colorado State University to support graduate education and research in the area of tailings and mine waste. This attribute of the conference cannot be overstated. Our team has come together with a combined vision to host the world's leading technical conference in tailings and mine waste while supporting the growth of the next generation of professionals.

We thank the Organizing Committee, Conference Leadership Committee, Sponsors, Exhibitors, all the authors of the technical papers, and all Conference delegates for supporting the Conference. This Conference is for all of us.

Christopher Bareither and Joseph Scalia,

Chairs, Tailings and Mine Waste 2024

PLENARY ABSTRACTS

Plenary Session 1

A Corporate Look at Tailings Management – Lessons Learned

Moderators:
Jason Andrews & Michael Henderson

Speakers:
Tamara Johndrow
Jon Lapwood
Scott Martens
Jaime Awmack

Join us for the first plenary session of the 2024 Tailings and Mine Waste conference. The event will feature a welcome address by a representative of Freeport McMoRan, our Patron Sponsor, highlighting the 20-year evolution of tailings management. This session will also feature speakers from three mining companies discussing their tailings management journey. They will discuss lessons learned along the way and their outlook for future tailings management. The session will conclude with an interactive panel discussion with live questions form the audience.

Tamara Johndrow

Tamara Butler Johndrow is Director of Tailings, Crushed Leach, and Water at Freeport-McMoRan. She received her B.S. and M.S. in Civil Engineering and is a licensed Professional Engineer with 26 years of experience in water resources and geotechnical engineering, management and program development. She began her career as a consultant at Golder Associates (WSP) and Engineering & Hydrosystems (WSP Golder).

Ms. Johndrow joined Freeport-McMoRan in 2008, creating the Tailings, Crushed Leach, and Water team to support business critical areas of tailings storage facility, crushed leach stockpiles, and dam safety as well as water management across Freeport's portfolio. She has had responsibility for strategic planning, design, construction quality, operational support, inspection, review, governance processes and reporting, and due diligence for tailings storage facilities as well as for crushed leach stockpiles, levees, and water dams. Her current focus includes tailings & water governance, tailings innovation, and water management strategy.

Ms. Johndrow is a trusted advisor to Freeport-McMoRan executive leaders, and she represents the company in various external tailings research and management engagements. She currently chairs the International Council on Mining and Metals (ICMM) Tailings Management Working Group and the GeoStable Tailings Consortium Steering Committee.

Jon Lapwood
Principal Advisor Major Hazards, Group Technical Rio Tinto

Jon Lapwood is the Principal Advisor Major Hazards in Rio Tinto's Group Technical Major Hazards team. Jon is a geotechnical engineer with a broad range of experience in open pit mining operations, data integration and analysis, and the design, development and implementation of systems. He has a strong interest in geotechnical monitoring instrumentation, data, software and technologies and how these can be an integral part of effective risk management in dynamic mining environments.

Jon's current role includes the provision of technical guidance, technical support and undertaking second-line assurance activities. He is currently the project lead for the implementation of the Global Industry Standard on Tailings Management for Rio Tinto's diverse portfolio of tailings facilities, and is coordinating the implementation efforts across the business. Jon also leads a project which will combine geotechnical data with other technical and business information for enhanced understanding and improved oversight of Rio Tinto's major hazards.

Scott Martens
Director, Tailings, Tech Resources Limited

Scott Martens is the Director, Tailings at Teck Resources, providing corporate oversight of tailings governance and engineering at Teck's operating mines, development projects and legacy facilities across North and South America.

Scott has 29 years of geotechnical engineering experience, with 15 years in geotechnical consulting and 14 in geotechnical mining operations. He has a Bachelor of Civil Engineering degree from the University of British Columbia and a Master's degree in Geotechnical Engineering from the University of Alberta.

Scott is an Adjunct Professor of Geotechnical Engineering at the University of Alberta, a member of the independent review board for the tailings facilities at a gold mine, and is the Chair of the Mining Dams Committee for the Canadian Dam Association. Scott was a keynote speaker for TMW in 2021.

Jaime Awmack
VP, Operational Support, *Eldorado Gold*

Jaime Awmack is the VP, Operational Support at Eldorado Gold, where she works closely with site and technical teams to facilitate change at the operational level and drive continuous improvement globally. She is a professional mineral processing engineer with around 20 years' experience, and prior to joining Eldorado, she served as Process Manager at Newmont's Peñasquito mine in Mexico. Her current role ranges widely from tailings and heap leach stewardship to operational technology and asset management, and she's always looking to keep learning from the brilliant and fascinating people across this industry.

Moderator: Michael Henderson
Principal, Strata-Geo LLC

Michael Henderson has spent nearly all his plus 40-year career in the engineering and environmental aspects of managing mine waste, including tailings. Mr. Henderson's experience extends to projects in North America and overseas. Mr. Henderson has operations experience at several large mines, research experience at a National Laboratory where he conducted mine and energy research for the US Bureau of Mines and Department of Energy, and as a consulting engineer for the past several decades.

Mr. Henderson is a Professor in the Mining Engineering Department at the Colorado School of Mines and was the first Director of the Tailings Center, which is a multi-university/industry effort aimed at addressing the educational and research needs around tailings management. He is now a Director-at-Large, remaining fully engaged with the Tailings Center. He has taught professional development, undergraduate and graduate engineering courses on geotechnical issues, mine waste management, and risk assessment at Colorado School of Mines, Colorado State University and the University of Nevada.

Mr. Henderson is also a Principal with the firm of Strata Geo, where he is an Engineer of Record (EOR) on several large mining projects, an Independent Tailings Review Board Member (ITRB) for several mid-tier and large mining companies, and an advisor in establishing tailings stewardship and management programs for several mining companies. Mr. Henderson has authored dozens of papers on geo-environmental issues around mine waste, has contributed to three textbooks on the subject, and holds three patents on geophysical systems related to mine waste containment. Mr. Henderson has a B.S. in Civil Engineering from Colorado State University; an M.S. in Civil Engineering from the University of Pittsburgh; and a PhD (ABD) from the University of Nevada.

Moderator: Jason Andrews

Senior Geotechnical Engineer, Senior Vice President, Engineering Analytics

Mr. Andrews has experience in geotechnical engineering pertaining to mine site remediation, construction defect litigation, retaining wall design and repair, field investigations, and quality assurance and quality control oversight relating to geotechnical and environmental projects. He has served as a senior engineer and project manager for many mining design and reclamation projects, construction defect litigation projects, and civil engineering projects. His areas of experience include site investigation and characterization, feasibility investigations, engineering investigations, development of remediation alternatives, implementation of remedial design, and construction oversight. His areas of emphasis include slope stability analyses, expansive soils, collapsible soils, settlement analyses, and other aspects of geotechnical engineering. Mr. Andrews has performed geotechnical engineering and environmental investigations for forensic, mining, and public works projects in California, Colorado, Illinois, Nevada, New Mexico, Oregon, Washington State, Wyoming, and Peru.

Plenary Session 2

2030 and Beyond – Perspectives on Evolving Tailings Management

Moderators:
Amanda Adams & Martin Rust

Speakers:
Andrew Witte, KCB
Chris Sonntag, BHP
David Slack, ConeTec
Antonia Mihaylova, ICMM

Plenary Session Abstract: Tailings Facility Engineering – The Next Frontier

The future of tailings engineering is poised to embrace innovative technologies and methodologies to enhance sustainability and safety. Real time information management, advanced monitoring, predictive modeling and new deposition techniques aim to mitigate environmental impacts and ensure the integrity of structures, reflecting a shift towards more responsible and efficient industry practices. Tailings engineering continues to evolve, integrating new research and technologies to meet the challenges of modern mining operations and environmental stewardship. This session will explore the near-future through the presentation "What could Tailings Facility Engineering look like in 2030," presented by Andrew Witte, and speculate about the more remote future, through a panel discussion with diverse industry experts.

Panel Abstract: 2030 and Beyond – Perspectives on Evolving Tailings Management

The panel session will expand on the concepts presented by Witte et al. by engaging a number of diverse tailings management professionals. The panel will provide their perspectives of the 2030 vision of initiatives and advancements from owner, engineering, and other perspectives. Then, the panelists will explore even further into the future. They will discuss how we can build competency and capacity from the current shortage of qualified tailings professionals, how characterization of tailings and development of improved tools for characterization will change classical design approaches, and how a new vision for closure planning could emerge. The panel will be moderated, and opportunities for audience engagement will be available

Andrew Witte

Senior Geotechnical Engineer, Principal at Klohn Crippen Berger

Andrew is a Senior Geotechnical Engineer with over 20 years of consulting experience in geotechnical and water resources engineering on various mining, infrastructure, municipal, and industrial-related projects. Andrew's chief area of practice is the design, construction, safe operation and closure of earthfill and rockfill embankment dams within Canada and around the world; specifically, he is currently the lead engineer for several major cyclone sand tailings dams in British Columbia. Andrew also holds various design and review roles for numerous other proposed, operating, and closed tailings dams, each with their unique challenges.

Chris Sonntag

Chris graduated from the University of Saskatchewan with a BSc. In Civil Engineering and is the Manager Technical for BHPs Legacy Assets portfolio. He leads a team of Tailings, Groundwater and Geotechnical specialists who steward technical studies, support decisions and progress closure activities across approximately 20 mine sites in North America. Chris is active with tailings and mine workforce activities and currently chairs the SME Advanced Tailings Talent Attraction sub-Committee (ATTAC) and represents BHP on Industry Advisory Board for the Tailings Center.

David Slack

David is the Chief Operating Officer at ConeTec, where his passion for technological innovation and operational excellence drives his leadership in the geotechnical site investigation industry. With a degree in Mechanical Engineering from the University of British Columbia and nearly two decades of experience at ConeTec, David's progression from field technician to executive has provided him with both a robust technical foundation and a deep understanding of the industry. Prior to his current role, he served as Vice President and General Manager in Chile and Peru, where he was instrumental in expanding ConeTec's footprint across Latin America.

David believes in the immense potential of innovation and technology to address the pressing challenges of today. Within ConeTec, he is committed to fostering an environment that encourages innovation and technological advancement, strengthening the company's position as a leader in sustainable site investigations while also contributing to the advancement of industry standards and practices.

Antonia Mihaylova

Antonia Mihaylova is a Senior Manager at ICMM, leading the tailings management workstream and the Consolidated Mining Standard Initiative. Prior to ICMM, Antonia was at the International Union for Conservation of Nature (IUCN), where she headed the Director General's Office, serving as Special Adviser to the Director General. Prior to that, she managed the Global Tailings Review, the process that led to the development of the ICMM, UNEP and PRI-backed Global Industry Standard on Tailings Management (GISTM). She also served as a member of the International Advisory Panel convened by UNEP, the Church of England Pensions Board and the Council on Ethics of the Swedish National Pension Fund (on behalf of PRI) to support the establishment of a Global Tailings Management Institute. Antonia has spent several years at an international

development consultancy, working on World Bank and European Bank for Reconstruction and Development (EBRD)-funded mineral resource governance projects across Africa and Asia. In the early stages of her career, Antonia worked for an environmental NGO Global Greengrants Fund, supporting grassroots nature conservation initiatives. She holds a bachelor's in economics and politics; and a Master's in environmental policy from the London School of Economics (LSE).

Moderator: Amanda Adams

Amanda Adams, P.E, PMP, is a Principal Engineer at Stantec with 18 years of mining industry experience. Amanda currently serves as a member of Stantec's US Mining leadership team in the role of Business Center Operations Leader. She is a Colorado School of Mines Graduate with a B.S. In Geological Engineering. She has been employed at Stantec (through acquisition) since 2008. Her technical experience is primarily focused on the design of tailings storage facilities for mining clients. Her design experience has spanned all phases of project development from siting studies to pre-feasibility, feasibility, basic engineering, detailed design, construction, operation and closure. Amanda is a passionate advocate for diversity, equity and inclusion (DEI) in STEM fields. She is Past President of the Women in Mining (WIM) Denver Chapter and in 2024 received a Distinguished Service Award from WIM. She is a one of the founding members of the US Society on Dams (USSD) DEI Committee. Amanda is also involved in professional organizations to promote mining and tailings practices, including previously serving as the USSD Tailings Dams Committee Chair and she is the current Chair of the SME Tailings and Mine Waste committee.

Moderator: Martin Rust

Martin Rust, PhD, PrEng. is a Professional Civil Engineer with 24 years' experience primarily in the field of Geotechnical engineering. His experience includes various roles on some world class tailings and ash storage facilities mainly in Africa, and more recently in the Americas. He has served as Designer of Record (DoR), Engineer of Record (EoR) and member of the Independent Tailings Review Board (ITRB) on various sites. Martin has also conducted multiple Dam Safety Reviews (DSR). His experience includes design and construction quality assurance for large construction projects. He actively stays abreast of international best practices such as those published by GISTM, ICOLD, CDA and MAC.

Plenary Session 3

Are we getting distracted? How can we best use the GISTM as an effective path to risk reduction rather than it becoming a path to box-check auditing?

Moderator:
Ryan Shedivy
Speakers:
Mike Davies
Susan Joyce
Daniel Landers
Louise McNab

The International Council on Mining and Metals (ICMM), the United Nations Environment Programme (UNEP) and the Principles for Responsible Investment (PRI) co-convened a global tailings review (GTR) to establish the Global Industry Standard on Tailings Management on the 5th of August 2020.

The Global Industry Standard on Tailings Management strives to achieve the ultimate goal of zero harm to people and the environment with zero tolerance for human fatality. Underpinned by an integrated approach to tailings management, the Standard aims to prevent catastrophic failure and enhance the safety of mine tailings facilities across the globe. It embodies a step-change in terms of transparency, accountability and safeguarding the rights of project affected people. (GTR 2020)

Is the Global Industry Standard on Tailings Management effective at achieving its goals? Are we, as the tailings practitioner industry, getting distracted from these goals and in particular the ultimate goals and commitment to zero fatalities? How do we best use the GISTM as a path to risk reduction rather than having it become simply another path to auditing and consuming valuable time from the limited number of qualified tailings practitioners.

This plenary session will focus on these questions as we hear from four different perspectives followed by a moderated discussion based upon questions from those attending on how the industry can best achieve the GTR goals.

Susan Joyce: President, On Common Ground Consultants Inc.

Susan Joyce is a Social Performance Specialist with 30 years of experience working to achieve integrated decision-making and effective incorporation of non-engineering criteria in the management of mining operations, including management of tailings. She has worked extensively assisting companies, communities and financial institutions to manage social and human rights risks and to meet and exceed international standards. Her work includes development of effective on-the ground strategies for reducing risk to companies and communities and enhancing potential social value of mining activities. She served on the Expert Panel that developed GISTM and her current focus is on the effective integration of social performance into tailings management. She serves on an ITRB and provides technical support to others. Susan has a Professional Certificate of Tailings Management from the Australian Institute of Mining and Metallurgy and an MSc. in Development Sociology from Cornell University.

Dr. Michael Davies, P.Eng., P.Geo.

Dr. Davies is a Geotechnical/Geological Engineer, has spent his entire roughly 40-year career in the mining industry. Prior to founding his own consultancy in 2022, he was an Executive with Teck Resources. He also has official affiliations with several academic institutes. Prior to coming to Teck he spent over 25 years in consulting including projects and senior management. He has had a career-long involvement in industry groups and was the mining industry's advisor for the Global Industry Standard for Tailings Management (GISTM). He has worked on all stages of mining projects from advanced exploration through decommissioning and reclamation. He has direct experience with more than 100 tailings facilities and, while retired from full-time work, currently a member of several Independent Review Boards around the world.

Louise McNab

Group Principal Engineer: Tailings, Hydrology and Closure, at Gold Fields

Louise is a Group Principal Engineer: Tailings, Hydrology and Closure, at Gold Fields. With a global role, she oversees operational and technical support for 37 Tailings Storage Facilities across 5 continents.

Originally from Scotland, Louise earned her Master's in Civil Engineering from the University of Edinburgh. With over a decade of experience, she specializes in tailings management, design, operations, and closure, ensuring safety and sustainability in mining operations worldwide.

Daniel Landers
Vice President – Risk Engineer, Mining at Swiss Re

Daniel Landers is a Risk Engineer for a global insurance company, where he supports underwriting of the mining risk portfolio. He completes assessments for mining operations worldwide, analyzing risks that could generate insurable property losses, provides recommendations to insured clients on risk management, and supports the assessment of mining and energy construction projects. In this role he provides subject matter expertise on tailings facilities and assists in the development of underwriting guidelines related to the subject.

Prior to working in the insurance industry Mr. Landers held the role of corporate tailings manager for a senior gold mining company. He has held project engineering and execution roles at large engineering and gold mining companies, and his experience has included project permitting, design and construction delivery of mining dams, civil infrastructure and process facilities for projects in the USA, South America, and Africa. He is also involved in digital innovation and data analytics initiatives around risk assessment management and evaluates ways to improve the evaluation of man-made risks in mining, and specifically in the field of tailings operations and stewardship.

Moderator: Ryan Shedivy, PE
Assistant Vice President, Geotechnical Engineer, WSP USA Inc.

Ryan Shedivy is an Assistant Vice President, Geotechnical Engineer at WSP with experience leading interdisciplinary teams in the mining, power, and solid waste industries. His field, design and ranges from conceptual level design and cost estimation through permitting and issued for construction level design and bid package development in support of tailings, waste rock, heap leach, coal combustion residual, and landfill facilities. He is currently the EoR of three closed tailings facilities and deputy EoR of two active tailings facility.

Abstract

Over the past five to ten years, there has been a surge in many different aspects of tailings facility engineering as the mining industry pays more attention to the importance of their tailings facilities as part of the overall success of their mining operations. This has been partly related to the Global Industry Standard on Tailings Management (GISTM) that was released in 2020, but is also due to other initiatives by several mining companies and organizations around the world that are committed to safe tailings facilities. There are major initiatives occurring on many fronts, including:

- Tailings technology and deposition strategies.
- Characterization of tailings and foundation soils, slope stability assessment (including deformation analyses), liquefaction predictions, dealing with high stresses, closure, filtered tailings, and so on.
- Closure strategies.
- Surveillance techniques.
- Competency building.
- Guidance documents that bolster the capabilities of the engineers working on tailings facilities.

This paper presents a summary of key issues that are currently confronting tailings facility engineers, owners, and regulators for each of the above topics. It describes initiatives that are currently underway or issues for which there are plans to address, and provides a vision for 2030. A survey of leaders in tailings facility engineering was conducted and the results of the survey are summarized in the paper.

Introduction

This paper envisions what tailings facility engineering could look like in 2030. Significant advances have been made in the field in recent years, and the pace of innovation is accelerating. The volume of tailings to be managed is also increasing, as mining operations are expected to increase production by about 3% per

year until at least 2030[1], while ore grades are decreasing (requiring more volume to be milled to realize a unit of each desired commodity).

Major focuses of this paper include improved tailings technology and deposition strategies, closure strategies, improved characterization methods for tailings and foundation soils, enhanced surveillance techniques, and the development of technical capacity and competency within the industry. Governance is a key aspect for safe tailings management that is also evolving, but is beyond the scope of this paper.

The authors have defined "tailings facility engineering" as covering the following areas of knowledge:

- tailings milling and processing,
- tailings storage facility design,
- closure design,
- geotechnical engineering,
- hydrogeological engineering,
- hydrotechnical engineering,
- geology,
- geochemistry,
- environmental protection,
- construction,
- operations,
- surveillance,
- risk assessment, and
- governance.

This paper continues with some context and discusses the method used to gather supporting information related to the key topics noted above. The paper presents the authors' understanding of these key topics summarized under the subheadings: Current Situation and Vision for 2030.

Context and why 2030?

Over the past five to ten years, there have been significant efforts to reduce the likelihood of catastrophic tailings failures through training, guidance documents, increased regulation, improved surveillance, etc. Increases in computing power have made complex analyses more efficient and have supported the use of artificial intelligence (AI).

Investors and insurance companies are paying close attention to the efforts to reduce risks associated with tailings storage facilities (TSFs). However, as these efforts drive the TSF risks to lower levels, a key challenge will be the demand for qualified people, as well as the demands on those qualified people. The demand for capable and experienced engineers of record (EoR), responsible tailings facility engineers/persons (RTFE/P), independent tailings review board (ITRB) members, and regulators is far greater than the supply, which is declining due to the age demographic of the people currently fulfilling

[1] This percentage is based on information from (i) Mining. Com: Copper production, price rebound on the horizon – report, July 2022; (ii) expertmarketresearch.com: Global precious metals market size, 2022; (iii) Canada Energy Regulator: Canada's energy future, raw bitumen production by type – evolving policies scenario, 2021, (iv) finance.yahoo.com: Investing in gold: Global gold mining market size is projected to grow at 3.5% CAGR, exceed $260 billion by 2030, September 2023.

these roles. The next ten years will see a significant reduction in the number of senior tailings facility engineers practicing, and there are not enough younger engineers available to backfill the current and expected demand.

The International Commission on Large Dams (ICOLD) has developed a world-wide registry of TSFs that has catalogued over 24,000 entries (Rana and Small, 2024). As noted above, the volume of tailings to be stored will increase by more than 3% per year over the next six years, which means more TSFs and larger TSFs.

Repurposing or expanding older TSFs to meet storage needs with the aim of reducing additional disturbance area, as well as upgrading those that were not built to today's standards will be undertaken, which pose significant technical challenges. For example, demonstrating the safety of existing TSFs, particularly those that employed classical upstream construction (i.e., upstream construction on unconsolidated fine tailings), is very complex. Furthermore, water conservation is becoming more important to operators and communities due to climate change and increasing regulation of the use of "clean water" and requirements on discharge of water to recipients.

From some perspectives, the year 2030 does not seem that far away, but, after reflecting on what has been accomplished in the past six years, the authors selected the year 2030 for this paper; six years from when this paper was prepared.

A number of guidance documents have been issued related to TSF safety. Table 1 shows that for the six-year period from 2011 to 2017, there were at least seven major guidance documents issued, whereas, for the following six years, 2018 to 2024, there were at least another nine (despite the industry navigating a global pandemic).

A major contribution to recent developments was Dr. Morgenstern's Victor de Mello lecture on performance-based risk-informed design (Morgenstern, 2018), which has influenced and impacted many of the guidance documents listed in Table 1 as well as regulations.

Additional key changes that have occurred over the past six years include:

- In 2018, there was significant trepidation associated with the EoR concept as a viable career path. Whereas in 2024, more young engineers see this as a career path (Prince and Boswell, 2023).
- In 2018, a limited number of dam safety surveillance programs had automation, but in 2024, there is extensive automation, remote monitoring, cameras, and monitoring centers.
- In 2018, AI was on the horizon, but in 2024, AI is being used to support complex surveillance data gathering and interpretation.

Table 1: Tailings dam safety guidance documents within the mining industry from 2011 to 2024

Year	Organization	Document title
2011	ICOLD	Bulletin 138: Improving Tailings Dam Safety
2011	ECCC	Guidelines for the Assessment of Alternatives for Mine Waste Disposal
2012	ANCOLD	Guidelines on Tailings Dams
2013	ICOLD	Bulletin 153: Sustainable Design and Post-Closure Performance of Tailings Dams
2014	CDA	Mining Dams Bulletin (Revised 2019)
2014	OSTDC	De-Licensing of Oilsands Tailings Dams
2011-2024	MAC	Updates to Guides on Management of Tailings Facilities and Developing OMS Manuals
2019	ICMM	Integrated Mine Closure: Good Practice Guide
2020	GTR	Global Industry Standard on Tailings Management (GISTM)
2021	ICMM	Tailings Management: Good Practice Guide
2021	CDA	Bulletin: Tailings Dam Breach Analysis
2021	ICOLD	Bulletin 181: Tailings Dam Design, Technology update
2022	SME	Tailings Management Handbook
2022	ICOLD	Bulletin 194: Tailings Dam Safety Guideline
2022	ACR	Assessment Tool for Landforms in the Oilsands
2011-2024	MAC	Updates to Guides on Management of Tailings Facilities and Developing OMS Manuals

ICOLD = International Commission on Large Dams, ECCC = Environment and Climate Change Canada ANCOLD = Australian Commission on Large Dams, CDA = Canadian Dam Association, OSTDC = Oil Sands Tailings Dam Committee, MAC = Mining Association of Canda, ICMM = International Council on Mining and Metals, GTR = Global Tailings Review, SME = Society for Mining, Metallurgy and Exploration, ACR = Alberta Chamber of Resources.

The authors believe that over the next six years, much can be done to maintain the momentum and to do more than just "continuous improvement." This paper explores additional initiatives and advancements in the next six years presented as a collective vision for 2030.

Method

To support the creation of a vision of what tailings facility engineering could look like in 2030, the authors reached out to colleagues and leaders in the tailings space around the world with a survey questionnaire to obtain a global perspective. An extensive questionnaire was issued to over 240 tailings practitioners covering the following topics:

1. Tailings technologies and deposition.
2. Closure strategies.
3. Characterization of tailings and foundation soils.

4. Surveillance of tailings facility performance.
5. Design approaches for slope stability assessment.
6. Guidance documents for tailings facility safety design.
7. Building competency and capacity.
8. Artificial Intelligence.

Over 60 people responded to the questionnaire (as of the end of May 2024) from 15 countries; the majority of the responses were from Canada and the United States. Presentations were given in Canada in May and June 2024 on the vision for tailings facility engineering in 2030 and additional input was obtained from the audience members from those presentations. The authors also consulted with several key people and organizations within different areas of tailings facility engineering.

This paper will also be presented at the ICOLD Symposium on Dams for People, Water and Environment and Development in India in September 2024 and at the Panamerican Conference on Soil Mechanics and Geotechnical Engineering in Chile in November 2024. The questionnaire results and an updated version of the paper will be available at the end of 2024 through the ICOLD committee on tailings dams and waste lagoons (Technical Committee L).

In this paper, the authors endeavored to summarize the results of the questionnaire and input from contributors. This paper was not prepared on behalf of ICOLD Committee L.

Building competency and capacity

Current situation

As noted above, there is, and will likely continue to be, a shortage of qualified engineers providing services for TSF safety and this topic was considered the most important by the respondents. Hence, this topic is presented first in this paper.

On the one hand, the field of tailings facility engineering is challenging, complex, interesting, and rewarding. It is no longer viewed as commodity engineering, and the professional contributions are viewed as being of value by mine owners and regulators. There are many training programs being offered by universities and technical associations. Consulting companies and mine owners are also providing in-house training.

On the other hand, with the growth in tailings, the limitations associated with how TSFs can be developed, and the higher expectations of regulators and stakeholders, the demands of tailings facility engineering will increase. Some universities are offering graduate degree programs in tailings engineering, but there is limited training at the undergraduate level and more master's level programs are needed.

Mining is not considered an attractive career opportunity to young people. Abenov et al. (2023) conducted a survey of people between the ages of 15 and 30 and asked if they would be interested in working in one of nine different sectors, including health care, financial services, construction, and mining. Mining ranked last among the nine sectors, with 70% of the respondents saying that they would not be interested in working in the mining sector. One possible reason for this is that there could be a disconnect between the value that mining provides and the perception of young people; that is, they do not realize that most of the conveniences and necessary infrastructure that they have comes from mining. These conveniences and infrastructure are taken for granted.

Vision for 2030

To help address the challenge of the human resources shortage, the authors recommend establishing the discipline of "Tailings Management Professional" (TMP) as a first step. In this context, tailings management includes the design, construction, operation, and closure of systems that are used to produce tailings and the facilities that are constructed to store tailings. This would include the following facilities:

- Conventional slurry, thickened, paste, filtered tailings.
- Co-mingled, co-disposed, co-deposited, and co-placed mineral residue (e.g., tailings and waste rock, fines and coarse discards, etc.).
- Containment facilities for sludge and sediment from process, water treatment plants, or runoff.

Ash lagoons for power-generating plants could also be covered here.

The TMP should have knowledge in the areas of knowledge listed above (in the Introduction) as tailings facility engineering, with a specialty in one or more of those knowledge areas and a general knowledge of the others.

ICOLD is forming a working group to develop the scope for the TMP discipline and will work with other organizations to define it. With this discipline defined, it will be possible to identify the TMP discipline as a distinct career path for young engineers, rather than, as so many do now, "just falling into tailings engineering."

Further, it will be possible to develop focused training that supports the development of TMPs. As noted above, there is a significant amount of training occurring, but there is not a comprehensive database that captures this training. Such a database is being developed by the Society for Mining Metallurgy and Exploration (SME), which will allow organizations to list the training they are providing. For example, Organization X may be planning to conduct slope stability training in Africa and can post that training to this database, indicating if it is in person and/or virtual. Then, engineers from around the world can search the database for slope stability training, find the one in Africa and determine if it meets their requirements.

With the discipline of TMP defined and a database offering current available training available, then a gap analysis can be done between what is required and what is currently being offered. Plans can then be developed to fill these gaps and provide additional opportunities to develop competency and capability.

One of the survey respondents recommended that graduate programs be developed to focus on the development of TMPs, but not have a significant research component. This program would be course-based and structured to run for one year. Because it would not have a research component, it would not be funded by research grants, which would require funding from industry to help support students who are interested in taking this program. Colorado State University and the University of Alberta are both considering this approach and plan to work with other universities to advance this concept.

As a result of discussions held with colleagues in the industry, the authors included the following question in the questionnaire: "Should there be an international certification program for tailings facility engineers?" There was a wide range of responses, from "Yes, this is important" to "No, this is not required." The reference to certification was not in the context of receiving a certificate after having completed a set of courses. Rather, it was intended to be a certification that is received after having also obtained experience from course work. There are some advantages to certification, but there are several challenges with establishing an internationally recognized certification program, which would require significant infrastructure to support. There was sufficient interest in this topic that ICOLD is creating a working group to explore the issue and provide a recommendation on whether such a certification is of value and, if so, then what such a program could look like. This would be done in concert with other key organizations to help decide whether certification should be pursued or not.

Given the disconnect between the perception of mining and the benefits of mining (and therefore tailings management), more work needs to be done by organizations such as ICMM, MAC, CIM, SME, etc. to educate young people about the benefits of mining to society and the value of being involved with responsible tailings management.

Tailings technologies and deposition

Current situation

The vast majority of existing TSFs worldwide employ conventional slurry-deposited tailings. Slurry deposition often results in loose, saturated deposits that are potentially prone to liquefaction.

Filtered tailings technology has evolved but the actual number of filtered tailings facilities is not quantified. The TSF registry that has been developed by ICOLD and the general consensus from the survey is that dewatered tailings operations (including high-density thickened, paste, and filtered tailings) make up less than 1% of existing tailings operations. The authors' experience, reinforced by the survey responses, is as follows:

- Filtered and paste tailings technology initially developed in the 1990s, but widespread application of this technology has been limited by economics, operational challenges at high throughputs, and technical challenges in wet climates.
- Combined management of tailings and waste rock (i.e., co-mingling, co-disposal, co-depositing, co-placement, etc.) is gaining traction in research trials but has not been fully proven at operational scale (Burden and Wilson, 2023).
- For new tailings facilities, the general approach to technology selection often involves performing a structured multi-criteria alternatives analysis of feasible sites, technologies, and strategies for tailings management (GISTM Requirement 3.2). However, this practice has not been widely adopted by the industry and is required by regulation in only a few jurisdictions, for example, British Columbia, Canada (Ministry of Energy, Mines, and Low Carbon Innovation, 2024).
- Water management is a key driver in tailings technology selection, with mines in arid climates opting to recover water in the process by dewatering to reduce evaporation losses, while mines in wetter climates tend towards conventional slurried tailings and managing surplus water via large supernatant ponds (MEND, 2017).
- Tailings geochemistry, including acid-generation potential, leads to a generally binary choice between wet or dry cover solutions, but there is a movement toward dry covers for closure with respect to risk (post-closure dam failure). Limited effort is put into designing tailings processing to reduce future risk, such as segregation of tailings into geochemically non-reactive and reactive streams and management of reactive streams in separate facilities. Tailings geochemistry is gaining much more importance in many mining districts, with a focus on source control.

Vision for 2030

The consensus among the survey respondents is that conventional slurried tailings will continue to be the norm for new tailings facilities in 2030. However, the selection of conventional tailings technology as the best available technology (BAT) for a site will need to be objectively demonstrated through tailings alternatives assessments (ECCC, 2011), supported by risk assessments to define design and operational controls. This position is based on a view that classical upstream construction methods will cease and be replaced by centerline construction, modified upstream construction (i.e., upstream construction that employs an engineered structural zone such as a compacted tailings beach) or downstream construction.

It is envisioned that filtered tailings will continue to gain popularity due to technological advances that allow scaling to throughputs of greater than 50,000 tonnes per day. However, filtered tailings will likely still represent a low percentage of future tailings facilities due to the high capital and operating costs, and the inability to match the scales of the world's increasingly high-throughput low-grade porphyry mineral

deposits. Rather, it is likely that filtered tailings may find a place as a feasible companion technology to support a primarily conventional operation, with the filtering process used to create dewatered tailings for use as a construction material for perimeter embankments, or to create smaller-scale deposits of reactive tailings concentrates that would be managed outside of a larger conventional facility. Such applications would benefit from guidance documents specific to filtered tailings with emphasis on hydrotechnical, geotechnical, and geochemical considerations, including surface water management, unsaturated strength, dust control, and seepage behavior. Some documents have been developed, but are not publicly available.

Multi-criteria alternatives analysis will move away from just focusing on the tailings facility and will include the overall mine plan that optimizes the mining operation, in concert with the tailings plan and closure plan. Factors such as water conservation and climate change will be given more prominence in these analyses.

Regardless of the tailings technology selection, we see tailings geochemistry taking a more active role in tailings-related decision-making due to increasing regulation of surface water and groundwater, and a perceived lack of appetite in the investment community for planned long-term water treatment in new mining propositions. The MAC tailings working group plans to update their *Tailings Guide* by 2026 to include more emphasis on geochemical failure modes in its guidance on risk and alternatives assessment.

Combined, the above vision for tailings technology selection requires the adjustment of classical financial models (e.g., net present value, NPV) to capture the true lifecycle cost or benefit of the tailings technology without discounting long-term costs to low present values. Although the world financial system is unlikely to make such a step-change by 2030, it is hoped that the momentum achieved by PRI and UNEP through the development of the GISTM will continue.

Closure strategies

Current situation

In 2024, there is no one global definition of "closure." ICOLD's Bulletin 194 (Preprint) – Tailings Dam Safety defined closure as: *A planned, final cessation of tailings disposal and the modification/engineering of the tailings dam with the objective of achieving long-term physical, chemical, ecological, and social stability, and a sustainable, environmentally appropriate after-use* (ICOLD, 2022). GISTM defines safe closure as: *A closed tailings facility that does not pose ongoing material risks to people or the environment which has been confirmed by an ITRB or senior independent technical reviewer and signed off by the Accountable Executive.* (GISTM, 2020).

The ICMM gap analysis of closure guidance documents for responsible closure (Slingerland and Hedley, 2023) differentiates "responsible closure" from "safe closure." The definitions of the two are:

- responsible closure means a final closed state where environmental, ecological, and social conditions are incorporated; and
- safe closure is a physically and chemically stable final closed state.

Because there is no consensus on the appropriate term at this time, the authors adopted the term "closure" for this paper, including all aspects of closure, i.e., both responsible and safe closure.

The survey responses indicated that the concept of TSF closure could encompass a broad range of considerations such as:

- long-term vision;
- alternative land use;
- environmental and social integration;
- regulatory compliance;
- limiting risk to humans and the environment by long-term physical, chemical, ecological, and social stability;
- principles related to ALARP (As Low as Reasonably Practicable); and
- limiting credible failure modes, i.e., elimination of potential failure modes or alternative ways to manage remaining risks/failure modes.

When it comes to care after closure, opinions on monitoring and maintenance differ. Some view safe or responsible closure as a state where no further human intervention is required, while others hold that, in some cases, there may be a need for ongoing monitoring and maintenance in perpetuity.

Many jurisdictions require closure plans and promote, or require, progressive closure at the permitting stage as well as financial guarantees for closure. Some jurisdictions require TSF closure plans as part of permitting conditions, prior to a mine starting or expanding. Efforts are being made by the industry to improve dialogue with stakeholders with respect to closure, but to gain the trust required for a constructive and transparent dialogue takes time.

At many facilities (particularly those that are not acid-generating), tailings deposition plans include reducing water volumes as the operation proceeds and, ultimately, the removal of impounded water after operations cease. Monitoring is planned to continue until the results show stabilized conditions, which in some jurisdictions are defined to be up to 30 years or so. Many companies are improving how they deal with closure, but implementation of today's ambitions varies across the industry.

The importance of tailings management and safe or responsible TSF closure is gaining recognition. Research initiatives are ongoing in several specialized fields of closure. Some mining companies have developed their own closure guidance documents.

Many mining companies use the economic principle of NPV to make decisions about whether to proceed with an operation or an option. NPV favors lower up-front capital and operating costs and encourages postponing costs and rehabilitation works, thus often creating significant liabilities at the end of a mining operation at a time when there is no revenue, or the mining company is not viable.

Vision for 2030 regarding TSF closure

Based on the results of the survey, the vision for 2030 when it comes to TSF closure is as follows:

- There will be a global definition of "closure." This will help to achieve consensus on closure strategies.
- There will be an engaged, open, and meaningful dialogue between all parties involved in TSF closure (i.e., mining companies, regulators and authorities, consultants, communities, NGOs, and other stakeholders) based on mutual trust and transparency.
- Global guidance documents and technical manuals will be developed that will provide guidance on goals to be achieved, closure criteria, acceptable levels of risk and the process of how to achieve closure, as well as an appropriate level and detail of closure cost estimates to reach a suitable accuracy to be relied upon.
- The knowledge and understanding of TSF closure will be improved and there will be improved acceptance of closure practices among all parties involved, including involvement and collaboration with academia.
- It will be acknowledged that the TSF owner will likely not be the future land user, and therefore will not be solely responsible for the closure vision. Therefore, all parties involved will take part in the process and take shared responsibility in determining the vision through a meaningful dialogue and process.
- TSF closure will be an adaptive process from first planning through design and operation to post-closure, where the design will include: a lifecycle perspective, processing methods to either limit tailings generation or produce benign tailings, integrated waste management (i.e. tailings, waste rock and possible other waste), long-term geotechnical aspects (including liquefaction, erosion etc.), geomorphological/landform design, chemical stability, water management (including surface water, acid rock drainage (ARD) etc.), climate change, and risk assessment and management.
- Large-scale trial areas will be used to test proposed closure designs.
- Financial models and systems will be developed for operating and new TSFs that support progressive closure, encompassing real costs and economic risks over time, and appropriate value will be paid to social benefits.

- All TSF operations will have integrated closure into operations, meaning operation is equal to preparing for closure, with the optimal goal being mining for closure, i.e., mining is done for two reasons: a) to extract a metal/mineral; and b) to create a new landscape/land use.
- There will be effective monitoring and maintenance systems available for closure monitoring and maintenance in perpetuity.
- TSFs will have a Reclamation Designer of Record (RDoR) who is responsible for closure design and progressive rehabilitation works over the life of the facility. The skill sets of an RDoR are different than the typical EoR. This framework may also include an Independent Reclamation Review Board (IRRB), like that of an ITRB but more multidisciplinary. Alternatively, the closure/reclamation discipline could be included in an ITRB.
- Third-party audits, covering technical, environmental, social and financial aspects, will be done for closure plans and closure for all TSFs.
- Responsibility for historical TSFs that have been abandoned by irresponsible operators will be allocated to bodies/parties with resources to properly close these (not just taxpayers) and there will be cost-effective strategies for closure of abandoned and historical TSFs.

Integrating the management of all waste materials produced, environmental sustainability, and economic development will be prime milestones in the circular economy (Das et al., 2024).

Many actions are required to achieve the vision for 2030. The following initiatives, underway or planned, will not fully address the requirements, but will make important contributions:

- The CDA Mining Dams Committee is developing closure guidelines and criteria for when a dam is no longer a dam and is developing guidance on risk-informed closure design.
- SME is developing a closure handbook that will provide comprehensive guidance, and details related to closure. Many of the topics identified above will be addressed in this handbook.
- MAC and ICMM are developing or updating their closure guidance.

The efforts by MAC, ICMM, SME, and CDA will be coordinated.

- The LDI[2] is developing detailed guidance on landform design.
- Ten mining companies have established the GeoStable Tailings Consortium[3] where large-scale closure field tests are run.

[2] The Landform Design Institute have a mission to make landform design routine in the mining industry by 2030 and focus on governance, leadership, and education in landform design.
[3] A consortium led by Newmont with Antamina, Barrick, BHP, Freeport McMoRan, Gold Fields, Teck, and Vale.

A change of the NPV financial model is required, but it is not clear at this time how the financial models can evolve to place more emphasis on low-risk closure solutions. This will require efforts by a number of stakeholders.

Despite current efforts, the challenges that are faced highlight the need for a comprehensive, transparent, interdisciplinary, and multifaceted approach to achieve closure of TSFs (safe or responsible). To design with the end in mind, building TSFs to final landform designs from the beginning and viewing closure costs as part of the lifecycle of TSFs is necessary. In support of this, flexibility and continuous update of closure plans are required to adjust for changes in mine planning and the development of good closure practices.

Characterization of tailings and foundation soils

Current situation

The geotechnical community has made great strides over the past century, refining site characterization tools that were introduced starting in the 1930s, such as the cone penetrometer (now with many add-ons) and the triaxial compression test (now the standard for critical state line [CSL] testing). These tools, and others, allow for detailed engineering characterization of soil elements both in-situ and in the laboratory. Fourie et al. (2022) provide a detailed account of the standard of practice for the characterization of mine tailings with detailed discussions on the applications of such tools. However, reliance on the tools alone, without appropriate consideration for geological and geomorphological processes, can lead to errors. Furthermore, lack of recognition of the fundamental mechanics of soil behavior (especially understanding of critical state soil mechanics [CSSM]) has contributed to the propagation of what Dr. Morgenstern termed "weak engineering" (Morgenstern, 2018).

Historically, budgeting to support extensive site characterization efforts for tailings facilities was constrained by short-term operational mindsets (e.g., focusing on characterizing only the minimum requirements for a single dam raise). These constraints have now been largely removed in most parts of the world by evolving Owners' commitments and regulatory requirements to develop an integrated knowledge base for the whole TSF (GISTM Principle 2), underpinned by a detailed site characterization model.

The consensus among the survey respondents is that most of the tools required for adequate site characterization are already available today (e.g., piezocone, shear vane, piston sampling, advanced laboratory testing, etc.), but the toolbox could be better organized, and the tools sharpened. Specific challenges are:

- Methods for establishing potential for liquefaction, especially in the absence of a significant earthquake triggering mechanism. There are indirect methods available with the CPT and

laboratory testing, but there is no direct method of discerning the in-situ void ratio of the tailings, which can be used to inform the liquefaction potential.

- Methods for discerning brittleness of tailings. As described in ICOLD preprint of Bulletin 194 (ICOLD, 2022), brittleness is a key aspect of discerning the risks associated with a TSF that has contractive and potentially liquefiable units in the dam and/or foundation. Methods for discerning brittleness are limited to laboratory testing, which has challenges with respect to sample quality and the extension of findings to field situations.
- Methods for assessing the post-liquefaction/large strain/residual strength of brittle materials.
- Methods for characterizing and understanding the behavior (for both strength and seepage) of unsaturated tailings are severely limited, and these will be essential for assessing and demonstrating that "safe/responsible closure" of tailings facilities can and has been achieved.
- Methods for understanding the evolution of geotechnical and hydrogeological properties of tailings (and mine wastes in general) in light of long-term geochemical weathering.

Vision for 2030

The vision for site characterization in 2030 is to fully embrace the principle of an interdisciplinary knowledge base for tailings management. This involves developing and regularly updating integrated site characterization models.

Site characterization should be treated as an iterative risk-informed process, in concert with the design process where conceptual models of the foundation, tailings embankments, and tailings deposition process are developed based on a geotechnical, geological, geomorphological, and hydrogeological understanding of the site and the tailings depositional scheme. Involving more engineering geologists in this activity would be beneficial. Once this is done, uncertainty (both geological and depositional) can be characterized and used to inform site investigation targets and methods; each drill hole or laboratory test should have a clear objective linked to reducing model uncertainty or facility risk.

Liquefaction characterization and unsaturated soil mechanics was a specific theme in the survey responses. Based on the survey results, the vision for 2030 includes:

- Characterization of liquefaction potential and post-liquefaction strength with the ability to accurately estimate in-situ void ratio is standardized and common practice in the industry.
- Characterization of brittleness is standardized and common practice in the industry.
- The impact of fabric/layering on tailings behavior is understood.
- Better methods for recovering "undisturbed" samples of fine and coarse tailings have been developed.

In addition, for large facilities, methods will be developed to characterize the soil between discrete investigation points.

Several university and industry groups are currently tackling these challenges through ongoing research and guidance initiatives. For example:

- The University of Western Australia (UWA) recently completed a round robin on CSL testing involving 15 independent laboratories around the world. The results indicated that the best reproducibility was obtained using end-of-test soil freezing to measure void ratio, which has been accepted as the industry standard (Reid et al., 2021).
- The University of Toronto (UoT) is researching the impact of partial drainage conditions on CPT penetration using calibration chamber testing, which indicates that the negative pore pressures observed in some tailings CPTs are indicative of dilative behavior (Lizhi et al., 2024).
- The ICOLD Bulletin 194 (2022) provides design guidance on soil brittleness and liquefaction potential with a flowchart on application of strength concepts (peak or residual) to factor of safety computation.
- Drilling contractors are adapting the nuclear and magnetic resonance technologies to in-situ tools for in-situ density (i.e., void ratio) and water content estimation.
- There is active research and development to incorporate pore pressure measurement on the electric vane shear test to overcome the uncertainty of drained conditions during vane shearing.

To continue moving forward, there is a need for innovation in non-destructive/non-invasive technologies that can provide screening level information or reduce uncertainty in conceptual site characterization models. This could take many forms, but emphasis should be placed on vadose zone geophysical surveying from the surface to estimate degree of saturation in tailings deposits, stacks, and cover systems.

To make this vision a reality, there also needs to be a focus on widespread sharing of common characterization data (e.g., adjacent operators in mining districts sharing data) and the formation of groups like the Canada's Oil Sands Innovation Alliance (COSIA) or the GeoStable Tailings Consortium to pool research funding and resources to develop solutions to common challenges.

Surveillance of tailings facility performance

Current situation regarding surveillance

The importance of surveillance of TSFs has become more apparent to mine owners; not only to provide information on the performance of the TSF and provide early warning of potential concerns, but to support the adoption of the performance-based design approach. There is widespread use of "point" measurements

(e.g., vibrating wire piezometers [VWPs], survey prisms, inclinometers, and seepage monitoring weirs) with automation of the instruments and data gathering becoming more the norm than the exception. However, the data management interfaces can be cumbersome and there are challenges with false positives in so-called "real time" data.

Cameras are in place for many dams. Monitoring centers are being established that have computer monitors showing the view of the TSF and the dams and the instrumentation results. Alert levels are set for the instrumentation that can trigger a response to preserve the safety of the TSF.

Drones, often equipped with survey capability, are commonly used to observe the TSFs, and INSAR[4] has proven to be an effective tool for monitoring features on a broader scale than "point" measurements.

Providers of surveillance methods have been at the cutting edge of developing new approaches and technologies, with many owners embracing these innovative techniques.

However, the surveillance methods are not necessarily linked to a comprehensive and realistic understanding of the potential failure modes, particularly for dams that have contractive elements in the structural body of the dam or foundation that can fail in a brittle manner. If the dam can fail by static liquefaction, then monitoring movements and pore water pressures to guard against static liquefaction may not provide adequate warning time in the event of a failure. Establishing trigger levels based on stability analyses alone can be misleading. Deformation models with appropriate constitutive models based on comprehensive field and laboratory testing programs can provide insight into the possible triggering mechanisms and a determination of whether an observational approach can be applied to this situation.

However, there have been instances of a "false confidence" being established that the surveillance will help to protect from failure in these circumstances. If a seismic event were to occur and cause a dam to fail by liquefaction, surveillance may be of little value other than to support the back analysis of the failure.

Internal erosion can occur at discrete points within a dam that are distant from where the instrumentation is established and cannot be discerned by point measurements.

Vision for 2030

By 2030, we anticipate the following to have been achieved:

- Surveillance programs will be targeted to address instability and internal erosion failure modes through the use of performance-based design to support slope stability assessment and seepage controls (refer to section above entitled "Current situation regarding surveillance"). Or it will have been demonstrated that surveillance cannot be effective to guard against those failure modes, that

[4] INSAR = Interferometric Synthetic Aperture Radar

the observational approach cannot be used, and additional controls need to be implemented to preserve the safety of the facility. ICOLD is developing a new Bulletin on surveillance that will address these items.

- Automation and data management interfaces will be improved to the point that the surveillance information can be directly integrated with engineering models to support calculations related to performance (e.g., deformations, factor of safety, seepage, etc.). AI will support the data acquisition and interpretation. Because of the massive amount of data that will be available, data scientists will be employed to assist with gathering and processing the data so that it can be interpreted effectively by engineers and operators. This will be led by service providers and data scientists.
- Methods of monitoring on a more areal extent will be commonplace. INSAR and drones are widely used, but other systems are evolving that can monitor performance over an aerial extent:
    - Fiber optic cable technologies can detect changes in temperature (which can provide indications of seepage), tension (to indicate deformations) and acoustic properties (to indicate changes in the material) and can be placed in critical positions of the dam section where seepage and deformations are expected and/or critical.
    - Permanent geo-electric monitoring of a dam and its foundation can be undertaken that can track the location of the phreatic surface over the length of a dam and identify areas where there may be concentrated seepage.
    - Deep penetrating radar and muon radiography from satellites can provide information on the internal configuration of a dam.

These initiatives are being advanced by service providers.

Design approaches

Current situation

With respect to slope stability assessment, limit equilibrium methods (LEMs) are the most commonly used tool, with conservative approaches adopted for dams that have contractive elements that are potentially liquefiable. However, there are a number of limitations with LEMs that need to be recognized when undertaking these analyses and establishing suitable targets for factor of safety (Krahn, 2001).

In 2018, Dr. Morgenstern (Morgenstern, 2018) advocated for the adoption of performance-based design for slope stability assessment that integrates a comprehensive understanding of the geotechnical conditions of the dam and foundation, performance information (deformations and pore water pressures), and deformation models to simulate the behavior of a TSF. Measurable performance objectives are established and as a TSF is constructed and performance information is obtained, the performance is

compared to the objectives and modifications made to the design, if necessary. “History matching” is done by updating the deformation model to match the performance information, which permits refinements to the understanding of the TSF and project future performance. Performance-based design has proven to be effective in cases in western Canada (Gelletta et al., 2023; Nguyen et al., 2022; Nguyen et al., 2023; Quinn et al., 2014) where water retaining dams built on pre-sheared clay shale have experienced significant deformation. Limit equilibrium analyses were not sufficient to represent the conditions and establish the potential for failure. Three-dimensional deformation analyses were able to demonstrate that the dam was safe and that the movements were tolerable.

For dams with contractive elements that are potentially liquefiable, case studies are being developed that show that the classical approaches for predicting liquefaction due to seismic events are possibly conservative. The use of deformation modeling, with appropriate constitutive relationships, may provide predictions of deformations that could occur as a result of a seismic event, rather than liquefaction (Kafash et al., 2021).

ICMM has provided training materials on performance-based design and CDA is also developing training materials.

LEM will still play an important role for stability analysis (when done properly and recognizing the associated limitations) and can be supplemented by performance-based design methods, particularly for complex geometries with multiple soil units.

Performance-based design can be extended to other facets of design such as flood control, seepage control, and internal erosion.

Risk informed design is an overarching philosophy that applies to all facets of design that account for the risks that are posed by a TSF. Because of the potentially significant losses to a mine owner and the downstream environment in the event of a TSF failure, ICMM recommends that extreme loading criteria be adopted for TSFs. The GISTM recommends that consideration be given to adopting extreme loading criteria. The GISTM states the following as Requirement 4.2:

> *A. Develop preliminary designs for the tailings facility with external loading design criteria consistent with both the consequence of failure classification selected based on current conditions and higher Consequence Classifications (including ‘Extreme’).*
>
> *B. Informed by the range of requirements defined by the preliminary designs, either:*
>
> 1. *Implement the design for the ‘Extreme’ Consequence Classification external loading criteria; or*
> 2. *Implement the design for the current Consequence Classification criteria, or a higher one, and demonstrate that the feasibility, at a proof-of-concept level, to upgrade to the design for the ‘Extreme’ classification criteria is maintained throughout the tailings facility lifecycle.*

Many owners have adopted this approach, but there are exceptions, particularly for TSFs that do not have life safety consequences.

Dam breach analyses are an important tool to understand the potential consequences associated with a TSF, and thus the risks. Significant progress has been made in the past five years on this topic, including the issuance of the Tailings Dam Breach Analysis Technical Bulletin by CDA in 2021 and the establishment of a consortium of universities in Canada to form CanBreach. The University of British Columbia, Queen's University, and Waterloo University formed CanBreach in 2019 with the goal of better understanding the tools and methods available to simulate a tailings dam breach. Part 1 of the research program was completed in 2023, and Part 2 is planned to commence in 2024. Part 1 advanced the understanding of the physical processes of a tailings dam breach and the outcome of a breach, as well as the computer models that are available to predict the extent of a breach. Part 2 will continue this work with further research on computer modeling, the released volumes of tailings, and the behavior of unsaturated tailings during a breach.

A key driver of TSF design can be the geochemical considerations, especially as they relate to closure and how the initial designs and operations need to account for this.

Vision for 2030

By 2030, we anticipate the following:

- Performance-based design for slope stability assessment will be a widely recognized and accepted approach.
- LEM analyses will still play an important role in design.
- Performance-based design for slope stability assessment and LEM will be viewed as complementary.
- Fully coupled deformation and seepage models will be able to achieve results closer to reality.
- The concepts of performance-based design will be extended to other facets of design as noted above.

For performance-based design for slope stability assessment to gain widespread acceptance, additional case studies need to be developed and presented in the literature with a critical view to the limitations associated with deformation modeling. Conferences and training sessions should convene targeted sessions related to performance-based design and how it can be integrated with LEMs.

A challenge that will limit the advancement of performance-based design is regulatory capacity; the ability of the regulators to understand performance-based design as opposed to simply meeting a factor of safety requirement.

With respect to dam breach analyses, the CanBreach consortium is initiating Part 2 of their research that will explore:

- Unsaturated soil behavior and how this should be considered in a tailings dam failure.
- Breach processes and how tailings dam breaches actually form, which will enable better predictions of failures associated with tailings dams that are buttressed with rockfill.
- Improved correlations between modeled failures and actual failures.

The geochemical aspects will be given greater prominence in the design in support of closure plans that will properly address these aspects and not simply result in pump and treat scenarios.

Guidance documents for tailings facility safety design

Current situation

As noted in Table 1, there are many guidance documents available to support the design of TSFs and some respondents to the questionnaire stated that there was sufficient guidance, i.e., "we should use what we have." However, there is a recognition that the state of practice for TSF engineering is evolving rapidly, and hence, several organizations are modifying their current guidance or developing new guidance related to TSF safety. These include:

- CDA – modifying the Mining Dams Bulletin that was issued in 2014 (revised in 2019) and the overarching dam safety guidance.
- MAC – modifying the tailings management guidance.
- United States Society of Dams (USSD) – developing a tailings dam safety guidance for the US.
- CDA and USSD – developing guidance for the EoR role and for risk informed decision making.
- SAICE (South Africa Institute of Consulting Engineers) – updating the Civil South Africa National Standard 10286 Mine Residue Code of Practice to be more aligned with GISTM.

A number of regulatory jurisdictions around the world have developed or updated their regulations related to TSF safety.

The questionnaire identified a number of gaps related to guidance, including:

- closure (see section above titled "Vision for 2030 regarding TSF closure");
- filtered tailings;
- methods for characterizing tailings and foundation soils; and
- spillway design.

Vision for 2030

As noted above, a tailings closure handbook is in progress by SME that is expected to be completed before 2030. Also, the LDI will have developed their guidance on landform design. The following additional guidance documents should also be available:

- Updates to the MAC tailings management guides.
- A document on filtered tailings that integrates the process and geotechnical aspects. This is to be led by representatives from industry who specialize in filtered tailings, supported by input from ICOLD and other organizations on the geotechnical aspects.
- A revised version of ICOLD Bulletin 194 that provides additional guidance on site characterization, hydrogeology and hydrology, spillways, undrained stability analyses, and brittleness.
- An ICOLD Bulletin on surveillance of tailings dams.

There will likely be additional guidance documents developed in addition to these.

Artificial intelligence

Current situation

Six years ago, AI was hardly discussed. Today, AI seems to be incorporated into our basic computer software (e.g., Microsoft Copilot). Regarding TSFs, AI is, in some cases, being used in surveillance activities to support the gathering and processing of large amounts of data. Discussion and research are ongoing regarding future possibilities and opportunities with AI. Some of the survey respondents are very interested and positive about AI, whereas others are more skeptical and negative and think AI is overhyped.

From the questionnaire there was a concern expressed with the increased computing power and AI as that might reduce emphasis on learning the fundamentals of tailings engineering. The authors agree that the use of AI does not replace the need for humans to understand how to do a task, but should be used as a means to improve efficiency of a task that the person already knows how to do well.

Vision for 2030

From the responses to the questionnaire there is no clear vision for 2030, and some emphasize a vision can only be for 2040 or beyond. However, the authors believe that by 2030 we will see AI used frequently within the industry and for TSFs within the following areas:

- Managing, processing and analyzing large data sets (weather, hydrology, monitoring – especially on-line monitoring) to identify trends and deviations to help in understanding the TSF performance.
- Integration of data sets such as mineralogy, geology, hydrology, and seismology to provide a more multifaceted picture of the TSF conditions.
- Pre-processing of data and prediction of operational aspects of tailings management to help in identifying potential risks and predicting future performance.

- Numerical modeling for stability and deformation analysis as well as breach inundation simulations.
- Enhanced adaptive management by monitoring real-time stability, identifying trends, anticipating risks, etc.
- Training programs and live guidance and support for operations.
- Reviewing literature and documents, summarizing information/reports, and reporting to standards/regulators.

Overall, while there is cautious optimism about AI's potential in tailings facility engineering, there is also a strong emphasis on the need for human oversight and the importance of integrating AI as a supportive tool rather than a replacement for expert judgment. However, AI could be part of the solution to the coming challenge of fielding enough TMPs to meet the growing demand.

To reach the vision for 2030 the industry will have to have an open mind towards AI and invest time and money in developing methods to use this potential tool that in many ways can improve, speed up and simplify data analysis, predictive modeling, numerical simulations, surveillance, and training, and enhance decision-making and risk management in TSF engineering. In addition, we cannot lose sight of the importance of understanding the fundamentals of tailings engineering and the role that models should play.

Conclusion

Through this work and while reviewing the provided information, the authors have been impressed by the overall developments and achievements in recent years and have been even more impressed by the anticipated and possible developments ahead to 2030. All the people who contributed to this work through the questionnaire, interviews, and discussions have shown a positive attitude to this work, and have displayed a general optimism regarding the changes and improvements on the horizon. The aim is to keep the momentum of improving tailings facility engineering and, with the support of ICOLD's Technical Committee L on Tailings Dams and Waste Lagoons and many other organizations, to work towards achieving the vision of what tailings facility engineering can look like in 2030.

We will publish a comprehensive summary at the end of 2024 of this work, including further input from this and coming presentations during the autumn.

Chapter Two
Analysis

Numerical Simulation of Trigger Mechanisms of Static Liquefaction Applied to a Tailings Dam

Miguel A. Villalobos Bravo, Geocoba Projetos de Engenharia, Brazil
Richard Witasse, Seequent, The Netherlands

Abstract

Various possible triggering mechanisms of static flow liquefaction are well identified through a considerable body of data consisting of empirical observation of historical cases, and laboratory and field tests. In parallel, in computational soil mechanics, advanced numerical simulations and predictive models have also been developed to address the evaluation of soil liquefaction potential in engineering practice.

In this study, a back analysis of Dam I failure (Brumadinho, Brazil) is being considered to run a series of sensitivity analyses considering two potential triggers of liquefaction and investigate both their individual and combined contribution to the onset of static liquefaction.

The first mechanism is associated with a rising water table in the dam, which can be caused by intense rainfall and poor drainage conditions. More recently some efforts have been made in the field of computational analysis using models like NorSand to perform numerical simulations of the soil behavior observed in laboratory testing associated with this type of loading.

The second mechanism investigated was the effect of the fluid pressure used in drilling for instrument installation. The rapid increase in pore pressure could provoke a localized liquefied zone (loss of shear strength) at the bottom of the borehole that propagated generating a global collapse of the dam.

The results point out that a disturbance caused by the fluid overpressure of the borehole drilling was necessary to cause the collapse of the dam. However, the combined scenarios showed that the contribution of an infiltration that raised the water table increases significantly the chances of global instability.

This investigation also explored the application of constitutive models capable of reproducing this behavior. The two soil constitutive models considered, namely NorSand and Hardening Soil Small (HSS). They proved to be suitable for simulating the mechanism of static liquefaction analyzed, involving a rapid progression of instability throughout the model.

Introduction

Most flow-type slope failures are associated, to some degree, with an increase in pore pressure, the principal

causes of which are periods of intense rainfall, deficient drainage system and underground inflow, or even redistribution of pore water pressure from adjacent liquefied material (Morgenstern, 1994; Castro et al., 1992; Lade, 1993; Junaideen et al., 2010).

The mechanisms of a constant shear (CS) effective stress path, where decompression of the material (loss of mean effective stress) is caused by a slow buildup in pore water pressure, are often associated with a raising water table caused by intense rainfall, as well as surface and internal drainage conditions of the structure. Another related mechanism first investigated by Arroyo and Gens (2021) was the effect of the fluid pressure used in a drilling borehole, which provoked a localized liquefied zone at the bottom that generated a global collapse of the dam.

More recently some efforts were made in the computational analysis field to perform numerical simulations of this behavior observed in the laboratory, using critical state-based models like NorSand, and having to deal with theoretical aspects about work dissipation of stress dilatancy during yield in unloading, for which some idealization is required to define the yield surface (Jefferies and Been, 2015).

The case study of the present paper is the flow liquefaction failure of a tailings dam in Brazil. The geotechnical investigations for modeling these structures will be taken from well-documented available information in the public domain. The methodology of modeling was mainly based on the previous technical reports of Roberson et al. (2019) and Arroyo and Gens (2021).

After extensive investigations and the performance of many numerical simulations to back-analyze dam failure by Robertson et al. (2019) and Arroyo and Gens (2021), two main triggers emerged as more probable. One is increasing pore pressure due to rain infiltration, and the other is local liquefaction caused by the fluid pressure exerted while drilling a borehole, which was being conducted at the time of the dam collapse.

The PLAXIS FEA analyses proposed in this study include the simulation of the two more probable triggers separately, as well as their combined occurrences in both 2D and 3D simulations. Furthermore, with the aim of exploring the application of available and reliable constitutive models to reproduce the mechanisms that triggered static liquefaction of the dam with a rapid progression of instability throughout the structure, the constitutive soil models NorSand and Hardening Soil Small will be used.

Case study: numerical modelling of a tailings dam

The case study will be the flow liquefaction failure of a tailings dam in Brazil. The methodology of modeling was mainly based on the previous technical reports of Robertson et al. (2019) and Arroyo and Gens (2021).

Material properties

For the mechanical characterization of the tailings, two constitutive models were considered. First, the NorSand model (Jefferies, 1993), which is a critical state-based model that incorporates the state parameter that defines the plastic volumetric behavior of the material and can reproduce the softening behavior observed in loose saturated sandy and silt materials.

The other constitutive model considered in this study is the hardening soil with small-strain stiffness (HSS) model. According to Sottile et al. (2022), this model is based on the hardening soil model (HSM) but incorporates the xtress-dilatation formulation of the model family SaniSand (Li and Dafalias, 2000), which is more suitable for very loose materials.

Indeed, Benz (2007) implemented on the HSS model a dilatancy formulation based on the critical state soil mechanics framework, where the dilatancy is dependent on the state parameter. This formulation works with negative dilatancy angles characteristic of contractive material, making it possible to reproduce the peak strength and subsequent softening behavior of loose tailings in undrained conditions. This is a significant difference from the original hardening soil model, where a dilatancy cut-off of $\psi_m = 0$ is systematically considered even for negative values of ψ_m, consequently yielding too little plastic volumetric contraction, which is not representative of loose soil behavior.

The numerical model of the dam was based on the previous reports of Robertson et al. (2019), where the constitutive model used to simulate the liquefaction behavior of tailings was NorSand (Table 1). The parameter for the HSS model was calibrated against the stress-strain curves obtained with the NorSand set of parameters, following the methodology proposed by Sfriso et al. (2022), in the following sequence:

1. calibrate the model for drained behavior;
2. reduce parameters of elastoplastic rigidity in shear and compression to the minimum fair value;
3. increase the Poisson's ratio until obtaining the target maximum undrained resistance; and
4. increase the parameter *R* until the target residual resistance is obtained.

The adjusted stress-strain behavior is illustrated in Figure 1. The calibrated hardening soil small model parameters are presented in Table 1.

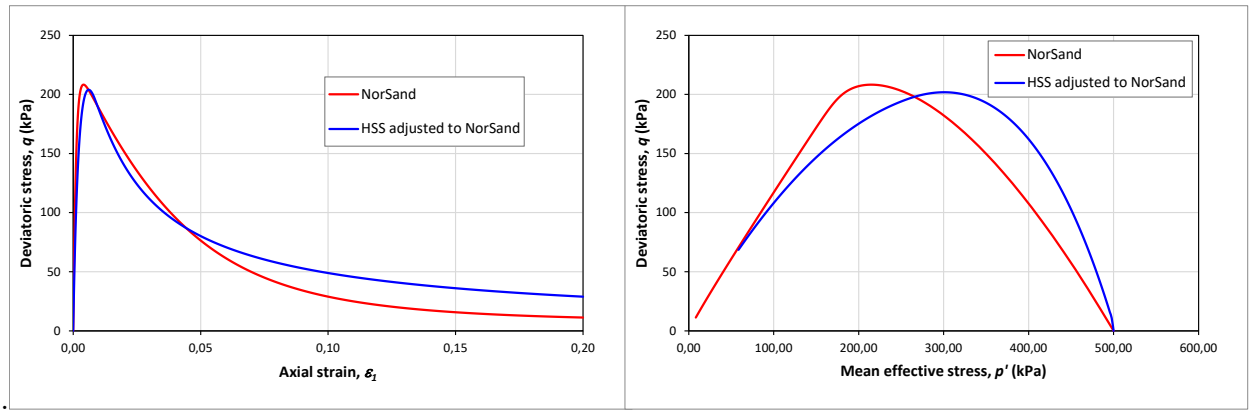

Figure 1 : Calibration of the HSS model parameters for and mean effective stress of 500 kPa

Table 1: Parameters for tailings. On the left, the NorSand model parameters (adapted from Robertson et al., 2019). On the right, the HSS model calibrated parameters

NorSand model parameters		
Parameter	**Unit**	**Value**

R_f		1.0

The constitutive models and the parameters for the remaining materials (dike, foundation, etc.) considered in this study were adopted from Arroyo and Gens (2021).

Model construction

The numerical 2D plane strain model considered in this study is based on the critical section (cross-section 3) of the Arroyo and Gens (2021) report. The main characteristics of the adopted model included geometry, construction history, material parameters, hydraulic and hydrological conditions, and site activities.

Initially, a 2D plane strain analysis is performed, given that the type of failure observed developed simultaneously along a length of 300 m over the main face of the dam.

In the 2D cross-section, the localized zone induced by the borehole drilling (suspected to be one plausible cause of global dam failure) extends along the out-of-plane direction to the model (as a consequence of the plane strain assumption). Consequently, to obtain a more realistic simulation, it was deemed useful to also investigate the 3D effect of the localized liquefaction during the drilling of a borehole. The 3D model was developed following the criteria of Arroyo and Gens (2021), considering a 15 m slice extruded from the 2D model.

Figure 2 shows an analysis of the location on the plane and general arrangement of the critical section (cross-section 3 from Arroyo and Gens, 2021). The horizontal layers represent each phase of the dam construction, together with the raising dikes at every step of the dam-raising process.

The numerical model simulated 15 phases of raising and filling of the dam. A total of 30 numerical phases were necessary to reproduce the construction process of the dam plus the initial state phase, estimating the time based on the historical record of the structure over the 43 years of existence of the dam, as described by Robertson et al. (2019) and Arroyo and Gens (2021).

Following the numerical modeling process of Arroyo and Gens (2021), the first two phases establish the initial conditions of the foundation in terms of stress and pore pressure, adopting an initial stress ratio K_0=0.5 for the initial phase, and then using the flow boundary conditions to calculate the pore pressure distribution, considering relevant tailing ponds.

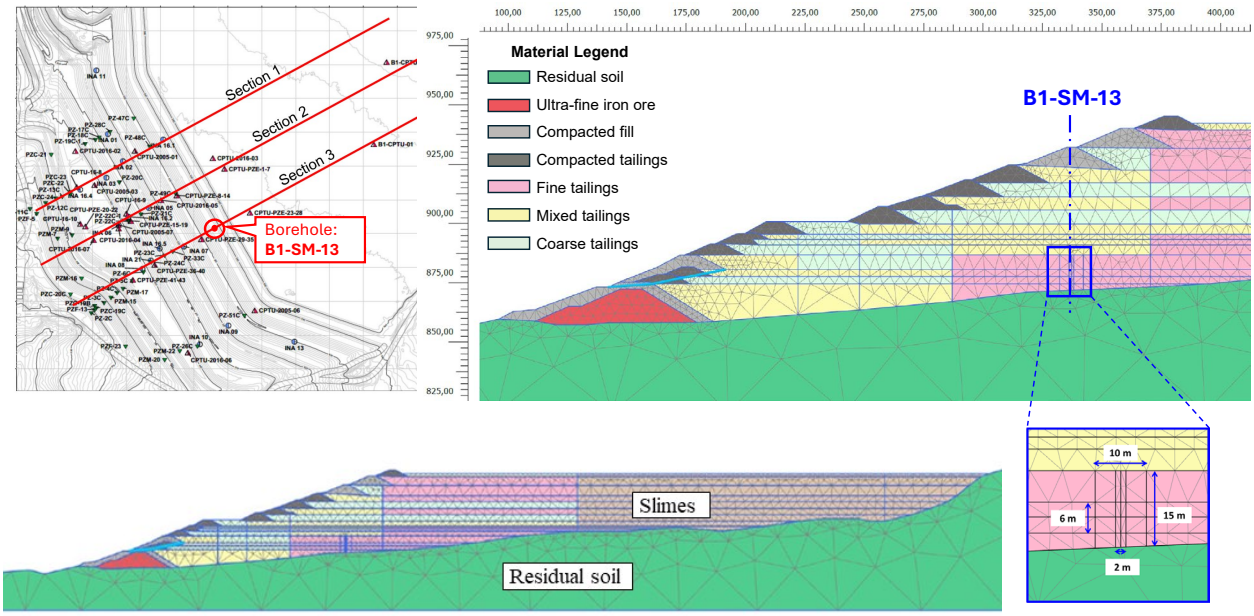

Figure 2: On the left is the location of cross-section 3; on the right is the 2D model of section 3 and material distribution of the dam and detailed location of borehole B1-SM-13; at the bottom is a general view of the 2D model. Adapted from Arroya and Gens (2021)

The final phase represents the inactive period of 912 days, after stopping tailings disposal, at elevation 942 m. During this phase only the ongoing consolidation process, along with the precipitation prescribed over the surface of the model, was considered.

Methodology for triggering static liquefaction

For this study, two potential liquefaction triggers were evaluated, performing simulations with effective stress conditions (and corresponding pore water pressure computed by mean of groundwater flow analysis), corresponding to the final state of the dam at the end of phase 30.

The first mechanism investigated was the elevation of the pore pressure within the dam due to precipitation (which was worthy of consideration, since the failure occurred during the rainy season). The other potential mechanism analyzed was associated with the drilling of borehole B1-SM-13 for the installation of a piezometer, which was happening at the time of the dam collapse. According to the technical registers gathered by Robertson et al. (2019) and Arroyo and Gens (2021), a coring technique with HQ-sized (i.e., 96 mm outer diameter) core and double barrel (wireline) was used. Also, the drilling of the borehole included a water recirculation system that involved the application of water overpressure with a total hydraulic head at least equal to the top of the borehole (~930 m). Arroyo and Gens (2021) ran numerical simulations of the conditions at the bottom of the borehole, demonstrating that liquefaction of tailings can be induced in a borehole with a combination of a fast trigger in terms of overpressure and low permeability developing in undrained conditions.

The two potential triggers were evaluated in different scenarios considering three different events of increased rainfall (1,095, 1,642, and 2,190 mm/year) and borehole overpressure independently, as well as in combination.

Section model of local liquefaction of borehole B1-SM-1

During the months prior to the dam failure, a series of drilling operations were undertaken to install complementary instrumentation. One of these boreholes, B1-SM-13, was being drilled when the failure occurred. The drilling of borehole B1-SM-13, where the overpressure of fluid used to cool the drilling bit is suspected to have caused localized liquefaction of loose, saturated tailings. It is therefore analyzed as a potential trigger for the instability.

The critical section under analysis (cross-section 3 of Arroyo and Gens, 2021) is very close to where the drilling of borehole B1-SM-13 took place, as shown in Figure 2. According to available records, borehole B1-SM-13 was initiated on January 21, 2019, and on the day before the failure, drilling had reportedly reached a depth of 65.5 meters below the ground elevation of approximately 930 meters, bringing it to a bottom elevation of approximately 863.5 meters.

All this detailed information about borehole B1-SM-13 was taken into account to develop a liquefaction trigger scenario, where the localized collapse at the bottom of the borehole was simulated by prescribing a small localized liquefied cluster (2 meters by 6 meters) around the tip of the borehole. The localized liquefaction region was modeled by assigning this small cluster at the bottom of the borehole (Figure 2) a liquefied residual strength of c_u = 10 kPa (and no friction angle). Calculations for this phase were performed under the assumption of undrained conditions, as instability progresses rapidly.

Numerical failure state in Plaxis (ΣM_{stage} multiplier)

In PLAXIS 2D, the changes to the geometry and loading configuration usually introduce changes in out-of-balance forces. These out-of-balance forces are stepwise applied to the finite element mesh (and of course subsequently balanced) using an automatic load-stepping procedure (Brinkgreve et al., 2022) until equilibrium is reached.

ΣM_{stage} is a multiplier that controls the staged construction process by monitoring the proportion of the out-of-balance force being equilibrated.

During a calculation phase, the multiplier ΣM_{stage} is increased from 0.0 to 1.0. As soon as ΣM_{stage} has reached the value of 1.0, the equilibrium is satisfied, the construction stage is completed, and the calculation phase is successfully terminated. If a staged construction calculation stops while ΣM_{stage} is still smaller than 1.0, the calculation cannot fully balance the introduced out-of-balance forces induced by the change of configuration compared to the previous phase, and the program will give an error message. The most likely reason in such a situation is that a failure mechanism has occurred. When failure of the soil body has occurred during the calculation, it is not possible to finish the construction stage and further calculations are meaningless, and therefore impossible in PLAXIS.

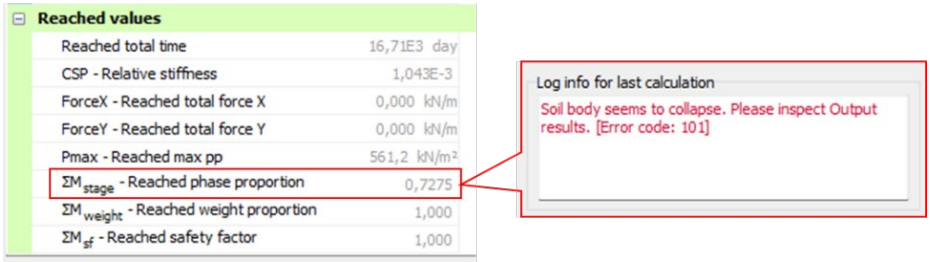

Figure 3: Plaxis results – phase calculation reached values and log information box

From the perspective of evaluating triggering mechanisms in our study, the ΣM_{stage} multiplier can be especially useful to determine the likelihood of reaching an unstable state for a given scenario. Knowing that a failure condition is established when a phase calculation finishes with ΣM_{stage} inferior to 1.0, the reached value indicates the proportion of the total loading or unloading that needs to be applied to result in the collapse of the body.

The patterns followed by the resulting values of the ΣM_{stage} multiplier for the series of combined scenarios analyzed will indicate whether static liquefaction is more likely to happen or not depending on the tendency (decreasing or increasing).

Results and discussions

In this chapter, a detailed examination of the numerical simulation results is presented. The evaluation is made over the critical section in 2D and 3D with contours in terms of effective stresses, pore pressure, displacements, and incremental shear strain.

Pre-failure stresses, displacements, and pore pressure

The stress state of the dam just before failure is derived by simulating the dam construction process according to historical records. Initiating the process by the construction of the starter dam on the foundation, every one of the 15 stages of raising and fill is simulated, considering the consolidation process the tailings underwent during the time of each phase.

The states of stress and pore pressure distributions are defined at the end of the last phase (phase 30), which corresponds to a period of 912 days (2.5 years) before failure, during which no further tailings were disposed on the dam. The construction phases were simulated with the calibrated HSS model for the tailings.

Figure 4 presents the contours of vertical and horizontal effective stress at the end of the last phase, representing the dam's state of stress field before collapse. Stresses increase with depth, accommodating to the geometry of the dam slope. Regions of maximum vertical and horizontal effective stresses are located at the base of the embankment below the crest, reaching values around 1,050 kPa and 650 kPa respectively.

Figure 5a shows the displacements that occurred over the last phase of the analysis, which simulates the last 2.5 years of the dam since it stopped operating in July 2016 until failure in early 2019. It indicates that the consolidation process continued for the last 2.5 years after the last loading of tailings was deposited at the storage facility.

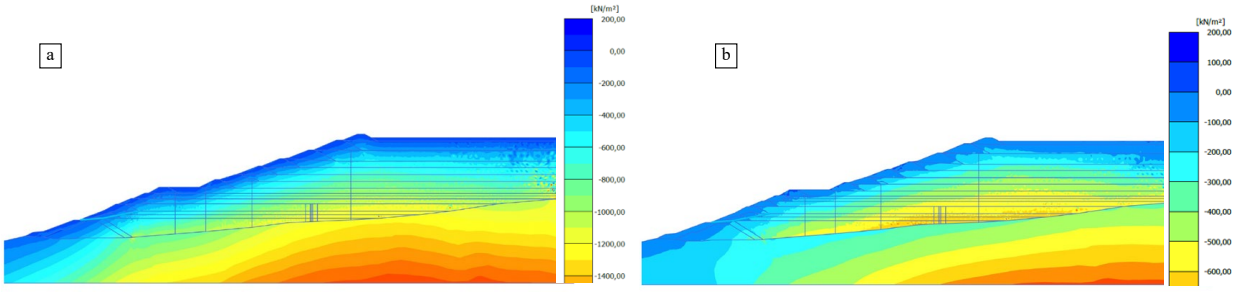

Figure 4: Contours of effective a) vertical and b) horizontal stress due to construction at the final stage before failure

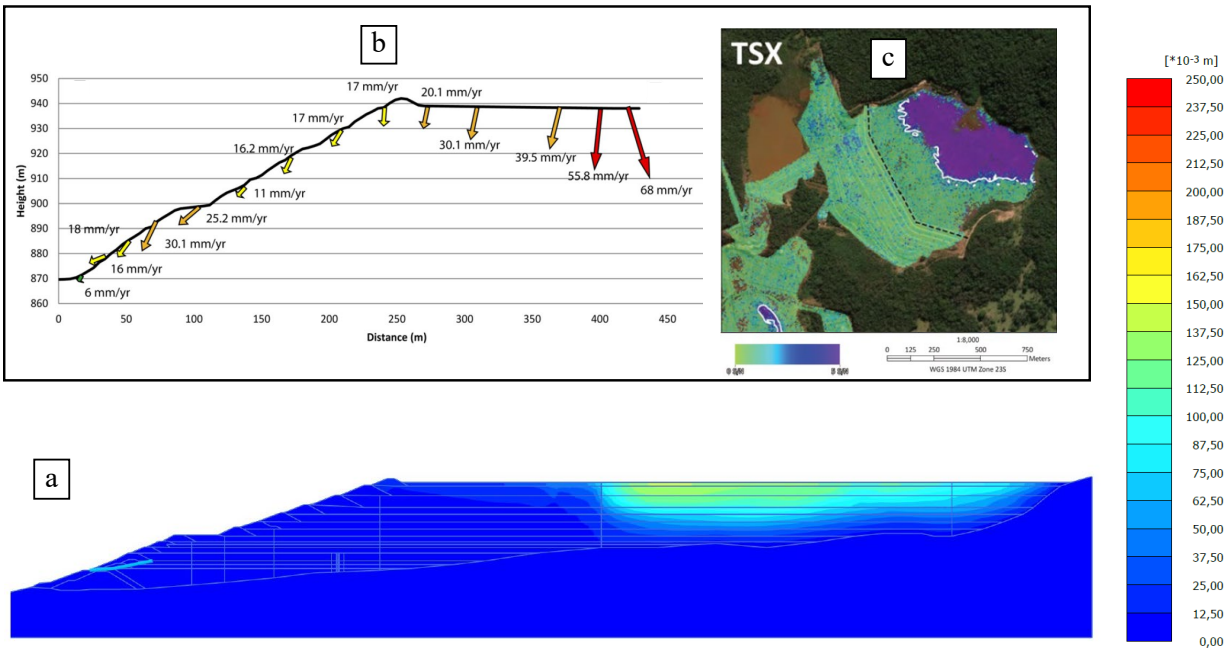

Figure 5: a) Calculated displacement in the last phase before failure, considering no precipitation, compared with b) the satellite measurements reported by Robertson et al. (2019) and c) the signal–to–noise ratio found by Holden et al. (2020)

The magnitude of the displacements found in the analysis, with values up to 150 mm, is consistent with the satellite measurements recovered and analyzed by Robertson et al. (2019). According to Robertson et al. (2019), larger vertical deformations, to a maximum of 140 mm/year, were detected in the tailing's impoundment. Since the settlements were mostly vertical and were well back from the crest, they were predominantly the result of ongoing settlement of the tailings due to long-term consolidation of the softer, finer tailings. This tendency of higher displacements toward the back of the storage facility is depicted by the satellite measurements in a cross- section (Figure 5b), showing deformation vectors obtained from InSAR TerraSAR-X-Sentinel-1 data by Robertson et al. (2019).

Satellite measurements presented by Robertson et al. (2019) in Figure 5b indicate a much lower rate of movement at the face of the dam. This is in contrast to the concentrated displacements at the rear of the dam, which resulted in our simulation (Figure 5a), showing minimal or very low displacements at the slope and near the crest region in the last phase. However, Holden et al. (2020) indicate that the settlements calculated at the crest and slope of the dam are highly affected by noise, presenting systematic estimates of the signal-to-noise ratio for their last-year average displacements (Figure 5c). The higher signal-to-noise ratio towards the back of the dam shown in Figure 5c is consistent with the calculated higher displacements in this same region (Figure 5a).

The field of pore pressure computed at the last phase of the dam, considering no contribution of infiltration due to rainfall and just before failure, is shown in Figure 6. These results are in good agreement

with the piezometric level registered in the last dam safety audit presented in 2018, according to Robertson et al. (2019), as well as with the simulation made by Arroyo and Gens (2021). Figure 6 also shows a comparison of the isoline at zero pore pressure, estimated by the instrument measurements of 2018 and the ones computed in this study (except perhaps for the starter dam).

In general, it can be observed that the zero pore pressure isoline is rather elevated within the dam, indicating that most of the tailings were saturated at the moment of failure, leaving just the upper part of the dam close to the crest in unsaturated conditions.

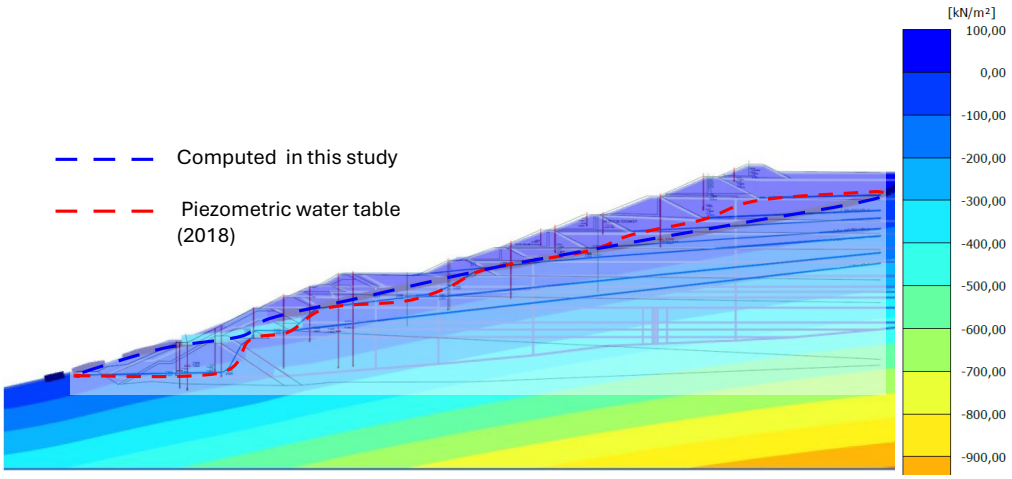

Figure 6: Comparison of zero pore pressure contours obtained in (1) this numerical simulation and (2) estimation from field testing and instrumentation

Analysis of potential liquefaction triggers

For this study, two potential liquefaction triggers were evaluated.

The first mechanism investigated was the elevation of the pore pressure within the dam due to precipitation. The progressive increase of pore pressure under a constant level of shear stress near a slope produces a loss of mean effective stress, represented in the stress space by a stress path moving horizontally in the direction of the failure envelope.

The other potential mechanism analyzed is associated with the drilling of borehole B1-SM-13 for the installation of a piezometer, which was happening at the time of the dam collapse.

These two potential triggers are investigated, including both their individual and combined contribution to the onset of static liquefaction.

Increased precipitation scenarios

The potential effects of increased precipitation were evaluated considering three magnitudes of rainfall (1,095, 1,642, and 2,190 mm/year). These values of precipitation were selected based on the average rainfall registered over the three years previous to the dam collapse. It was observed that the two highest values of

precipitation inflow simulated in the numerical model would correspond to a rate of infiltration that causes an almost complete saturation of the dam.

Comparing the pore pressure conditions simulated for the last phase before failure, the infiltration simulated by the highest precipitation rate indicates that 2,190 mm/year, as presented in Figure 7, caused a raising of the water table up to 15 m from the crest of the dam.

Figure 7 shows the contours of displacements in the final phase of analysis with the highest precipitation rate considered. The effect of increasing the precipitation rate is limited, with small movements appearing in a localized zone in the lower part of the dam slope. Overall, the increase of dam movements reaching a maximum value of 0.16 m, in relation to the scenario of no precipitation (Figure 5.3), is marginal.

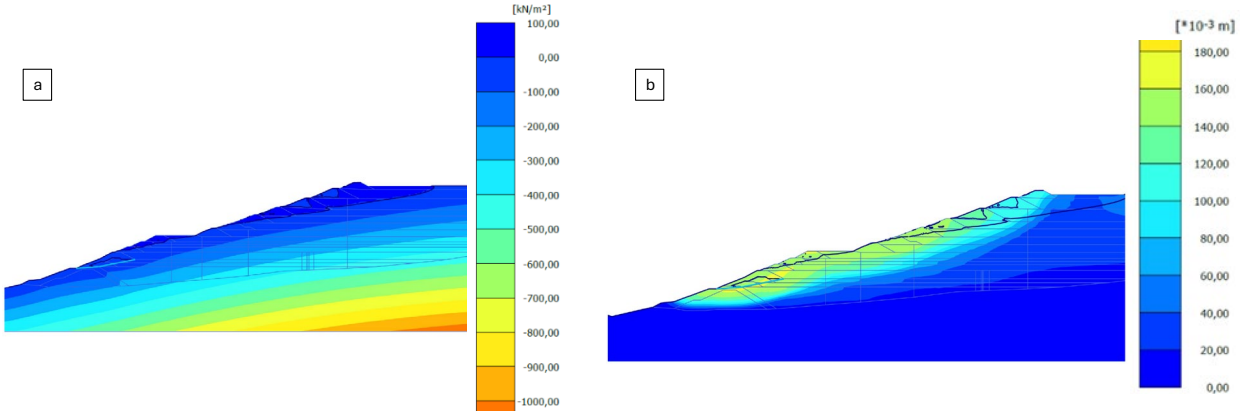

Figure 7: Contours of a) pore pressure and b) displacement during the final phase, with increased precipitation of 2,190 mm/year

Borehole local liquefaction scenario

The finite element model and associated numerical analysis strategy used for triggering static liquefaction have been described earlier in this paper. The localized liquefaction region is prescribed by a small cluster of 2 m × 6 m at the bottom of the borehole, to which a different material property set with only a liquefied residual strength of 10 kPa has been assigned. The calculation for this phase is done in undrained conditions, considering that instability progresses rapidly.

For these conditions, the simulation reached a global collapse state (as PLAXIS calculation stops with $\Sigma M_{stage}<1$) along the slope of the dam that propagates from the initial localized liquefaction region at the bottom of the borehole.

The simulated mechanism of the collapse using the NorSand constitutive model can be observed in Figures 8a, b, and c. Incremental displacements show the evolution of the movement at the time of failure. The incremental shear strains shown in Figure 8a give a clear representation of the failure surface, which propagates from the initial liquefied region at the bottom of the borehole.

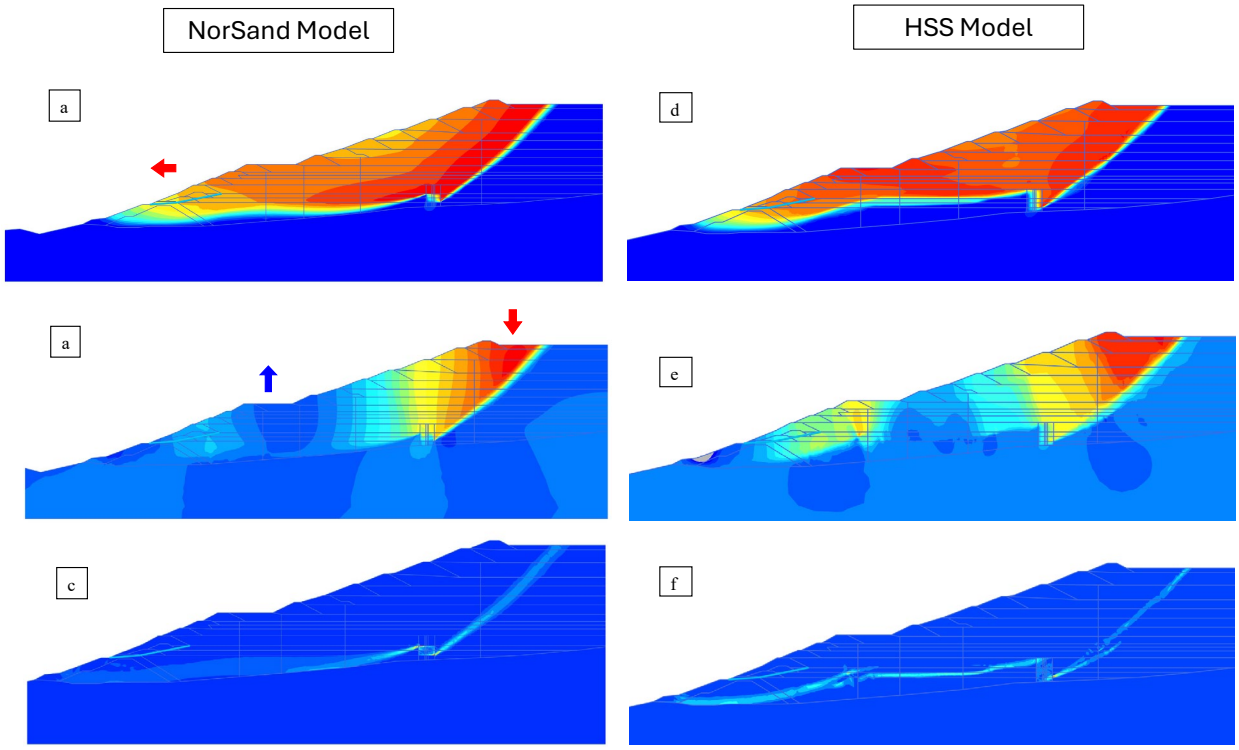

Figure 8: Liquefaction collapse using the NorSand and HSS constitutive model – a) and d) contours of incremental displacement; b) and e) contours of vertical incremental displacement; and c) and f) contours of incremental shear strains

Figure 8b shows the contours of incremental vertical displacement. The kinematic at the instant of collapse is clearly depicted with the rotation movement involving a downward displacement at the crest of the dam and a horizontal outwards bulging near the toe, consistent with the footage of the failure.

With the objective of evaluating the capability of the hardening soil small (HSS) model to simulate a mechanism of liquefaction collapse, the set of calibrated parameters (Table 1), was used to simulate the scenario of localized liquefaction at the borehole B1-SM-13.

Figures 8d, e, and f illustrate a remarkably similar pattern of instability simulated with the HSS model. The geometrical extension of the failure surface has a good correspondence to that obtained with the NorSand model simulation. Moreover, the kinematic analysis of the movement from the incremental displacements shown in Figures 8d and e also indicate the downward movement directions near the crest and bulging at the toe of the dam slope.

A plausible liquefaction trigger was found with the consideration of a localized liquefied zone at the borehole tip under pore water conditions encountered at the time of failure. As presented in Table 2, values for the loading parameter ΣM_{stage} closed to unity (roughly 0.9), indicating a clear but possibly limited likelihood of failure (especially as this corresponds to 2D analysis, for which endless propagation of the liquefied zone at borehole tip in the out-of-plane direction is implicitly being made).

Borehole local liquefaction and increased precipitation scenarios

Another set of sensitivity analyses was performed considering the combined effects of the borehole overpressure and increased precipitation with three levels of rainfall. The values of the loading parameter ΣM_{stage} for each intensity of rainfall and each constitutive model analyzed are presented in Table 2. The calculated values of the ΣM_{stage} parameter follow a pattern, with decreasing values as precipitation intensity increases. These results indicate that dam liquefaction likelihood increases, clearly demonstrating the influence of the infiltration process induced by rainfall (and the resulting increase in pore pressure).

Regarding the constitutive models employed, it is noteworthy that the calculated values of ΣM_{stage} for the HSS model were consistently slightly lower than those for NorSand. This suggests a more conservative tendency of the HSS model in predicting the onset of static liquefaction, showing a slightly higher probability of failure occurrence due to marginally lower ΣM_{stage} values.

Another relevant observation is that for a precipitation above 1,692 mm/year, where the infiltration simulated yields an almost complete saturation state of the dam body, the probability of failure occurrence remains approximately the same, as indicated by the low variation of the ΣM_{stage}.

Table 2: Loading parameter at failure phase, indicating reached proportion (ΣM_{stage})

Precipitation (mm/year)	ΣM_{stage} HSS model	ΣM_{stage} NorSand model
No infiltration scenario	0.874	0.905
1,045	0.728	0.735
1,692	0.514	0.673
2,190	0.539	0.698

3D-borehole local liquefaction analysis

Following the criteria used by Arroyo and Gens (2021), a 3D analysis of a slice of the dam was built to simulate a more realistic spatial extension of the disturbance produced by the drilling of a single borehole.

The 3D model was elaborated to represent a slice of the critical section over a width of 15 m, as was proposed by Arroyo and Gens (2021). Figure 9a shows the 3D, model including the material discretization used during the construction phases of the structure.

For the 3D model, the liquefied zone at the bottom of borehole B1-SM-13 was represented by a cluster of 2 m × 2m × 6 m, as depicted in Figure 9a, located at the center of the width of 15 m of the 3D slice.

The result of the 3D slice analysis, assuming a liquefied zone at the borehole B1-SM-13, is shown in Figure 9b. Global failure due to static liquefaction is obtained for this analysis as well, although the extension of the failure surface is slightly smaller compared to the one obtained with the 2D analysis.

Nevertheless, the kinematic of the movement is the same, showing a downward movement near the crest of the dam and an outward horizontal displacement at the toe of the unstable slope.

This may be taken as a different failure mechanism though, since this result shows an unstable mass restricted to the upper part of the slope, not corresponding to the footage of the propagation of liquefaction analyzed in detail during previous 2D analyses.

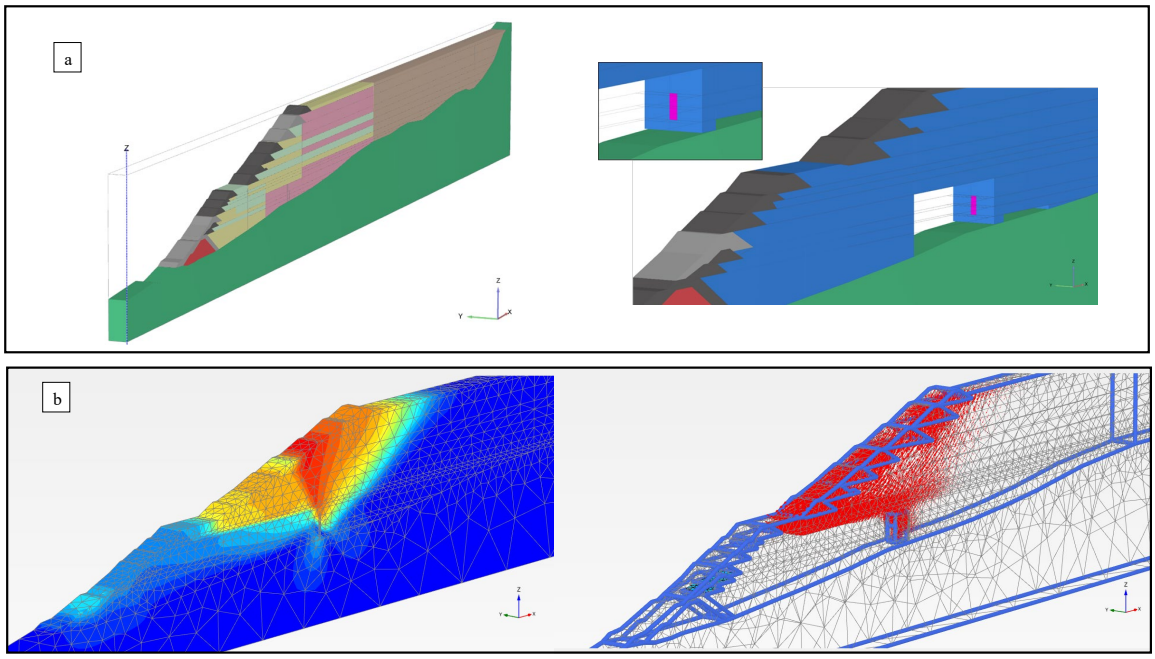

Figure 9: 3D model – a) slice over a width of 15 m and liquefied region at the bottom of borehole B1-SM-13. b) Contours of phase displacements and incremental displacement vectors

Conclusion

Simulation of the dam failure was conducted under varied conditions using both 2D and 3D numerical models to assess sensitivity and consistency in identifying possible triggers for liquefaction. Constitutive models, namely NorSand and HSS, were calibrated to replicate the same stress-strain behavior, proving to be effective in simulating the analyzed liquefaction mechanisms and in demonstrating a rapid progression of instability throughout the model.

Results from numerical simulations considering precipitation alone, even with a raised water table 15 m above the pre-failure elevation, did not exhibit signs of instability. This indicated that elevating the water table alone did not induce an unstable condition for the dam.

In the 2D analyses, considering a localized liquefaction zone in a borehole located on the main slope, the model exhibited a complete collapse with features consistent with the observed rapid failure and initial downward movement of the crest, followed by a horizontal downstream movement of the toe of the Dam.

Sensitivity analyses, considering the combined effects of the two triggers (water table elevation and borehole drilling), revealed an increased probability of occurrence. This was indicated by lower and below-1 ΣM_{stage} values.

The 3D analysis showed a similar collapse mechanism, although more restricted to the upper part of the slope, confirming the 2D initial evaluation and giving strong numerical evidence that the drilling of the borehole was a potential trigger of liquefaction.

Acknowledgements

Thanks to the Institute of Technology Vale and its dedicated staff for their unwavering support, provision of essential resources, and guidance that proved instrumental in the successful completion of this research endeavor.

Abstract

This paper introduces the TWIM (Tailings and Waste Interactive Management) Framework, a structured approach designed to enhance the management of dry stacking tailings operations through the integration of Digital Twin technology. The TWIM Framework leverages real-time monitoring, data analytics, and predictive modeling to address the complex challenges of tailings management. Developed as part of an Open Innovation initiative by Vale Company, and operationalized through the DSMS (Dry Stacking Management System) software, this framework provides comprehensive oversight and management capabilities. The paper shares key insights and lessons learned from the framework's implementation, highlighting its impact on improving operational efficiency, resource recovery, and environmental sustainability at Vale's "PDER Cianita" tailings facility in Brazil. The TWIM Framework and DSMS software represent a significant advancement in tailings management, promoting regulatory compliance and supporting sustainable mining practices. The findings suggest that this approach can be scaled and adapted to meet the specific needs of various operations within the mining industry.

Introduction

The primary aim of this paper is to introduce the TWIM (Tailings and Waste Interactive Management) Framework, a structured approach designed to enhance the management of dry stacking tailings operations. The framework leverages Digital Twin technology to integrate real-time monitoring, data analytics, and predictive modeling, addressing the complex challenges of tailings management. In addition to presenting the framework, this paper aims to share key insights and lessons learned from its implementation and operationalization as a cloud-based software solution.

The management of tailings and mining waste is a critical component in mitigating the environmental and operational challenges inherent in mining activities (Mining Association of Canada, 2021). Tailings, the by-product of ore processing, pose significant risks when stored in impoundments or upstream dams (Kossoff et al., 2014). Although the iron ore tailings dry stacking process is not new, recent structural failures of upstream tailings dams in Brazil have compelled many mining companies to adopt this method across various environments, processes, and waste types (Islam and Murakami, 2021).

Dry stacking tailings structures are designed for long-term operations involving repetitive tasks and the handling of massive material volumes, presenting unique management complexities. Current literature and market solutions reveal a significant gap in tools that can effectively integrate and organize technical documents, instrumentation data, and the management of processes and flows involved in tailings compaction. These critical elements must be compiled into a centralized and intuitive platform, capable of supporting at least a 6D model (3D Model + Schedule + Costs + "QAQC – Quality Assurance and Quality Control").

Digital Twin technology has emerged as a promising solution to these challenges by integrating real-time monitoring, data analytics, and simulation into a cohesive platform (Boje et al., 2020). This technology allows for the simulation of various scenarios, risk assessment, and process optimization, offering a comprehensive management tool that surpasses the capabilities of traditional methods. Although Digital Twin technology has been successfully applied in other industries such as manufacturing and urban planning, its application in tailings management is still in the early stages of development.

Current software solutions often fall short in managing the entire lifecycle of tailings operations, primarily serving as databases focused on storing data and documents without providing comprehensive oversight. There is a significant opportunity to advance these systems by integrating data collection, document management, real-time monitoring, and process optimization, thereby addressing the fragmented approach prevalent in existing practices. The increasing emphasis on regulatory compliance, particularly with standards such as the Global Industry Standard on Tailings Management (GISTM) (ICMM, 2020), highlights the urgent need for more integrated solutions. As the industry evolves, the adoption of advanced digital tools, such as Digital Twin technology, will be essential in enhancing the safety, efficiency, and sustainability of tailings management practices.

In 2021, in response to the adoption of dry stacking tailings in its tailings storage facilities (TSFs), Vale Company, in partnership with Mining Hub, launched an open innovation call to identify an integrated solution for managing the dry stacking tailings process. The sought-after solution was required to be based on the Building Information Modeling (BIM) concept and to offer an integrated environment for data management, while also enabling continuous improvement of the drained stacking processes.

Although BIM is a well-established design methodology in construction, primarily focused on creating and managing digital representations of buildings during the design phase (Egger et al., 2013), it falls short in addressing the ongoing operational needs of tailings facilities. BIM's design-centric approach lacks the flexibility and real-time data integration necessary for continuous monitoring and adaptive decision-making in dynamic environments like tailings management. In contrast, Digital Twin technology, introduced by Michael Grieves in 2002, offers significant potential for optimizing tailings management. By enabling real-time monitoring, simulation, and optimization, Digital Twins align operational processes with strategic objectives, ensuring software applications function effectively. Originally rooted in NASA's space programs, Digital Twin technology has gained momentum with advancements in IoT and 5G, becoming integral to Product Lifecycle Management (PLM) across various industries. As these technologies continue to evolve, Digital Twins are expected to play a crucial role in enhancing operational performance and problem-solving.

The TWIM (Tailings and Waste Interactive Management) Framework and its cloud-based software application, the DSMS (Dry Stacking Management System), were developed as part of an Open Innovation initiative led by Vale Company. Currently in their third year of development and implementation, these systems are being deployed at the "PDER Cianita" dry stacking tailings facility, which is part of the "Mina do Pico" mine managed by Vale Company in Minas Gerais, Brazil.

The TWIM Framework

The TWIM Framework was conceptualized and designed with the aim of establishing a robust foundation of best practices for managing the unique challenges of dry stacking construction methods. Rather than beginning with the creation of software tailored to specific user requirements, the framework was built on the principle that effective software emerges from strong methodologies and frameworks. In this approach, software development is an interpretation of the framework, remaining agnostic and guided by its structured principles. Frameworks like TWIM are essential tools that provide systematic structures for addressing complex problems across various fields, including scientific research, engineering, and project management (Kasser, 2019). They offer a flexible, overarching structure that ensures coherence and consistency across diverse practices, while also allowing for customization to meet specific needs.

The TWIM Framework is a structured approach designed to enhance the management and operational efficiency of dry stacking tailings operations in the mining industry. Central to this framework is the application of a systematic, target-driven Plan-Do-Check-Act (PDCA) cycle, which utilizes digital models within a controlled environment. This approach ensures continuous improvement by planning operational strategies, executing them, monitoring the outcomes, and making necessary adjustments to optimize tailings management processes. By integrating Digital Twin technology, the TWIM Framework brings together

real-time monitoring, data analytics, and predictive modeling to address the complex challenges of tailings management.

The framework is built on advanced management and optimization concepts that align with the principles of Industry 4.0, providing comprehensive operational oversight through continuous engineering data management, digital documentation, and precise control of stacking operations. Its primary focus is on enhancing the reliability, predictability, and auditability of tailings storage facilities, ensuring that all construction and operational processes are thoroughly documented and effectively managed. Key concepts underlying the TWIM Framework include:

- Engineering Data Management (EDM): Involves the systematic collection, storage, and analysis of engineering data, including geotechnical data, construction records, and instrumentation data;
- Digital Twin (DTs): Provides a virtual replica of the TSFs, enabling real-time monitoring, operational simulation, and forecasting;
- Cloud Computing: Offers scalable and secure data storage and processing capabilities, allowing real-time data access and collaboration among stakeholders, regardless of geographical location, thereby enhancing the overall efficiency and responsiveness;
- Geotechnical QA/QC: Implements a systematic approach to maintain geotechnical parameters, such as moisture, compaction degree, and layer thickness within specified values;
- Real-Time Instrumentation: Utilizes real-time data to monitor key indicators, automating alerts and notifications to the teams responsible for TSF management;
- Interactive Management: Emphasizes the importance of ongoing, real-time management of tailings operations, providing operational insights to ensure immediate responses to emerging issues;
- Regulatory Alignment: Ensures compliance with current regulatory standards, such as the Global Industry Standard on Tailings Management (GISTM);
- Strategic Goals (SGs): These are targets that align with company strategic goals and are incorporated in the design of solutions as KPI's that measure the adherence of operation and managing;
- Operation Cycle and Continuous Improvement: During the operational phase, continuous documentation, support, and methodological refinements are provided to enhance performance and ensure monitoring of critical components, enabling the system to adapt and improve continuously in response to operational needs.

Interactive management

The TWIM Framework is centered on interactive management, leveraging continuous versioning and digital twin models to create a dynamic, iterative process. This process ensures ongoing improvement in

tailings storage facility operations, while maintaining accurate, up-to-date "As-Is" documentation. The main cycle consists of operational ontologies, which act as parametric "recipes" that define the controlled constraints for simulating the operational environment. These ontologies are used to generate the Expected Digital Model (EDM), a 6D simulation of the tailings pile, offering valuable insights into resource demands. After planning and simulation, the execution phase begins, leading to the creation of the Realized Digital Model (RDM), where construction is continuously monitored to ensure it meets the desired parameters and requirements. All results are interactively collected during the Interactive Execution Management phase, reflecting real-time operations and providing key insights for management and ongoing improvements. This feedback loop informs the development of new ontology versions, driving a continuous cycle of enhancement and refinement.

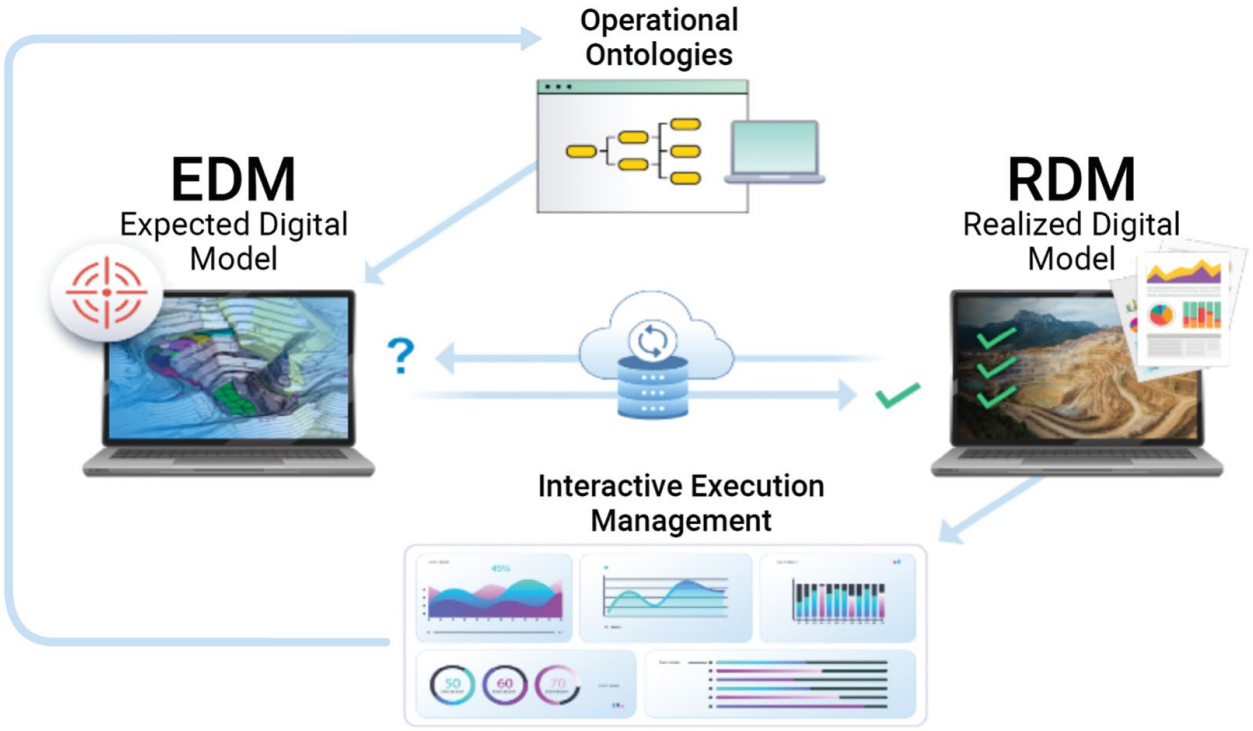

Figure 1: TWIM Framework continuous improvement cycle

The TWIM Framework enables the management of tailings stacking compaction operations, by means of a digital environment that guarantees the control of the five main pillars related to this type of structure: directory of documents produced, related to field and laboratory tests (routine tests for the approval of compacted layers and special tests for the verification of complete geotechnical parameters); control of geotechnical indicators that guarantee the quality of the filtered stacking operation process (e.g., material moisture, degree of compaction, layer thickness, etc.); visual control of the 5D model of the filtered tailings pile, based on continuous feeding of the model (continuous "as built"); control of the geotechnical

instrumentation to gauge the performance of the structure throughout its operation and useful life; and process control through the approval of activities present in the compaction flow of each layer.

The process of creating digital twins for tailings piles involves several steps. Initially, comprehensive data on the tailings pile's properties and behaviors are collected. This includes geotechnical data such as material moisture, degree of compaction, and layer thickness; operational data like stacking sequences and machinery used; and environmental data encompassing weather conditions and surrounding infrastructure. The aim is to gather detailed and accurate information to ensure the fidelity of the digital model. Once the data is collected, it is employed to develop a detailed multidimensional digital model of the tailings pile. This model represents the current state of the pile and serves as the basis for further simulations and analyses. By creating a precise digital representation, the model can be used to visualize the pile's structure and identify any potential issues that may arise.

A key feature of the digital twin is its integration of real-time data. Data input by humans, alongside sensor readings and other monitoring tools, continuously updates the digital model, ensuring it remains an accurate and dynamic representation of the physical tailings pile. This real-time or near real-time integration allows for ongoing monitoring and management, offering valuable insights into the current state of the pile and enabling predictions of future behaviors. The digital twins are then employed to simulate various management scenarios, helping to assess risks, optimize stacking processes, and forecast future conditions. By evaluating these scenarios, the most effective strategies for managing the tailings pile can be identified, ensuring both operational efficiency and safety.

Geotechnical stability simulations focus on evaluating the stability of tailings piles under various conditions, ensuring that management practices comply with regulatory standards. These simulations are crucial for identifying potential risks and developing strategies to mitigate them, thereby enhancing the overall stability of the pile. Equally important are environmental impact simulations, which assess the ecological consequences of tailings management practices. By analyzing different scenarios, these simulations help identify strategies to minimize adverse environmental effects, aligning management practices with environmental sustainability goals and reducing the overall environmental footprint of mining operations.

Currently, the framework requests the incorporation of rainfall simulations and runoff analysis, which are particularly critical for dry stacking operations in regions with significant rainfall. The dynamic geometry of the terrain in these operations changes rapidly over time, and without proper management, rainfall can reduce operational efficiency and necessitate the allocation of more space for ongoing tailings storage. By including these environmental factors in the simulations, the TWIM Framework can better anticipate and mitigate the effects of rainfall, ensuring that operations remain efficient and that the terrain is effectively managed.

Additionally, operational efficiency simulations aim to optimize the stacking processes, enhancing resource recovery and reducing operational costs. The parametric planning features automate the generation of Gantt charts for millions of individual items within the tailings management process. This advanced planning tool enhances resource allocation by providing a detailed and dynamic timeline of all operational activities. By simulating different stacking sequences and machinery usage, it is possible to identify the most efficient methods for managing the tailings pile. This leads to more sustainable and cost-effective operations, maximizing resource utilization and minimizing waste.

Ontologies and information organization

Ontologies play a central role in the TWIM Framework, organizing and structuring data to enhance the management of dry stacking operations. They consist of defined concepts and relationships that provide a standardized framework for data integration and analysis, ensuring data is interoperable and coherent across various domains. This enables effective structuring and querying of complex datasets, which is essential for comprehensive tailings management. Unlike simpler classification methods like taxonomies, ontologies offer a richer framework by capturing complex relationships such as part-whole and causal connections. This allows for more detailed modeling and deeper understanding of the data, which is critical for informed decision-making within the TWIM Framework.

In the TWIM Framework, ontologies integrate data across several key domains: the Physical Domain, which details the physical characteristics of tailings, including spatial dimensions and material properties; the Geotechnical Domain, capturing properties such as soil moisture, compaction levels, and stability indicators for precise management; the Management Domain, which integrates operational processes, documentation, and instrumentation data to ensure seamless management; and the Planning Domain, supporting scheduling, risk assessment, and long-term planning to optimize execution.

Adhering to the ISO/IEC 21838 standard ensures that the TWIM Framework's ontologies are compatible with high-standard data models, facilitating seamless information exchange. This alignment with international standards, combined with Digital Twin technology, makes the TWIM Framework a powerful tool for efficient and compliant tailings management..

Operationalization as a cloud-based application

This section highlights the key components of the DSMS software, developed to operationalize the TWIM Framework. The focus is on how the DSMS application translates the theoretical principles of the framework into practical tools for managing tailings storage facilities. The development process addressed significant challenges and provided solutions that ensure continuous, real-time management of tailings

operations, while maintaining technical and documentary quality. This digital tool enhances agility in controlling stacking activities, reflecting the practical outcomes of implementing the TWIM Framework.

The Ontology Editor (see Figure 2) within the DSMS application is a vital tool for managing the complex datasets associated with tailings storage facilities (TSFs). It provides a standardized framework for creating and managing operational ontologies, ensuring that all relevant data – such as physical characteristics, geotechnical properties, and operational parameters – are accurately represented and interconnected within the TWIM Framework. This standardization minimizes ambiguities, facilitates clearer communication among users and stakeholders, and maintains coherence across all digital twin models, leading to more effective data integration and analysis.

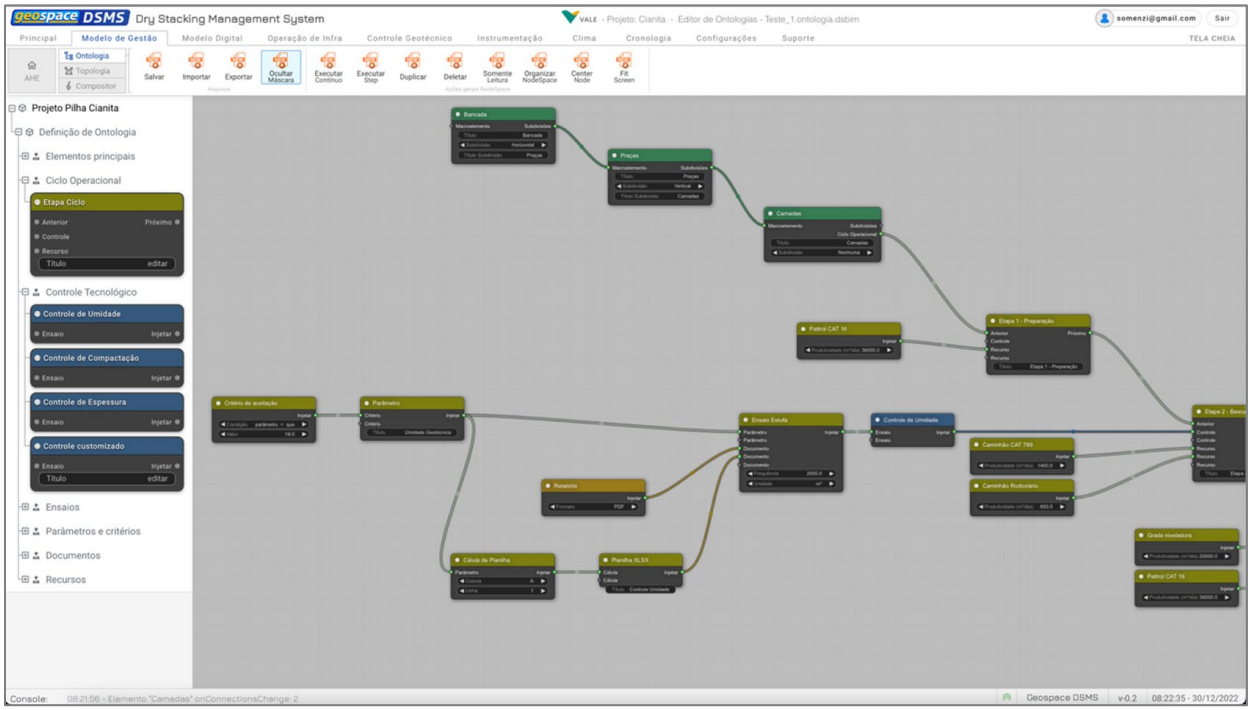

Figure 2: DSMS Ontology Editor

Additionally, the Ontology Editor enhances the DSMS's ability to integrate diverse data sources by offering a flexible yet structured approach to incorporating information from various origins. This capability is essential for comprehensive analysis and optimizing tailings management processes. By unifying data organization, standardization, and integration, the Ontology Editor supports better decision-making and improved operational performance, making it an indispensable component of the DSMS application.

In the DSMS application, parametric planning uses ontologies as a robust input mechanism to significantly improve the accuracy and efficiency of forecasting and scenario generation. Ontologies provide a detailed, standardized framework for capturing and representing knowledge across various

domains, such as physical, geotechnical, and operational data. This structured data forms the foundation for parametric planning, enabling the system to perform precise and comprehensive analyses. By integrating these complex datasets, the DSMS application ensures that all relevant factors are considered in the planning process.

Using ontologies as input, the DSMS application can forecast and generate multiple scenarios for tailings management. The system simulates various future conditions based on parameters like material properties, environmental changes, and operational strategies. These simulations allow stakeholders to understand potential outcomes and risks, leading to better-informed decision-making. The DSMS application then translates these scenarios into detailed Gantt charts, which visualize the timeline, sequence of activities, and resource allocation required for each potential outcome (see Figure 3). These Gantt charts provide clear, actionable plans that guide the steps necessary to achieve optimal results under varying conditions.

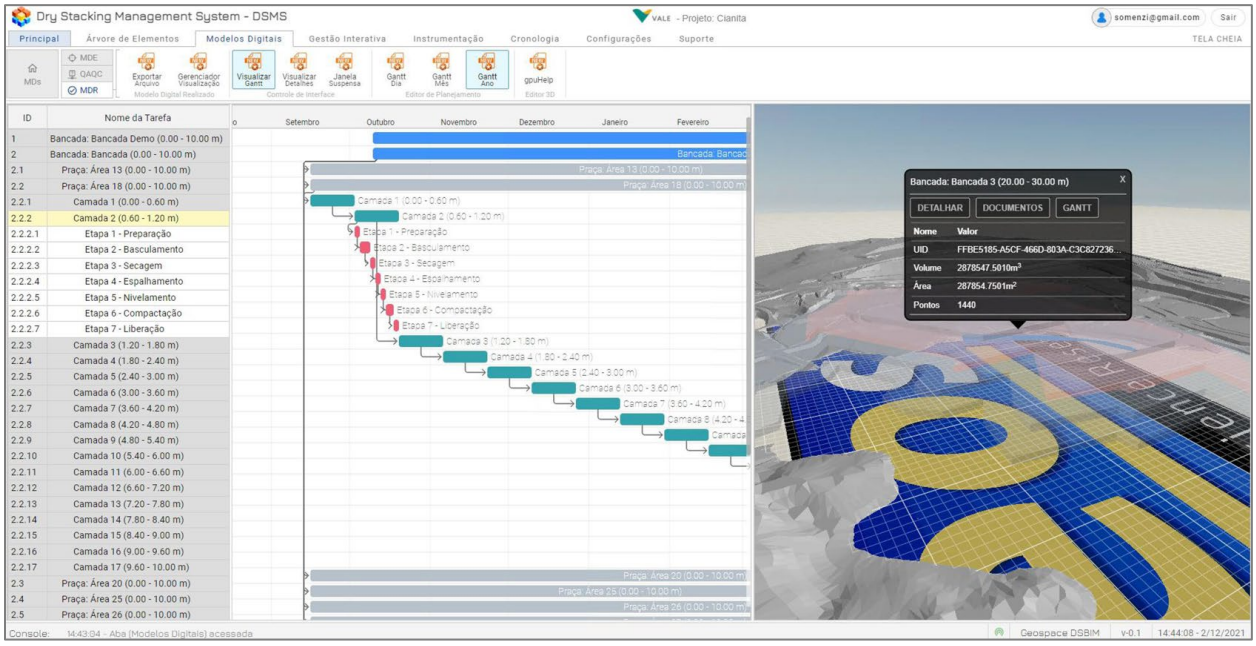

Figure 3: Parametric Gantt Simulator

By using parametric planning and ontologies, the DSMS application can generate distinct future scenarios to guide decision-making. For example, it creates a scenario of increase in material moisture due to predicted higher rainfall, necessitating adjustments in compaction processes and monitoring strategies. The Gantt chart for this scenario would detail the steps required to implement these changes, ensuring that the tailings storage facility remains stable and compliant with regulatory standards. In the second scenario, the system could predict a decrease in available workforce due to economic factors, requiring the

optimization of operational efficiency. The corresponding Gantt chart would outline a revised plan with reallocated resources and adjusted timelines to maintain productivity and safety.

Through the use of parametric planning, ontologies, and advanced forecasting, the DSMS application provides a powerful tool for managing tailings storage facilities. This approach allows for the creation of detailed, actionable plans that can adapt to varying future conditions, ensuring that operations remain efficient, compliant, and safe. Central to this functionality is the Registers Navigator (see Figure 4), an interface designed to enhance user interaction with digital models by offering an "explorer-like" structure. This intuitive navigation system allows users to organize and visualize 3D models, data, and documents within a unified interface. By enabling easy access to, and management of, all relevant information directly through the digital models, the Registers Navigator ensures that critical data is always at the user's fingertips, further streamlining the management and operational oversight of tailings storage facilities.

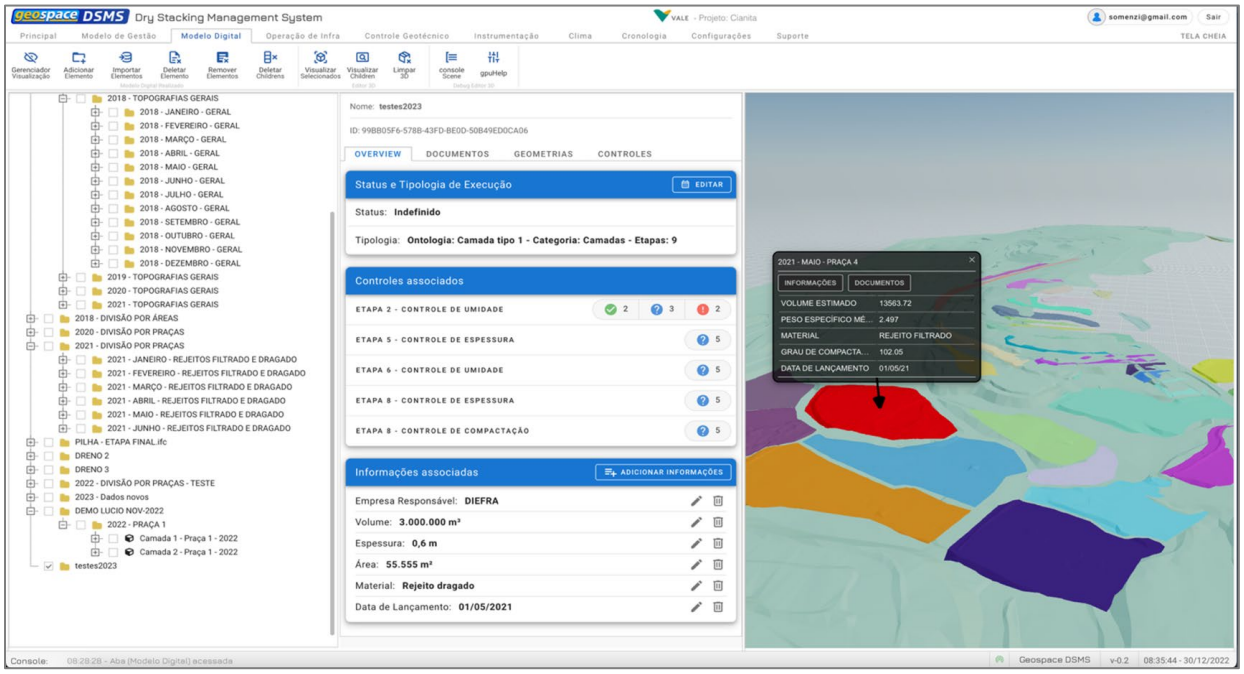

Figure 4: Registers Navigator interface in DSMS application

Conclusion

The TWIM Framework addresses critical challenges in managing dry stacking tailings by integrating Digital Twin technology, real-time monitoring, and predictive modeling. Initial deployment at Vale's tailings facility has shown promising improvements in both resource recovery and operational efficiency. The framework's development highlighted the importance of flexible software architecture and iterative testing, which were crucial in overcoming challenges like data integration and synchronization. As the framework continues to evolve, future efforts will focus on refining the software, expanding its use, and

ensuring it meets industry standards for safety and sustainability. The TWIM Framework provides a scalable, robust solution for the mining industry, enhancing the management of tailings storage facilities and supporting long-term operational success..

Acknowledgements

We sincerely thank Vale Company for their invaluable support and collaborate on, which were crucial to the development and application of the TWIM Framework. We also extend our gratitude to Geospace Digital Engineering Company for their technical expertise in developing DSMS Application.

CPT Calibration Chamber Testing of Tailings Sand at High Confining Pressures

Matthew Haynes, WSP, Australia

David Reid, University of Western Australia, Australia
Kyle Smith, WSP, Australia

Abstract

The cone penetration test (CPT) is the leading tool to assess the in-situ state, strength, and liquefaction susceptibility of sandy soils and mine tailings. Much of the interpretation of CPT results is based on the historic databases of calibration chamber tests on sand and, increasingly, mine tailings. While these efforts have led to the current procedures to interpret CPT data, two factors relevant to CPT application and interpretation require consideration: (i) the available calibration chamber data is dominated by tests with consolidated mean effective stresses < 200 kPa; and (ii) tailings storage facilities (TSFs) are being constructed to heights such that in-situ stresses are far higher than those of the available calibration chamber test database.

While much of CPT interpretation is carried out in a dimensionless framework, there is clear evidence that, even across the range of stresses for which calibration chamber tests have been carried out, relationships between some forms of stress-normalized cone resistance and in-situ state are dependent on effective stress. This stress-dependence is not accounted for in some CPT interpretation techniques. However, industry standard cavity expansion techniques, such as the CPTwidget, attribute the stress-dependence to a variation in shear rigidity with effective stress. Additionally, at high stresses, other factors, such as the curvature of the critical state line (CSL) in an e-log(p') plane, are another possible source of stress-dependence. Guidance on CPTwidget modeling for materials with a curved CSL has not been developed, which leads to a variety of possible techniques to input semi-logarithmic CSL parameters.

A new calibration chamber and miniature CPT capable of testing soils consolidated up to 2,000 kPa was developed to test sands at stresses relevant to large TSFs. A tailings sand, referred to as residue sand, originating from the separation of fine and coarse bauxite residue, was tested. The CSL of the residue sand was observed to exhibit significant curvature. Calibration chamber tests were performed at mean effective stresses of 50 and 1,000 kPa to capture the effect of the CSL curvature over the range of in-situ stresses

within the TSF. The results of the calibration chamber testing were compared to numerical simulations at equivalent stresses using the CPTWidget. The results of the testing were used to create a CPT calibration specific to the residue sand, to infer in-situ state parameter from normalized tip resistance.

Introduction

Characterization of tailings is crucial for design analyses of tailings storage facilities (TSFs). A combination of in-situ and laboratory tests are used to estimate the strength of tailings. However, the in-situ strength of low plasticity silt and sand tailings can be difficult to infer through laboratory testing on intact specimens due to significant sampling disturbance. Therefore, in-situ tests such as the cone penetration test with pore pressure measurement (CPTu) are required to estimate the state parameter (Ψ) of these materials.

Current state of practice methods to estimate Ψ from normalized CPTu tip resistance (Q) have been developed by Been et al. (1988) and Been and Jefferies (1992) based on a database of calibration chamber testing. Tip resistance was normalized by Been and Jefferies according to Equation 1, where Q_p is the tip resistance (q_t) normalized by the mean total stress (p) and the mean effective stress (p'). Further, Equation 2 normalizes Q_p by the pore pressure ratio (B_q) and presents the relationship with Ψ and coefficients k and m. Finally, Shuttle and Cunning (2007) introduced Equation 3, which is the equation used in this paper.

$$Q_p = \frac{q_t - p}{p'} \quad \text{(Equation 1)}$$

$$q^* = \frac{Q_p}{1 - B_q} = k e^{-m\Psi} \quad \text{(Equation 2)}$$

$$Q_p(1 - B_q) + 1 = k e^{-m\Psi} \quad \text{(Equation 3)}$$

Shuttle and Jefferies (2016) introduced the cavity expansion model, CPTwidget, to provide an alternative to undertaking physical calibration chamber testing. The results of the CPTwidget were scaled using a cone factor (C_q) to match calibration chamber tests from the updated database used by Jefferies and Been (2015). This calibration chamber database is limited to a maximum p' of 457 kPa, with a mean and median of 109 and 75 kPa, respectively. However, the CPTwidget is frequently used for interpretation of CPTu data (Q vs. Ψ) for TSFs where the in-situ stresses far exceed that of the Jefferies and Been database that was used to develop the software (Oberle et al., 2020).

CPTwidget allows for calibration of Q vs. Ψ over a range of shear rigidity (I_r) values to capture the influence of I_r variation with effective stress. Variation of I_r is the only stress dependent relationship for drained simulations in the CPTwidget. However, another potential source of stress level bias is present for materials with a curved critical state line (CSL), where λ_e (ln of λ) changes with stress. Curved CSL inputs

have not been implemented in the CPTwidget, and guidance for inputting λ_e for materials with a curved CSL has not been provided by the authors.

This paper presents a comparison of small-scale calibration chamber testing using miniature CPT and CPTu cones at low and high effective stress. A sand with significant curvature of the CSL at high stresses was tested. Comparison to the CPTwidget simulations allowed for an assessment of the CPT inversion parameters and the stress level bias of the CPTwidget against the results of the calibration chamber tests.

Calibration chamber

Equipment

A small-scale calibration chamber, illustrated in Figure 1, was created, based on a triaxial testing apparatus.

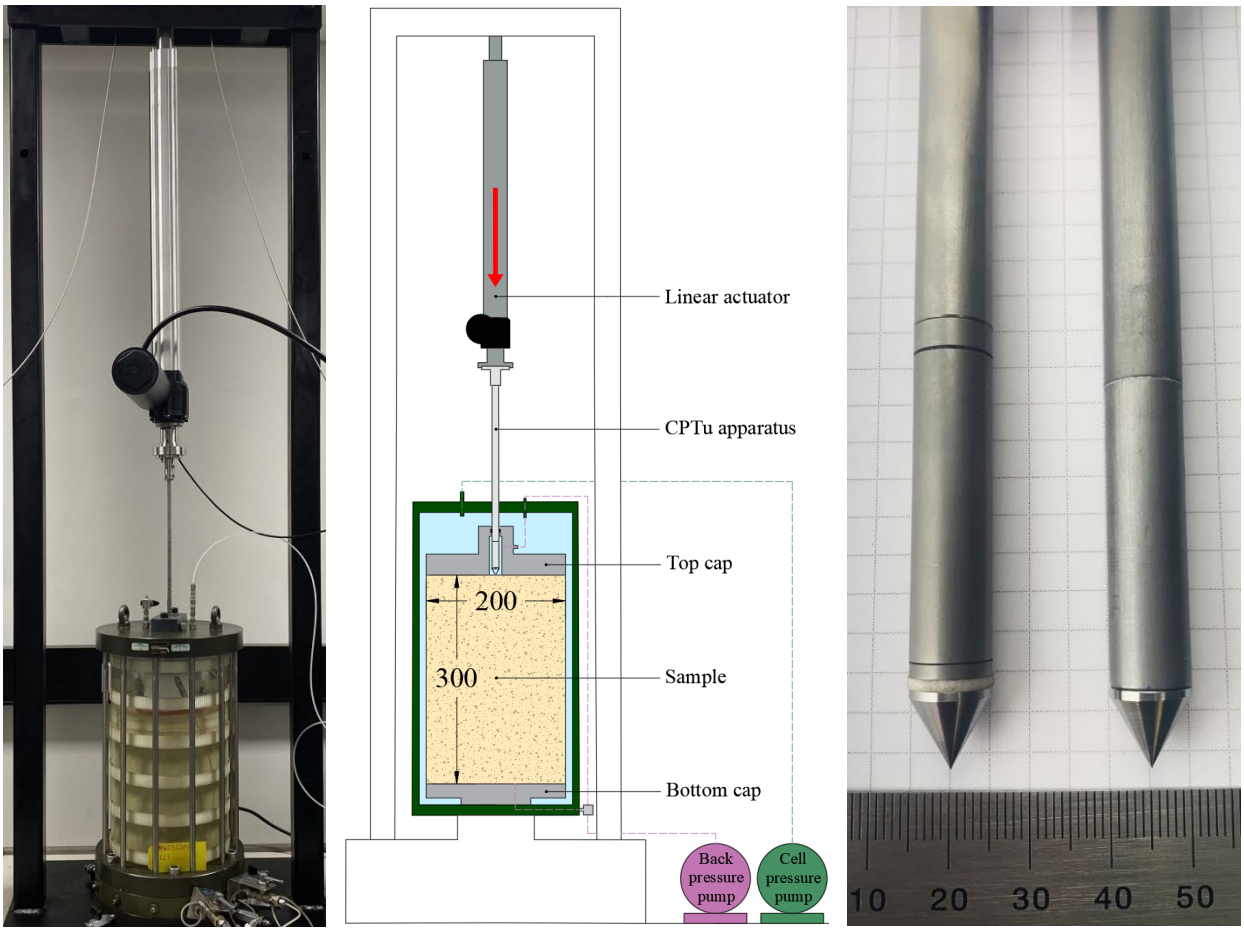

Figure 1: Miniature calibration chamber photograph (left), schematic (center), miniature CPTu and CPT apparatus (right)

The calibration chamber applies stress isotropically using cell pressure applied to the membrane and top cap. The steel bottom cap applies a fixed base restraint. Therefore, the boundary conditions are classified as BC4 (Been et al., 1986). The design of the testing apparatus was based on the design presented by Ayala

et al. (2020) and Damavandi-Monfared and Sadrekarimi (2015). Equipment from Haynes et al. (2024) was used with two modifications, as detailed below:

- 200 mm diameter stainless steel bottom cap modified with an external drainage port for connection to an access ring. The modification allowed for testing materials with corrosive pore fluid without damaging the aluminum triaxial cell.
- 400 mm stroke linear actuator, which replaced the triaxial loading frame. The linear actuator provided a larger stroke for cone penetration compared to the triaxial loading frame.

Additionally, the following equipment was used from the apparatus outlined by Haynes et al. (2024):

- 488 × 222 mm (internal height × diameter) triaxial cell with coupling to seal against the shaft of the CPTu apparatus.
- 2 × pressure/volume controllers to apply the cell and back pressures.
- 200 mm diameter top cap with a sealed opening for the shaft of the CPTu apparatus.
- 2 × 200 mm sintered-bronze porous stones for the top and bottom of the specimen. The top porous stone included an opening for the CPTu cone.
- 430 × 200 mm (height × diameter) latex membrane.
- 10 mm diameter miniature CPT and CPTu cones.

Both a miniature CPT and a miniature CPTu cone (refer to Figure 1) were used for testing. The CPT apparatus provided only a measurement of tip resistance, while the CPTu apparatus included a friction sleeve and pore pressure transducer. The miniature cones have an apex angle of 60° and are dimensionally consistent with the full-scale cones. Specifications of the CPT and CPTu apparatuses are provided in Table 1. The 30 MPa CPTu cone was limited to low stress tests (p' = 50 kPa) due to the tip loadcell capacity. The 100 MPa CPT cone was used for high stress tests (p' = 1,000 kPa). The 30 MPa CPTu cone was used for low stress tests due to the greater accuracy of the tip resistance load cell. The pore pressure (u_2) measurement also allowed estimation of drainage conditions at the penetration rate used.

Table 1: CPTu and CPT apparatus specifications

Parameter	CPTu	CPT
Tip resistance: q_t (MPa)	30	100
Frictional resistance: f_s (kPa)	1,000	N/A
Pore pressure: u_2 (kPa)	1,000	N/A

Specimen preparation

Specimens were prepared to a diameter of 200 mm and a height of 300 mm. The geometry of the specimens allowed for a 20:1 ratio of the specimen and cone diameter, as suggested by various studies (Bolton et al.,

1999; Gamez and Olson, 2022; Gui et al., 1998; Pournaghiazar et al., 2012). The specimen height of 300 mm allowed for penetration of the middle 100 mm, at a distance from the top and bottom boundaries which was greater than the distance from the horizontal boundaries.

Specimens were prepared using moist pluviation (MP), based on the method developed by Reid et al. (2024). This method was selected as pluviated specimens were shown to provide greater specimen uniformity compared to moist tamping (MT) (Haynes et al., 2024; Frost and Park, 2003). Dry or wet pluviation could not be used due to segregation of the specimens at low and high gravimetric water contents (GWC). To achieve a range of initial densities, a range of initial GWC and vibration frequencies were used for each test. This allowed for a range of Ψ to be achieved at the target consolidated p'. Due to the moisture in the specimen, pluviation through a funnel was not possible. Therefore, to place the soil in a controlled and evenly distributed manner, a 14 mm sieve was placed on top of the mold. The soil was then pushed through the sieve. This resulted in the pluviation height changing as more specimen was placed, which could have resulted in a denser to looser gradient from the bottom to the top of the specimen.

To confirm the specimen uniformity created by this technique, individually pluviated layers were placed in an acrylic column of similar dimensions to the calibration chamber specimens. The density of each layer was calculated after the specimen was pluviated. This check indicated that the specimen preparation technique used did not create a density gradient.

Procedure

A test procedure was developed based on the method used by Ayala et al. (2020). To estimate the change in void ratio (e) of the specimen during saturation and consolidation, a modified version of the cell calibration technique was adopted. End of test freezing was not used, owing to difficulties in freezing calibration chamber specimens due to the specimen size and cap arrangement. All tests using this procedure were back pressure saturated to 550 kPa. The test procedure is provided below:

1. Prepare a specimen using MP to the target density within a split mold. The specimen is sealed by the top and bottom caps and a latex membrane. During this stage, the cone is housed within a recess in the top cap.
2. Apply a suction of −50 kPa to the specimen and measure the height and circumference of the specimen at various locations.
3. Close the triaxial cell and fill it with water. The valves to the specimen are closed to maintain −50 kPa suction in the specimen.
4. Open the valves to the specimen and apply 0 kPa cell pressure and −50 kPa back pressure until a constant cell and back volume is achieved.
5. Increase the cell and back pressure in three steps:

a. 0 kPa cell and −20 kPa back pressure.
b. 30 kPa cell and −20 kPa back pressure.
c. 30 kPa cell and 15 kPa back pressure.

6. Flush the specimen by opening the top drainage line to atmospheric pressure, while applying a constant 30 kPa cell pressure and 15 kPa back pressure. After flushing, reconnect the top drainage line to the back pressure pump and reduce back pressure to 10 kPa.
7. Increase the cell and back pressure in 30 kPa increments, maintaining a maximum effective stress of 50 kPa. Achieve a constant cell and back pressure for each stage before going to the next stage. Repeat this process until reaching cell and back pressure values of 600 and 550 kPa, respectively.
8. Determine the B-value by increasing the cell pressure with valves to the top and bottom drainage lines closed.
9. Consolidate the specimen to the target effective stress by increasing the cell pressure in steps with a load increment of 1.
10. Test stage: insert the cone 240 mm into the specimen at a constant rate ≤ 1 mm/s, while maintaining a constant cell and back pressure.

Material properties

A bauxite tailings sand, referred to herein as residue sand, was tested. The residue sand was chosen due to its significantly curved CSL, with λ_e changing from 0.04 to 0.15 at p' of 50 and 1,000 kPa, respectively. The residue sand forms the embankment walls of an upstream raised TSF and is stored within the TSF at up to 50 m depth. Therefore, the in-situ vertical effective stress (σ_v') and p' are estimated to reach 1,000 and 700 kPa, respectively. The material properties are summarized in Table 2.

Table 2: Residue sand material parameters

Property	Value
Specific gravity: G_s (-)	3.37
Coefficient of uniformity: C_u (-)	3.78
D_{50} (mm)	0.425
Fines content (%)	4%
CSL: M_{tc} (-)	1.54
CSL power law: A (-)	1.19
CSL power law: B (-)	0.05
CSL power law: C (-)	0.70

The CSL of the residue sand was estimated based on six CID triaxial tests ranging from 30 to 550 kPa consolidated stresses. Four of the triaxial tests were performed using process liquor and two using demineralized water as pore fluids. This was done to assess if the pore fluid affected the CSL of the residue sand. The critical state points of the demineralized water tests tended towards the CSL derived using process liquor. The semi-logarithmic and power law CSL parameters are provided in Tables 2 and 3. Small strain shear modulus (G_{max}) and I_r were estimated from two bender element (BE) tests prepared to different initial densities. These results are presented in Figure 3.

Table 3: CPTwidget input parameters

Property (unit)	Value
State dilatancy: χ (-)	3.80
Volumetric coupling parameter: N (-)	0.29
Plastic hardening: H (-)	90-700Ψ
Poisson's ratio: ν (-)	0.20
CSL slope: λ_e (-)	0.04
CSL intercept: Γ (-)	1.32

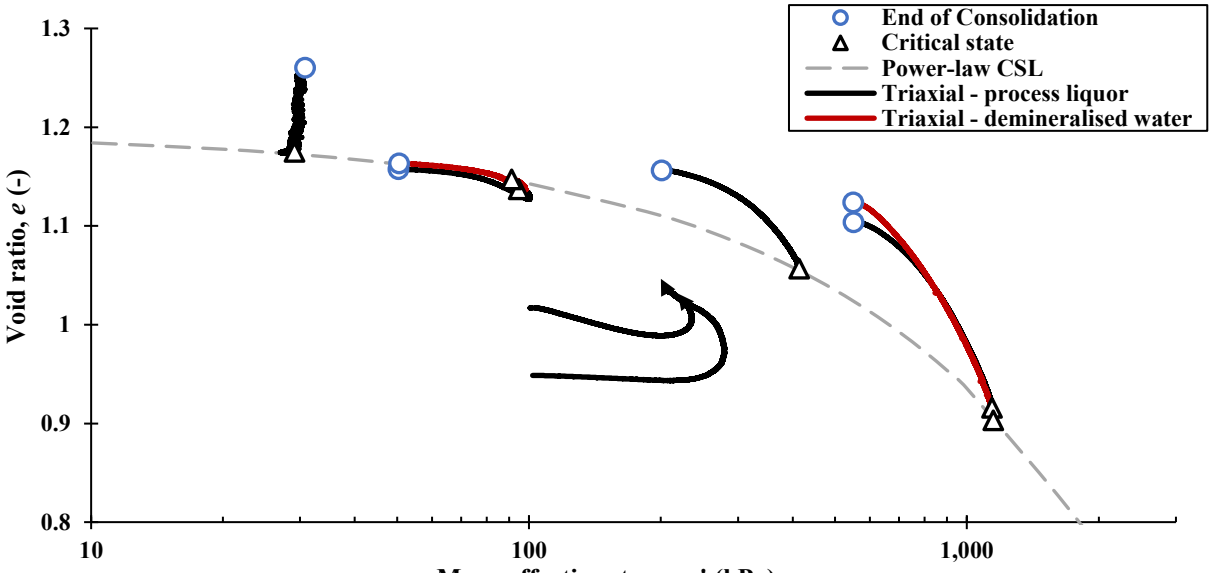

Figure 2: Residue sand CSL

Calibration chamber tests

Nine calibration chamber tests were performed, consisting of five tests at low stress (p' = 50 kPa) and four tests at high stress (p' = 1,000 kPa). All tests were performed under drained conditions during CPT and CPTu penetration. Specimens were prepared to a range of initial densities, resulting in a range of Ψ at the

target consolidated stress. Tests were performed using demineralized water as the pore fluid to avoid damaging the miniature CPT and CPTu apparatuses and to reduce the risk of leaks of large quantities of caustic liquor. This is not anticipated to affect the results of the tests, as the CSL of the residue sand was not affected by changing from process liquor to demineralized water.

Cavity expansion modeling

Spherical cavity expansion modeling was performed for comparison to the calibration chamber results using CPTwidget Version 2.5, developed by Shuttle (2019). Simulations were run for a range of Ψ at low and high stresses, equivalent to the stresses of the calibration chamber tests.

The constitutive soil model, NorSand, was used for the CPTwidget model (Jefferies, 1993). NorSand parameters were calibrated based on the results of two dense and six loose triaxial tests. Inputs for shear rigidity were estimated based on the BE tests presented in Figure 3. G_{max} was related to p' and e based on the equation (see Figure 3) proposed by Jefferies and Shuttle (2020) for calibration of NorSand. G was reduced by a factor of four from the BE result to allow for better calibration of NorSand. Use of similar reduction factors for this purpose was proposed by Shuttle and Jefferies (2016).

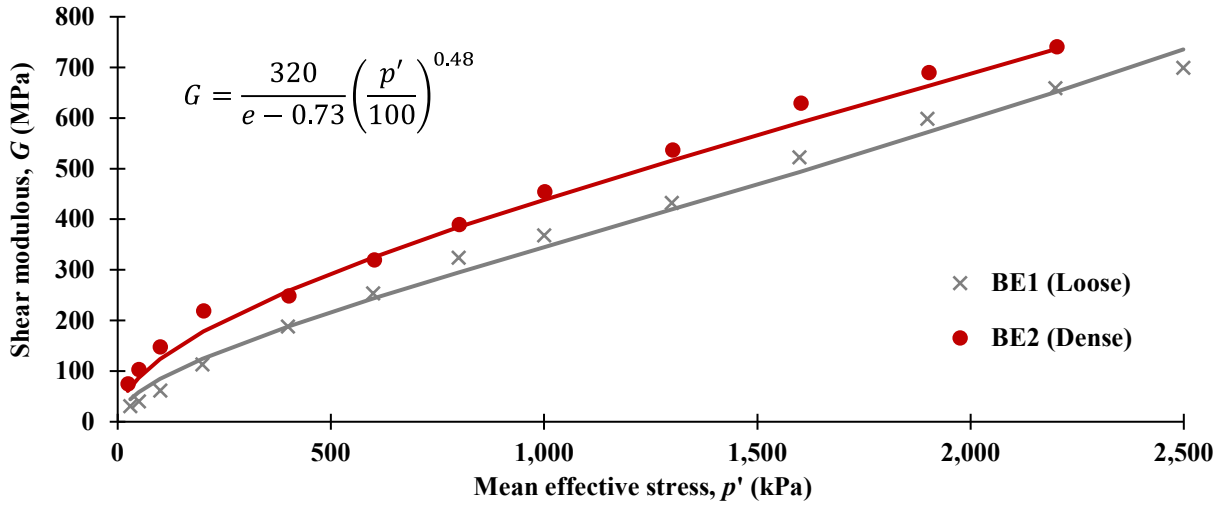

Figure 3: Bender element test results (G vs. p')

Inputs specific to the model are listed in Table 3. Semi-logarithmic CSL parameters (λ_e and Γ) were fit to the intermediate stress region of the CSL (Figure 2). A semi-logarithmic function does not fit well to the curved CSL at $p' > 200$ kPa.

Results

The results of the calibration chamber tests are presented in Figure 4, with trendlines fit to the low and high stress data using Equation 3. The tip resistance presented is the mean from the middle 100 mm of the

specimen. Error bars on the y-axis indicate the variability of tip resistance within the middle 100 mm of the specimen.

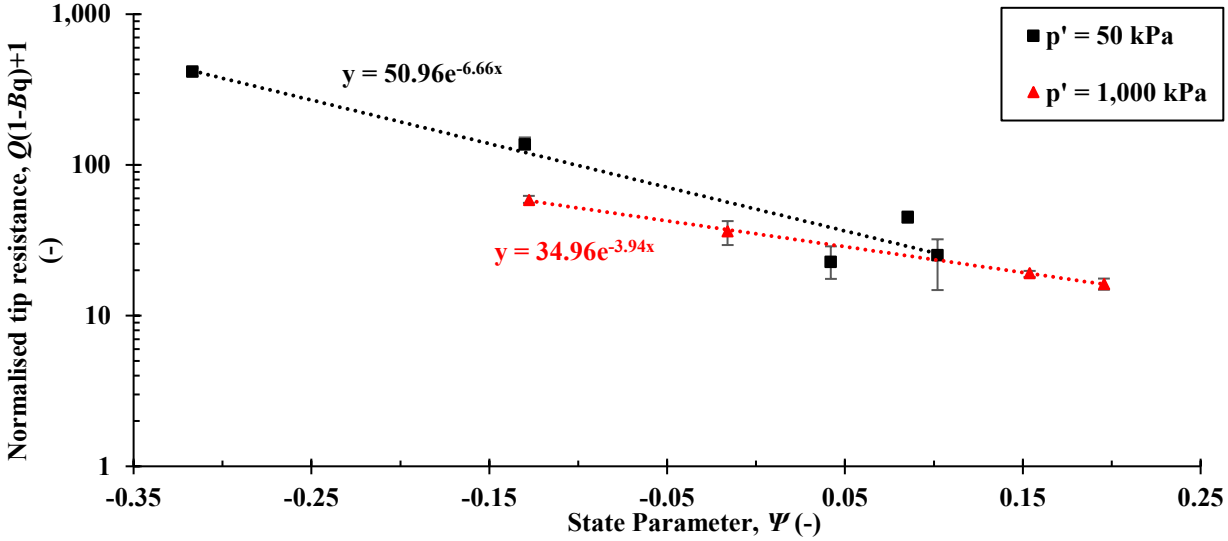

Figure 4: Calibration chamber results

The calibration chamber results at low and high stress show a linear semi-logarithmic trend consistent with the form of Equation 3. Based on the findings of Salgado et al. (1998) and Been et al. (1986), it is anticipated that the influence of boundary conditions would result in a reduction of $Q(1-B_q)+1$ at low Ψ. No significant reduction has been observed in the data.

The use of moist pluviation allowed for uniform loose specimens to be prepared and for several tests to be performed at a Ψ greater than the maximum Ψ in the Jefferies and Been (2015) database. Variability between tests and within each specimen was greater in specimens prepared to low initial densities, consistent with Haynes et al. (2024). Less variability was observed in high stress tests compared to low stress tests at equivalent Ψ. This may be due to the greater divergence of the normal consolidation line (NCL) and CSL at higher stresses, which allowed for high stress test specimens to achieve higher Ψ from higher initial densities.

Comparing the trendlines and inversion parameters, k and m, between high and low stress indicates a clear reduction of k and m with increased stress (Figure 4). This is consistent with stress level effects in the Jefferies and Been (2015) database, which are attributed to a reduction in I_r with increasing stress.

The results of CPTwidget modeling are plotted in Figure 5 for comparison to the calibration chamber result. The low stress CPTwidget simulation fits within the range of the calibration chamber data. However, the high stress CPTwidget result showed a significantly steeper trend (higher m) compared to the trend of the high stress calibration chamber data. Therefore, the stress level bias observed in the residue sand was larger than predicted by CPTwidget. This may be due to the effect of CSL curvature, which is not

incorporated into the CPTwidget result. This appears to be supported by the simulations of Martinelli and Pisano (2022).

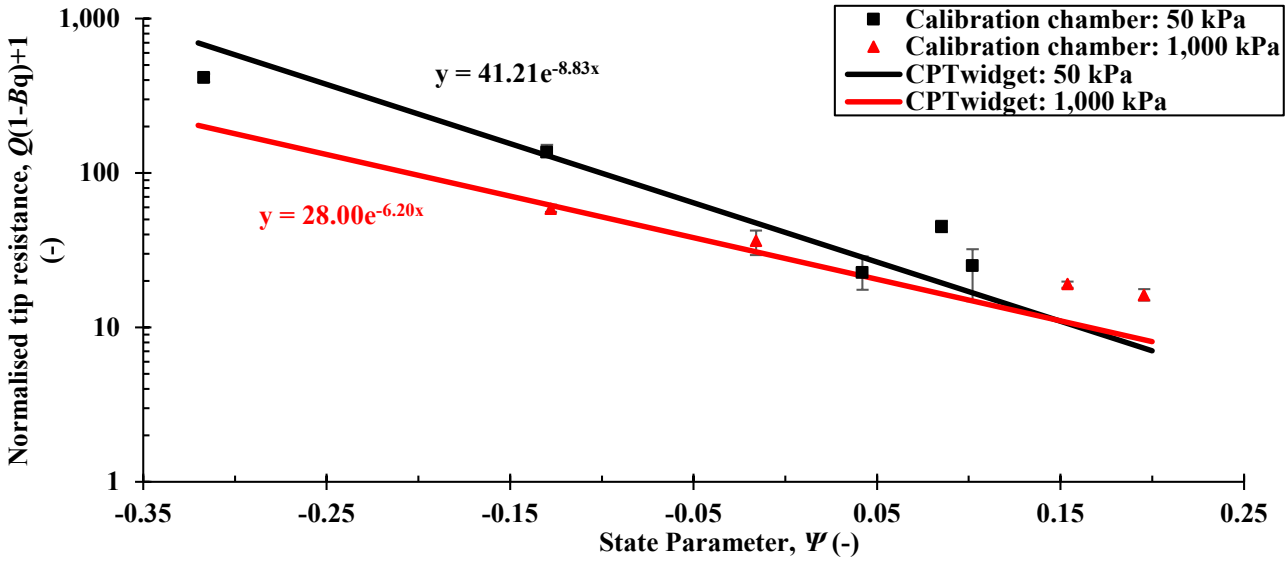

Figure 5: CPTwidget results compared to calibration chamber results

Conclusion

A series of calibration chamber tests were carried out on a residue sand under low and high consolidated effective stresses to assess the performance of the CPTwidget across a wide range of effective stresses in a material with a significantly curved CSL. This testing was carried out by incorporating modifications to a previously developed miniature calibration chamber system to enable higher stress testing. The following observations were provided by this work:

- Unique trendlines, with a linear semi-logarithmic form, were identified from the calibration chamber tests on residue sand at both low and high stresses.
- High stress calibration chamber tests showed a lower normalized cone resistance, with lower sensitivity to changes in Ψ (lower k and m values), compared to low stress tests.
- Comparison of calibration chamber results to the CPTwidget simulations showed a good fit at low effective stresses, but a poor fit at high effective stresses.
- Variances between the CPTwidget and calibration chamber result at high stress may be due to an additional source of stress level bias resulting from CSL curvature, which is not accounted for in the CPTwidget.

Interpretation of Pore Pressure Dissipation Test Results in Tailings

E. Rust, Osimo, South Africa
M. Rust, NewFields, USA

Abstract

When a Piezocone is advanced through saturated soil (or tailings) it induces dynamic pore pressure. The dynamic pore pressure can be higher or lower than the ambient pore pressure in the soil depending on whether the soil is dilating or contracting due to disturbance by the cone. When the cone penetration is stopped or halted temporarily, the dynamic pore pressure dissipates until it reaches ambient pore pressure. Permeability and the coefficient of consolidation, notably in the horizontal direction, can in some cases be approximated from the rate of dissipation. In almost all cases the asymptotic value at the end of the dissipation test provides a direct measurement of the ambient pore pressure in the surrounding soil.

The purpose of this paper is to provide examples of typical pore pressure dissipation test results and discuss the reasons why these signatures exist.

Introduction

A Piezocone investigation on mine tailings is often carried out at a number of cross-sections where the stratigraphy of all the material in the tailings storage facility (TSF), as well as the foundation, is investigated and their engineering properties are determined, including the degree of saturation above the water table. Furthermore, from the dissipation tests alone the complete flow regime, including permeability, coefficient of consolidation, anisotropy in permeability, possible excess pore pressures and two-dimensional or three-dimensional flow-net, can be determined.

Dissipation test results in tailings are discussed in this paper, and a conceptual model of the dynamic pore pressure distribution during a dissipation test is introduced at the end of the paper.

A detailed pore pressure with depth profile

The frequency of dissipation tests depends on several factors; however, a controlling aspect is often the permeability of the tailings. Tailings properties can vary over a wide range due to their origin and/or the mineral extraction process employed. For the purposes of this discussion, it is sufficient to distinguish

between tailings that behave as a natural clay (including kimberlite, often iron ore, highly oxidized ore, alluvial tailings, and some others) and hard rock milled tailings that are predominantly fine sand and silt-sized. The clay-like tailings have low permeabilities and require long dissipation tests, while the hard rock tailings require shorter dissipation tests.

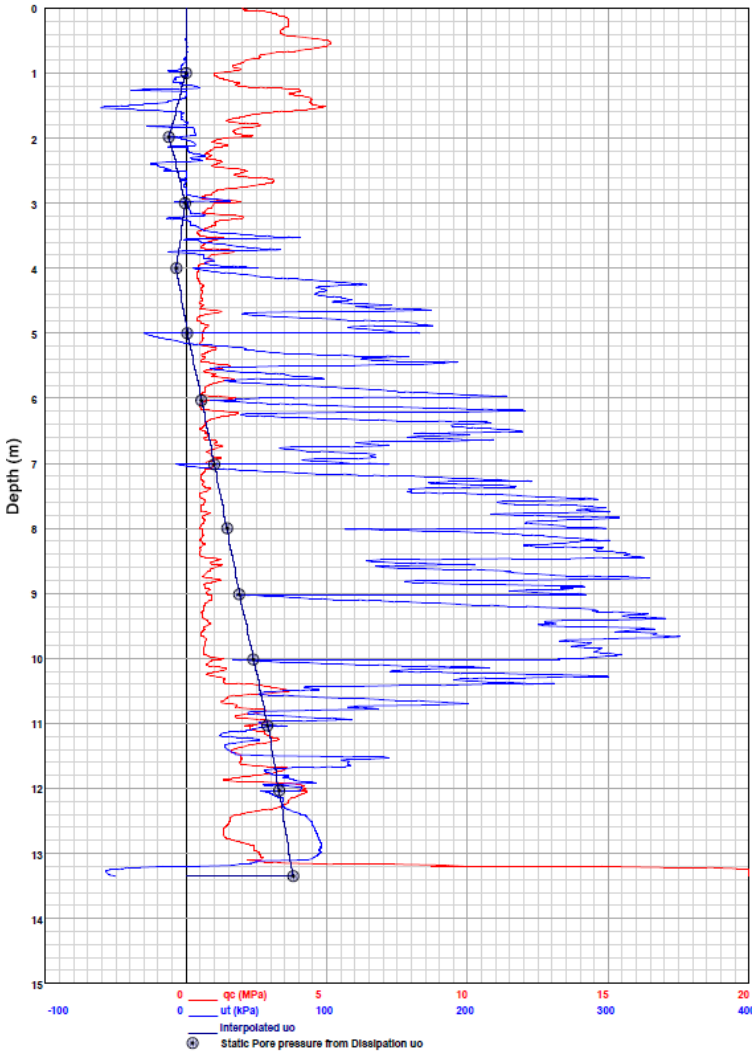
In high permeability tailings, as a rule of thumb, a dissipation test should be carried out every 2 m or 3 m. It is also recommended that the pore pressure be recorded continuously while the CPTu test is being carried out, even during a rod change that may only take a minute or so to produce an incomplete dissipation test. If it is possible to determine the ambient pore pressure every 2 m to 3 m, it may be possible to interpolate the pore pressure at all the short dissipations. This should allow for the determination of the time required to reach 50% of the dissipation (t_{50}) and maximize the information from the probe.

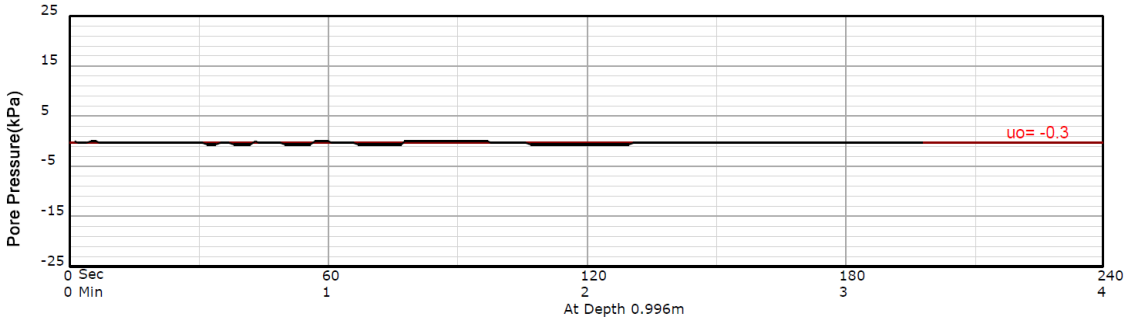
Tailings with a low permeability should be dealt with on a case-by-case basis. In some extremely low permeability tailings, the time required for dissipation of excess pore pressures could be several days, making it impractical to do as part of the probing campaign. In these cases, pore pressure dissipation tests are recorded until t_{50} is reached, as well as the installation of nested vibrating wire piezometers to provide a measurement of the ambient pore pressure is recommended.

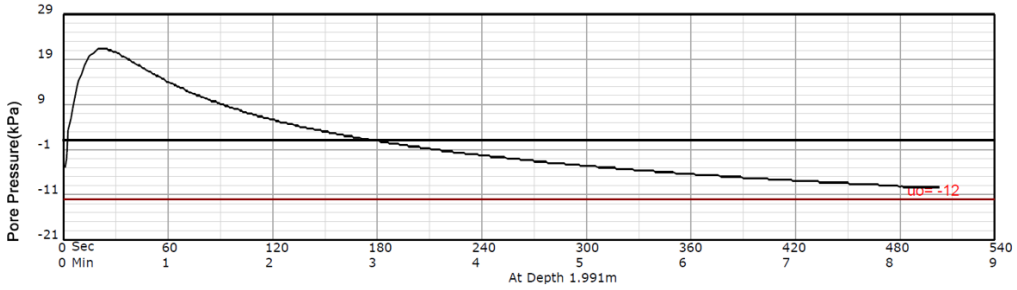
An example of a detailed pore pressure profile with frequent pore pressure dissipation tests is shown in Figure 1. A dissipation test was recorded at each meter in this example. Some of the dissipations from this sounding are shown in Figure 2 (a to g). The black dots on the figure represent the ambient pressure at each dissipation and the black line that connects these dots represent the interpolated tendency of the pore pressure with depth. Below the water table the line will follow the rate pore pressure buildup.

If a dissipation test is carried out above the water table in unsaturated coarse (sandy) tailings the dissipation line will be horizontal and tend to be zero or slightly negative (-1 kPa to -2 kPa), for example Figure 2a. In this zone the layers of saturated fine tailings (slimes) will have a negative pore pressure due to the suction pressures generated by desiccation, for example the dissipations in Figures 2b and 2c. Figures 2d to 2g present typical dissipation tests below the water table.

This dynamic pore pressure profile will also assist in determining the degree of saturation above the water table (Rust, 2023). It is necessary for the design of the Piezocone to have a small fluid chamber so as to improve pore pressure response as well as data sampling at a higher frequency than generally used in industry to get such a detailed pore pressure response. The data frequency rate for this Piezocone is set at 5Hz (implying a reading every 4 mm), whereas the industry norm is generally to sample at depth increments of 25 mm. A positive ambient (static) pore pressure is rarely measured above the water table. Perched water tables and detectable wetting fronts are uncommon. All the dissipations contribute to a detailed understanding of the flow regime, especially when combined with adjacent profiles in a cross-section.







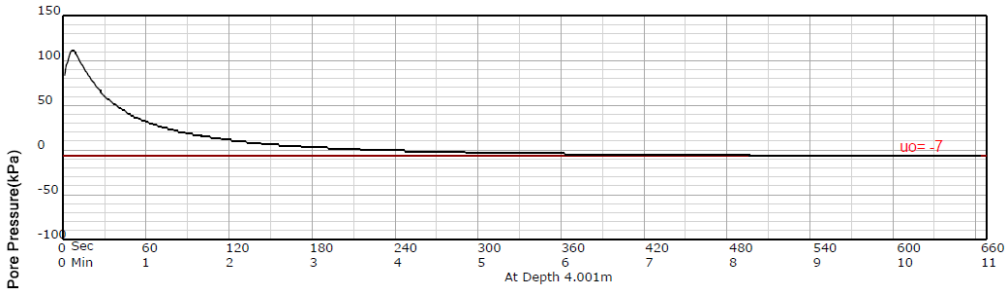


Figure 1: An example of a detailed pore pressure profile from a Piezocone sounding with the black dots indicating the ambient pore pressure from dissipation test results

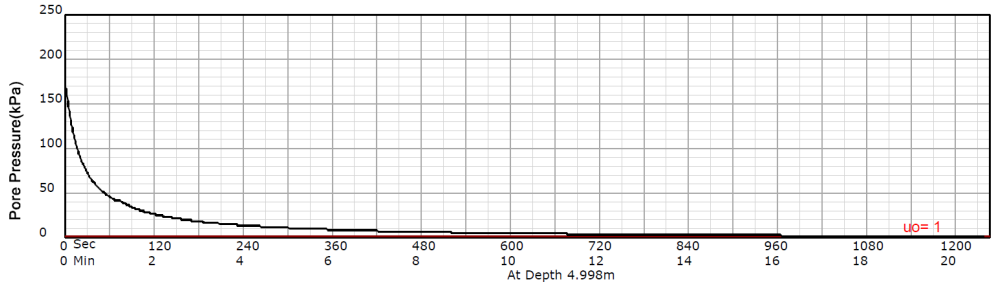
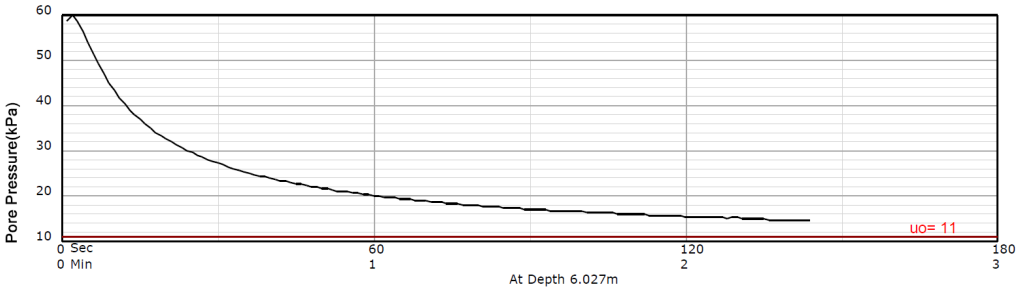
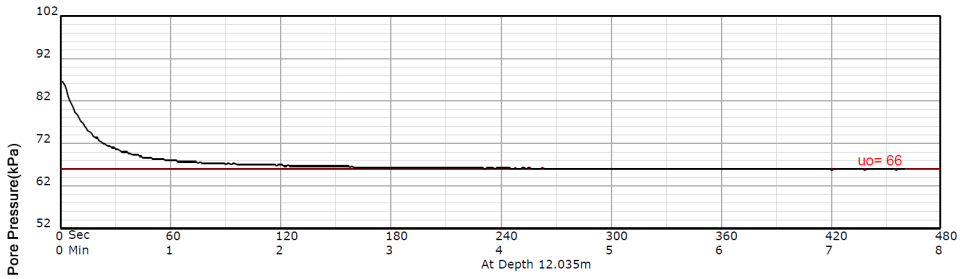


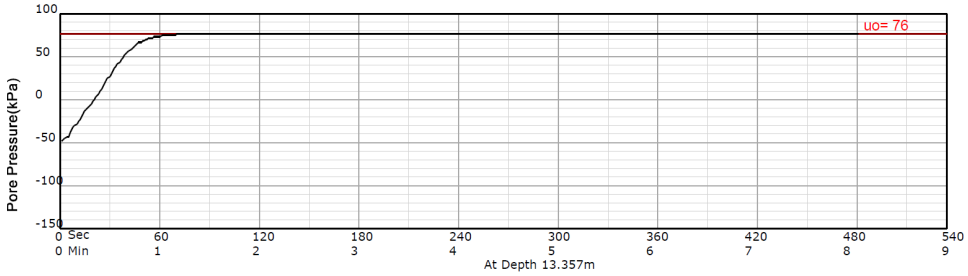
(a) Dissipation in unsaturated coarse (sandy) tailings. Pore pressure is usually 0 or slightly negative



(b) Dissipation in a fully saturated desiccating fine tailings (slimes) layer above the water table with an ambient pore pressure of -12kPa



(c) Dissipation in the capillary zone



(d) Dissipation at the water table

(e) Short incomplete dissipation test below the water table

(f) Last dissipation in the tailings

(g) Dissipation in the underlying very stiff clay (decomposed shale)

Figure 2: Selected dissipation test results from the Piezocone result shown in Figure 1

Flow regime from a cross-section

Figure 3 shows a cross-section of the Merriespruit facility after the TSF failed on 22 February 1994 (in South Africa). The dissipation test results and trend lines connecting the dissipation test are shown on the cross-section. It provides detailed information on the phreatic regime in this TSF at the probed locations. It is important that all the dissipations are used, or at least all the dissipations below the water table, if the flow in the capillary fringe is going to be ignored.

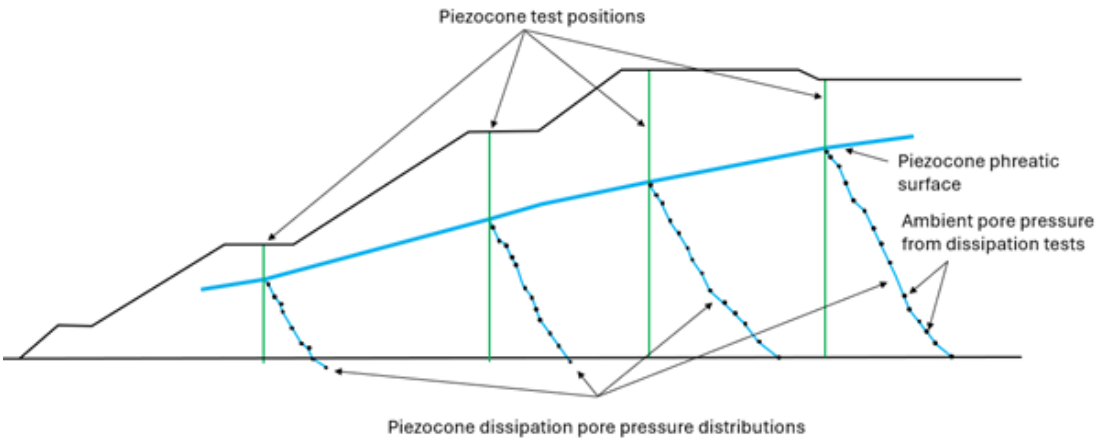


Figure 2: Cross-section of Merriespruit tailings facility showing the measured pore pressure distribution

The results from the dissipation tests can be used to develop a two-dimensional flow-net, and complex flow characteristics such as the anisotropy in permeability can be estimated by carrying out a detailed finite element flow analysis.

Shape of the dissipation test

A number of typical pore pressure dissipation responses or shapes are routinely found in tailings. Extensive research has been carried out on these dissipation tests and has been published by several researchers including Baligh and Levadoux (1980), Teh and Houlsby (1991), Rust (1996); Sully et al. (1998), Burns and Mayne, (1998) and Burns and Mayne,\ (2000). The shape of the dissipation test depends on the pore pressure generated during probing. This pressure is made up of the ambient (static) pore pressure, shear stress induced and normal stress induced pore pressure.

$$u = u_0 + \Delta u_{shear} + \Delta u_{normal}$$

$$u_e = \Delta u_{shear} + \Delta u_{normal}$$

Where u_e is the net induced excess pore pressure.

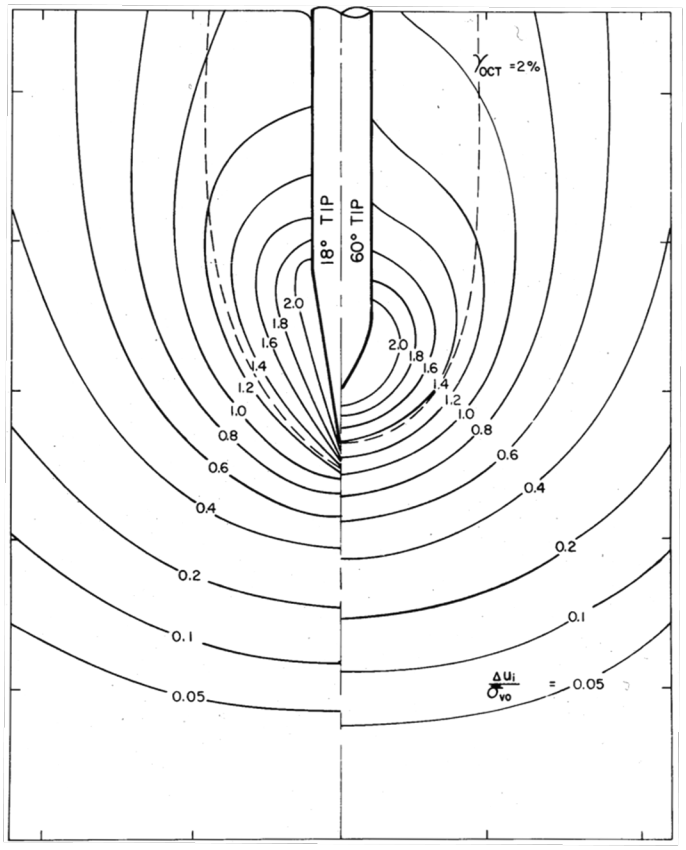

Figure 3: Predicted excess pore pressures during steady cone penetration in normally consolidated Boston Blue Clay (18° and 60° tips) (Baligh and Levadoux, 1980)

Figure 4 from Baligh et al. (1980) shows the induced excess pore pressure (u_e) determined using the strain path method. A normally consolidated multi parameter Boston Blue Clay model was used to derive the pore pressure distribution. The induced excess pore pressure is normalized with the initial total vertical stress.

The normally consolidated soil model shows a positive response in the net u_e (or u_i in the figure). Figure 5 from the same author shows the contribution of the shear induced excess pore pressure (Δu_{shear}).

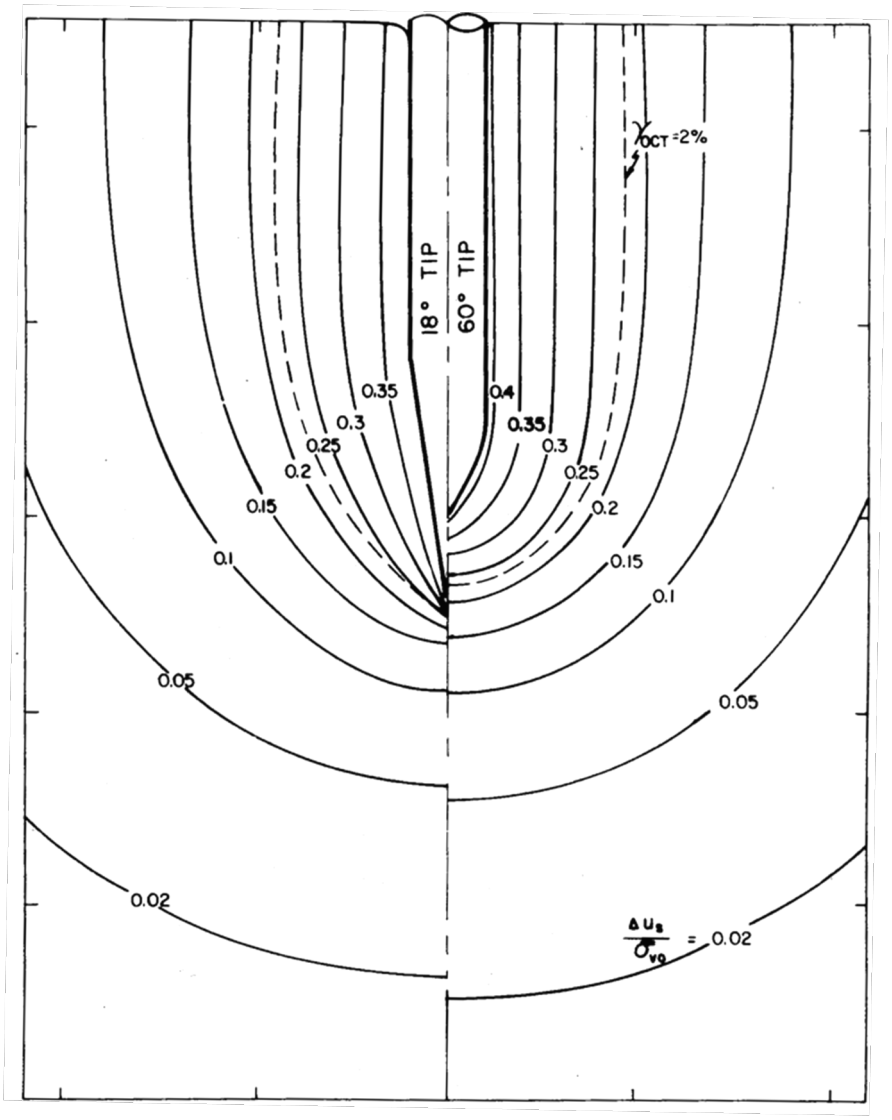

Figure 4: Predicted shear induced pore pressures during steady cone penetration in normally consolidated Boston Blue Clay (18° and 60° tips) (Baligh and Levadoux, 1980)

The pore pressures are positive because the soil model is for a normally consolidated soil. When comparing these two figures it is evident that the shear induced pore pressures are significantly less than

the total induced excess pore pressure and are limited to an area close to the probe. This distribution will produce a monotonic decaying dissipation with a clear t50 and u0 +, as per the example in Figure 6.

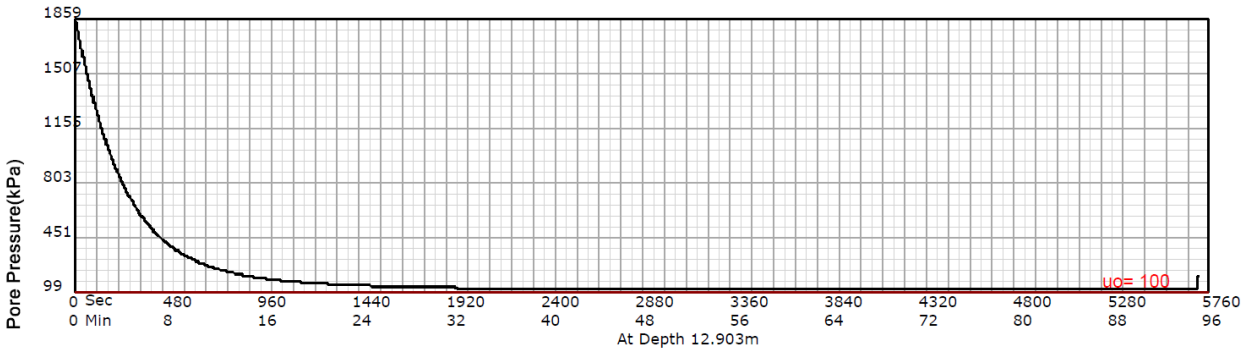

Figure 5: Monotonic decay of positive excess pore pressure in contractive tailings

However, a large proportion, if not the majority of dissipations in tailings, will display a different response. If the soil is over-consolidated, dilation may occur in the zone of high shear deformation close to the probe (Mayne, 2000). This will result in negative ushear pressures which will decrease pore pressure -close to the probe. This effect could be small, or it could dominate the entire dissipation regime and de-saturate the probe.

Dissipations with increasing dilation

Dissipation tests in tailings are commonly carried out in the layers of slimes (fine tailings). These layers tend to be slightly over-consolidated, mostly due to desiccation, and tend to dilate upon shearing. Therefore, one common type of pore pressure dissipation test result is an initial rising trend (increase in pore pressure) followed by subsequent decreasing pore pressure to an asymptotic value.

As the tendency to dilate increases, the shear induced negative pressure will increase and may dominate the dissipation test. Figures 7 to 10 show a sequence of pore pressure dissipation test results where shear induced dilation close to the cone has an increasingly larger effect on the pore pressure dissipation.

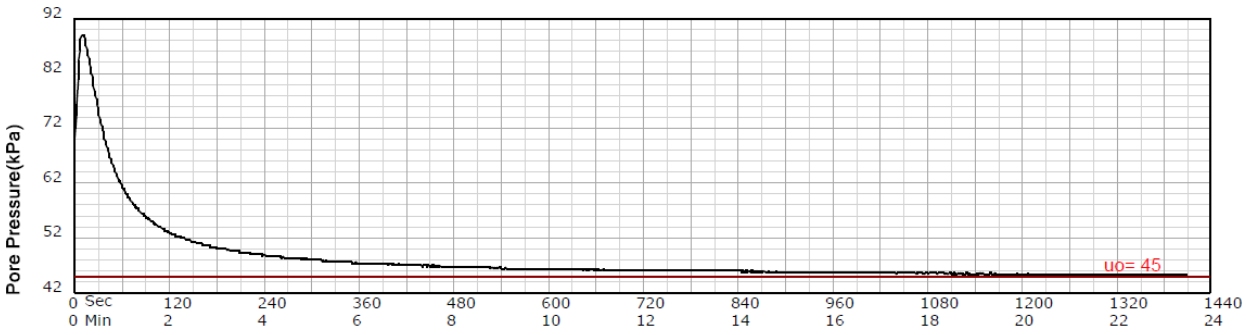

Figure 6: Dissipation test with moderate dilation

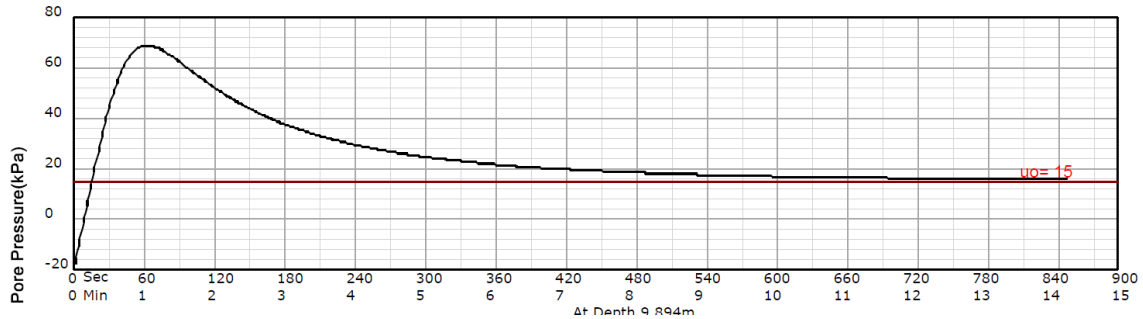

Figure 7: Dissipation test with dilation resulting in initial pore pressures less than ambient

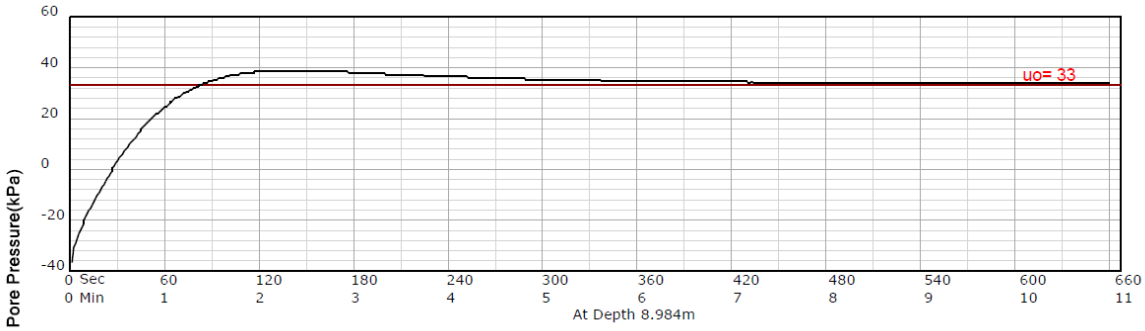

Figure 8: Dissipation test with shear induced dilation dominating the pore pressure dissipation showing only mild dissipation of positive excess pore pressures

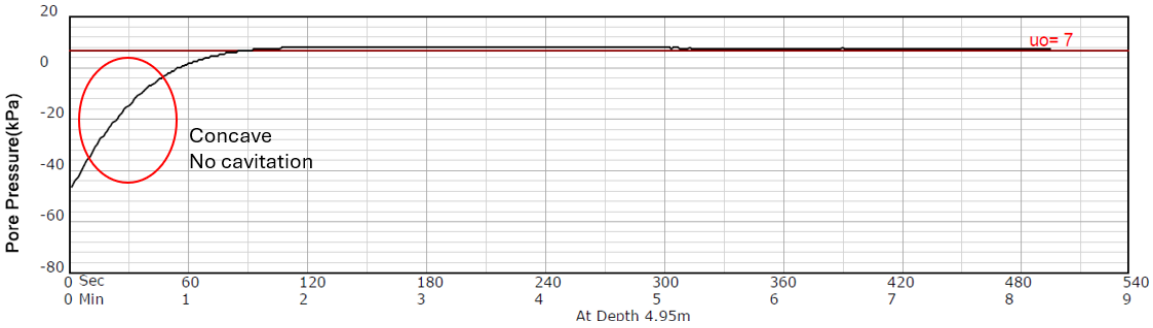

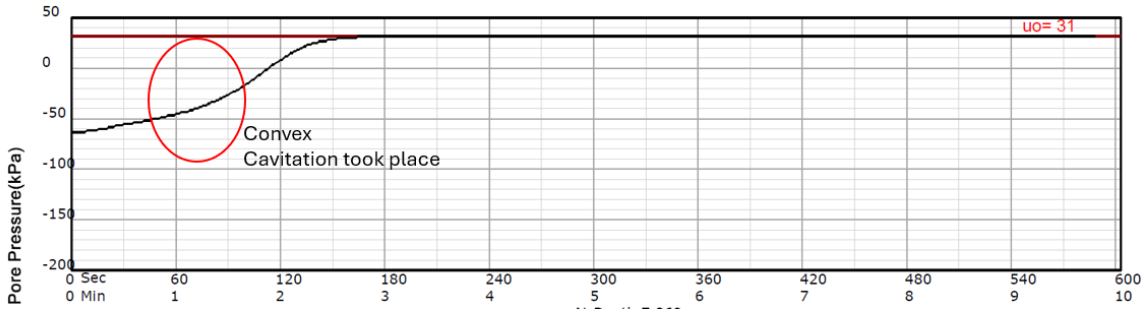

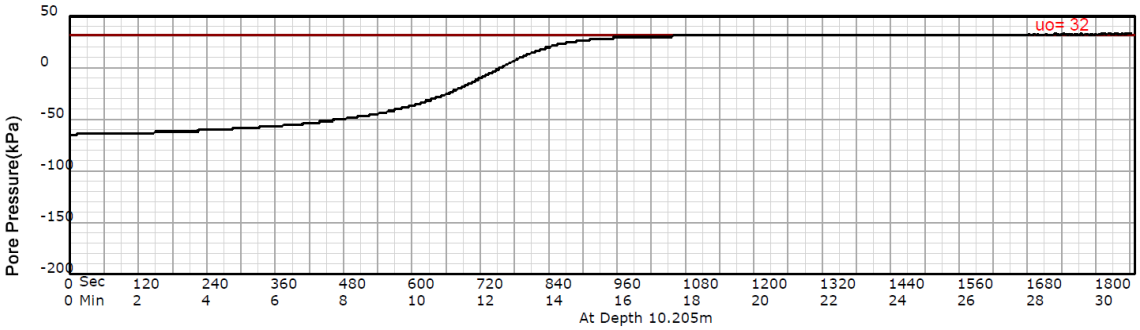

Figure 9: Dissipation test with shear induced dilation dominating the pore pressure dissipation with no dissipation of positive excess pore pressures evident

As the induced negative pressure gets larger (more negative) it may desaturate the probe through cavitation. The absolute maximum negative pressure recorded by the probe is equal to atmospheric pressure at the location of the site. At higher elevations (such as most of these examples done in South Africa at about 1,700 m above sea level) the atmospheric pressure is in the region of 80 kPa. For this reason, cavitation occurs at about -70 kPa to -80 kPa. In Figures 11a and b the measured pore pressure at the start of the dissipation test is -70kPa, indicating that cavitation had taken place. The cavitation occurred during probing, before the probe was stopped for the dissipation test. An example of this behavior is given in Rust

et al. (2022). Once the test commences, the pore pressure response is sluggish until the vapor bubbles reduce in size. Upon re-saturation, the excess pore pressure will dissipate, and the ambient pore pressure will be recorded (Figure 11a and b).

(a) Example of cavitation re-saturating in approximately 90 seconds

(b) Example of cavitation re-saturating in approximately 800 seconds

Figure 10: Two dissipation tests with shear induced dilation causing cavitation in the probe

Re-saturation of the probe results in a convex dissipation curve during the initial rising stage. This is highlighted by the red circle in Figure 11a. It can be noted from the dissipation test results of fully saturated tailings presented in Figures 7 to 10 that all the initial raising shapes are concave, as highlighted by the red circle in Figure 10. The shape of the initial rising stage can therefore be used to inform whether cavitation took place or not.

General model for dissipations in dilative tailings

The examples presented in the previous section were used to develop a model for the interpretation of dissipation test results. The model proposed in this paper is a conceptual model to illustrate the principles of Piezocone dissipation in a fully saturated material. There are two district zones, a dilative zone close to the probe where the soil is subjected predominantly to large shear strains, and a contractive zone further away, subjected to predominantly isotropic compression.

Figure 12 shows a horizontal line starting at the pore pressure transducer location and extending horizontally (radially) away from the probe. The variation in excess pore pressure response with radial distance from the probe is shown in the figure. The solid blue Lines 1 to 7 show the change in excess pore pressure response with time, with Line 1 the initial response and Line 7 following completion of most of the dissipation.

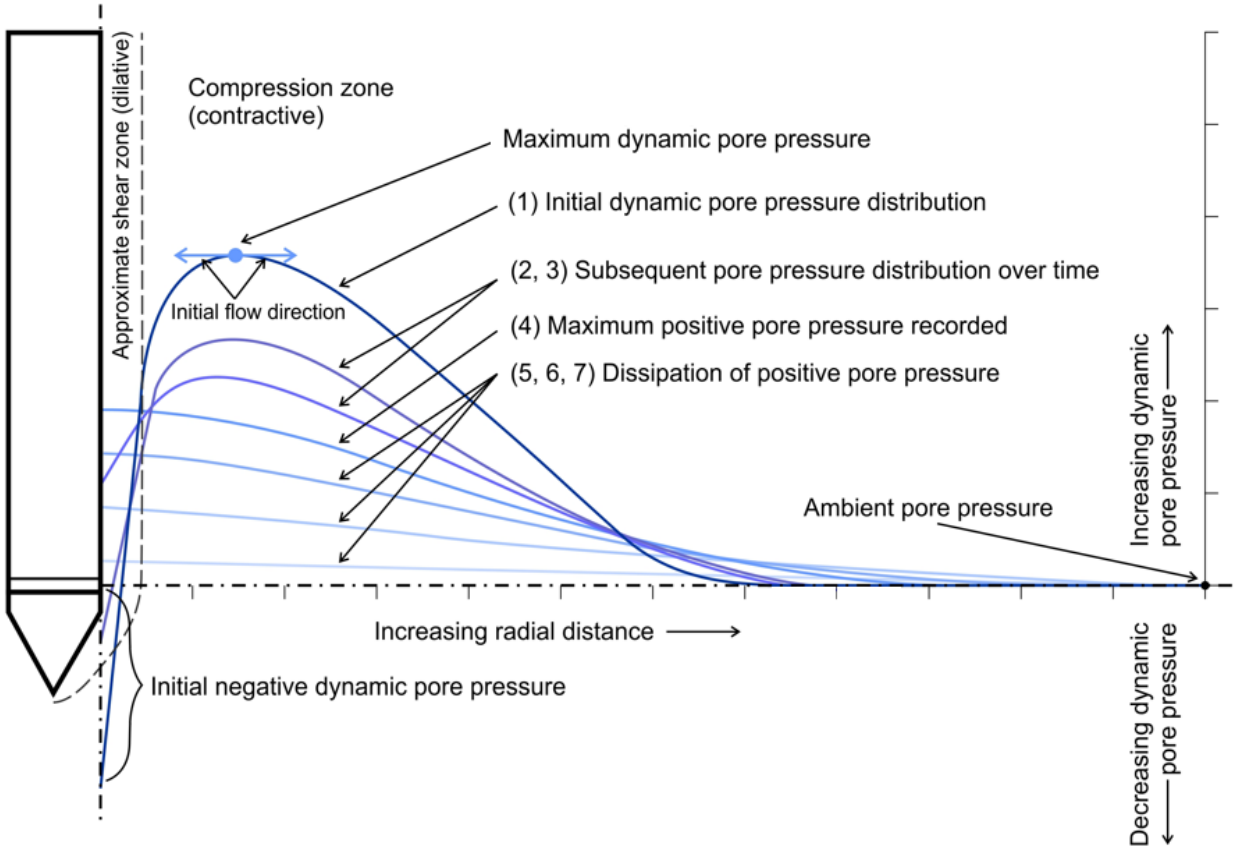

Figure 11: Excess pore pressure response developed in tailings that dilate in the shear zone and contract in the compression zone

The initial pore pressure response, depicted by Line 1, shows a negative excess pore pressure response due to dilation in the shear zone close to the cone and positive pore pressure response in the compression zone further away. A point of "Maximum dynamic pore pressure" and a point of "Initial negative dynamic pore pressure" can be noted. This large difference in pressure (on the same horizontal plane) over a short radial distance between these two points will cause a large gradient in hydraulic potential, or hydraulic gradient forcing flow towards the cone. At the same time there is a gradient from the "Maximum dynamic pore pressure" point to the "Ambient pore pressure" point at the edge of the zone of influence, as shown in the figure that will cause water to flow radially away from the probe as this pressure dissipates. As a result, the large negative pressure will dissipate relatively quickly when compared to the dissipation of the positive

pore pressure over a larger area (note that the upward dissipation in the result shown in Figure 8 is much steeper than the downward dissipation).

The initial negative pressure will dissipate (become more positive) until the maximum pore pressure is reached at the cone "Maximum positive pore pressure recorded," Line 4, which marks the end of the rising phase. Beyond this point, the dissipation will be radially away from the cone and the recorded pore pressure will reduce until the ambient pore pressure is recorded.

For the case of Monotonic dissipation tests, the shear zone will be contractive and the low pore pressure response close to the cone will be replaced by a positive pore pressure. A conceptual model of this case will only have lines similar to lines (4) to (7) in Figure 12.

Other pore pressure dissipation test results

The previous sections covered the classical pore pressure dissipation test results. However, a few cases remain that cannot be explained by the model presented. The first case deals with probing through relatively coarse tailings such as cyclone underflow that has a rapid rate of dissipation. The dynamic pore pressure may be zero (fully drained penetration) for the coarse tailings to a small response as the tailings becomes finer (say fine sand). If a dissipation test is carried out in this fine sand, it will have a very short dissipation (say 10 seconds with t50=1 second). Such a rapid dissipation test is not valid to determine the permeability since most of the generated excess pore pressure had dissipated during penetration. This raises the question of at what point is a dissipation test deemed to be valid? Several researchers have published on this topic, and they generally recommend a t50 of more than 30 seconds, with some recommending as much as 90 seconds. However, these rapid dissipation tests still provide a valid ambient pressure (see Figure 2a) and assist with the determination of the degree of saturation above the water table.

Another pore pressure trace occasionally found that cannot be explained by the mechanisms discussed involves the process of desaturation, or air entry, of layers of tailings above the water table (refer to Rust et al., 2022 for more detail). Saturated tailings layers often exist above the water table, and these are, in almost all cases, under negative pore pressure. When the negative pore pressure exceeds the air entry value of the tailings layer, air enters the voids between the tailings particles, displacing some of the pore water. The pore water pressure rapidly changes in these cases from the previously negative pore water pressure to atmospheric pressure. It is possible that disturbance by the cone could cause air entry or in some way damage the layer through micro fracturing or some other mechanism. An example of such a dissipation test is shown in Figure 13. In all such cases the pore pressure will revert to atmospheric pressure (or u=0).

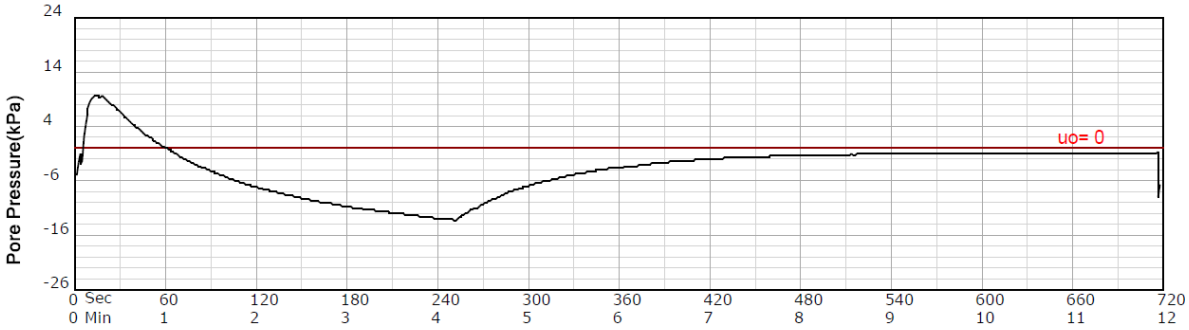

Figure 12: Initial classic dissipation test shape followed by air entry and pore pressure going to zero kpa

Conclusion

Dissipation tests in tailings have been presented to provide a variety of different characteristic shapes. These shapes depend on the soil characteristics. An improved understanding of the mechanisms causing the different characteristic shapes also improves the understanding of soil behavior.

If tailings are very loose and entirely contractive, only positive excess pore pressures are generated due to cone penetration. Denser tailings that dilate upon shearing induce some lower pore pressures in the shearing zone close to the cone. However, beyond the shear zone the tailing in pure compression may still contract and cause positive pore pressures. This interplay between negative and positive induced excess pore pressures can result in pore pressure dissipation test results that initially have low pore pressures that increase over time and subsequently decrease to ambient pore pressure. These features are apparent to a greater or lesser extent depending on the tailings state.

Detailed pore pressure distribution profiles in tailings facilities provide a wealth of information and these should be obtained and reviewed during the Piezocone investigation program. This requires a substantial number of complete pore pressure dissipation tests to be performed. The complete flow regime, including permeability, coefficient of consolidation, anisotropy in permeability, possible excess pore pressures, and two dimensional or three-dimensional flow-net can be determined from dissipation test results.

Estimation of Undrained Shear Strength Parameters from Laboratory Testing for Geotechnical Analysis: t_{ff} vs. q_f

Masood Kafash, AECOM, USA
Thomas Barham, AECOM, USA
Lisa Yenne, AECOM, USA
Ranjiv Gupta, Freeport-McMoRan, Inc., USA
Georgia Lysay, Freeport-McMoRan, Inc., USA

Abstract

The use of laboratory testing in undrained shear strength ratio (USR) characterization of soils has been a critical factor, along with in-situ measurements, in the design of tailings and earth dams for many years. However, there are still discrepancies between geotechnical consultants and other subject matter experts on how to reduce laboratory results and apply them to the limit equilibrium method (LEM) slope stability and deformation analyses.

This paper provides an overview of approaches typically used in industry to estimate undrained shear strength parameters from laboratory tests and how these parameters are used in design. The paper will discuss various approaches used for the selection of undrained shear strength, such as q_f (top of Mohr circle) vs. t_{ff} (shear strength on failure plane at the time of failure), normalization of shear strength, incorporation of the effects of stress anisotropy, and how shear strengths are assigned in LEM software packages. This overview covers the information obtained from a literature review, and a survey performed by the authors of several consulting firms, and personal communication with selected faculty at North American universities.

This paper aims to help readers understand how the LEM slope stability factor of safety (FOS) can vary with the same set of laboratory tests depending on parameterization used in the analysis. Understanding the methods used for reducing laboratory tests and applying these in analysis can inform the decision-making process. The variability in results is demonstrated in this paper with an example where, for a given set of laboratory results, the reported FOS can vary by up to 16 percent, depending on how the data are reduced and applied in stability analyses.

Background

The authors use an anisotropic undrained shear strength characterization for limit equilibrium analyses in the program UTEXAS4 (Wright, 1999) and for deformation analyses in the programs FLAC (Itasca, 2012) and FLAC3D (Itasca, 2013). The anisotropic undrained characterization is generally developed using isotropically consolidated triaxial compression (CIU) testing to define shear strength for the active wedge and direct simple shear (DSS) testing for the horizontal and passive portions of the failure surface. The final shear strength characterization is guided by in-situ testing, case histories, and empirical correlations.

Undrained shear strength is typically assigned in geotechnical analysis programs using an undrained shear strength ratio (USR). The USR is commonly denoted as an $^{S_u}/_{p'}$ ratio where S_u is the undrained shear strength normalized to p' the effective consolidation stress. The authors found that most consultants use USR or $^{S_u}/_{p'}$ to denote an undrained strength ratio; however, there is inconsistency in the definitions of S_u and p' that ultimately affects reported FOS.

The authors use τ_{ff} for Su, where τ_{ff} is the shear stress on the theoretical failure plane at the time of failure. An alternate definition of S_u is q_f, which is based on the top of the Mohr Circle and can be defined in the terms τ_{ff}. The method of deriving τ_{ff} and q_f from CIU triaxial results is shown in Figure 1. In this paper, the notation USR or $^{S_u}/_{p'}$ will be used for undrained shear strength ratios defined as $^{\tau_{ff}}/_{\sigma'_{fc}}$. Where σ'_{fc} is the effective confining consolidation pressure before shearing, also shown in Figure 1.

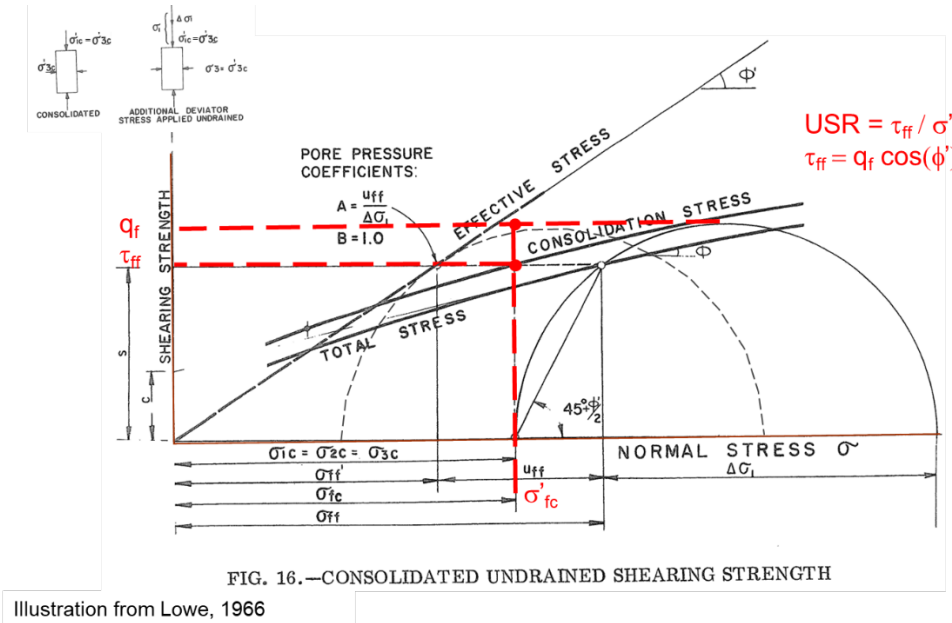

Figure 1: CIU undrained strength characterization

USR (τ_{ff}/σ'_{fc}) is similar to the s_u/σ'_{vc} defined in the SHANSEP procedure (Ladd and Foot, 1974) because the undrained shear strength is defined as a function of the effective consolidation stress before the load is applied. The initial SHANSEP process defined s_u as the top of the failure circle (q_f), consistent with Lambe and Whitman (1969). Later papers by Ladd (Ladd, 1991 and Ladd and DeGroot, 2004) recommended using the available shear strength on the "most realistic potential failure surface" when developing the undrained shear strength ratio from triaxial tests for use in limit equilibrium analyses (method of slices), when the base of the active wedge is inclined at angles other than 45 degrees from horizontal. Ladd defined the undrained strength as $c_u = \tau_{ff} = q_f \cos(\phi')$ in his 1986 Terzaghi lecture (Ladd, 1991). In Ladd and DeGroot's 2003 Casagrande lecture, they define $s_u = \tau_{ff} = q_f \cos(\phi')$ for undrained shear strength analysis in the method of slices (Ladd and DeGroot, 2004). Ladd and DeGroot (2004) acknowledge that many leading experts agree with Lambe and Whitman (1966) on the use of q_f for all undrained analyses.

Tailings materials are typically fine-grained soils that compress under increasing confining pressure and therefore should have effective confining pressure strength dependency and should be normalized. Shear strength is therefore normalized to the effective confining pressure (σ'_c). The effective confining pressure, σ'_c, is similar to the effective consolidation pressure on the failure plane, σ'_{fc}, in a sheared triaxial sample under isotropic conditions (CIU).

Many North American experts have adopted Ladd's approach for undrained shear strength assignment in undrained analysis; however, there are other opinions in industry supporting the use of q_f instead of τ_{ff}. Green and Marcuson (2014) provide a detailed discussion on this topic and present a clear understanding of the issues, particularly on the use of τ_{ff} with failure surfaces from effective stress analyses.

Consultants in support of using q_f argue that when a fully saturated soil is sheared under undrained conditions and the results are interpreted in terms of total stresses, it appears to behave as purely cohesive material (ϕ=0). The resistance under these conditions is actually based on the effective stresses mobilized at failure, but analyses in terms of total stresses are convenient because the shear induced pore pressures failure are not readily known and are implicitly accounted for in the undrained strength. This type of analysis is considered to provide the correct collapse load but probably not the correct kinematic mechanism. This has been used in practice for decades because of its convenience.

Ladd (1991) also discusses the difference between the undrained shear strength from a ϕ=0 analysis and the shear strength mobilized along a failure surface. Ladd observed that if adopting the latter shear strength in an undrained analysis is incorrect, it will generally be on the safe side by 10 to 15 percent.

To evaluate the effect of various approaches used for the selection of undrained shear strength, such as q_f (top of Mohr circle) vs. τ_{ff}(shear strength on failure plane at the time of failure), stress normalization

of shear strength, incorporation of the effects of stress anisotropy, and how shear strengths are assigned in analysis, the authors have surveyed several mining consulting firms approaches to undrained shear strength characterization and evaluated their impact on the limit equilibrium method (LEM) factor of safety (FOS) for a trial section.

Results of survey and potential implications review

AECOM, with support from Freeport-McMoRan, Inc. (Freeport), conducted a survey of five major geotechnical engineering consultants in 2024 to investigate the procedures commonly used for interpreting undrained shear strength from CIU tests. The survey questions included:

1. What is your company procedure for interpreting the undrained shear strength from isotropically consolidated undrained triaxial test (CIU test) for LEM Slope Stability analysis?
   a. Is it based on q_f or τ_{ff} as defined and depicted in the following figure (Figure 1)?
   b. What is your company procedure to incorporate the effect of stress anisotropy, such as CIU vs. CAU, when reducing the CIU data for use in stability analyses?
   c. What is the terminology your company uses for the undrained shear strength (i.e., Su/p', q_f/σ'_{vc}, q_f/σ'_{fc}, τ_{ff}/σ'_{vc}, τ_{ff}/σ'_{fc})?
2. What is your company procedure to incorporate the effect of structural anisotropy, such as weak bedding planes?
3. What is your company procedure to assign the undrained shear strength in stability analysis software packages? Is the shear strength for each slice calculated based on vertical effective stress or normal effective stress of each slide?

The results of the questionnaire are summarized in Table 1.

Table 1: Summary of surveyed consultants approach for undrained strength characterization

Source	q_f vs. t_{ff}	Common terminology	Assignment of shear strength on LE analysis	Stress anisotropy	Notes
Consultant # 1	t_{ff}	Su/p', t_{ff}/s'_{fc}	Normal stress	No additional reduction on CIU strength taken for anisotropic in-situ stresses	
Consultant # 2	q_f	S_u/p'_c for laboratory strengths, S_u/s'_{vc} for field strengths	Vertical stress	Mayne (1985) 13%	For critical situations, some CAU or DSS testing is done to inform judgement about the use of CIU
Consultant # 3	t_{ff}	S_u/p' for laboratory tests and interpretations, S_u/s'_{vc} for the analyses	Based on selected model	Laboratory based	Have used both q_f vs. t_{ff}
Consultant # 4	q_f	S_u/s'_{vc} or S_u/p'	Vertical stress	Laboratory based	
Consultant # 5	t_{ff}	S_u/p'	Both, project specific basis	Kulhawy and Mayne (1990)	

Table 1 highlights three key distinctions among industry approaches: the choice of undrained shear strength (i.e., q_f vs. τ_{ff}), consideration of stress anisotropy, and the strength normalization stress (vertical versus normal). Each of these factors is discussed briefly and their effects on calculated FOS are evaluated.

q_f versus τ_{ff}

Using the shear strength on the shear plane (τ_{ff}) versus the top of the Mohr circle (q_f) results in a reduction in shear strength given by $\tau_{ff} = q_f \cos(\phi')$. For tailings materials, typical friction angles (ϕ') range from 30 to 37 degrees, or a reduction on q_f of 13 to 20 percent. The impact of this strength reduction on FOS is highlighted with slope stability analyses using q_f and τ_{ff} strength selections in the active wedge portion of the failure surface. The results of this evaluation are summarized in Table 2 for Site 2, which had a friction angle of 34 degrees (17% difference in CIU strength from q_f to τ_{ff}).

Table 2: Summary of results for selected section and site

Site	CIU FOS τ_{ff}	CIU FOS q_f	Approx. % increase in FOS[1]
2	1.28	1.43	12

The authors performed similar analyses for eight cross-sections with various slope geometries and configurations. In summary, using q_f versus τ_{ff} increased the calculated FOS between 7 and 16 percent. Most of the sections (6 out of 8) increased less than 10 percent. The limited impact on FOS for these sections is attributed to the relatively small active (where CIU strength is assigned) versus horizontal and passive zones (where DSS strengths are applied). As the CIU portion of the failure surface is typically less than 50 percent, the impact on FOS between q_f and τ_{ff} is limited. Only two sections have more than a 10 percent increase on FOS. These sections have the biggest contribution from active (CIU strength assigned) on overall FOS.

Vertical stress versus normal stress

For non-cohesive soils such as tailings, the shear strength is typically dependent on in-situ stresses and incorporated using an USR. Assignment of shear strength parameters in limit equilibrium software packages varies based on the selected shear strength model (typically using either vertical (σ'_{vc}), or normal stress at the base of the slice (σ'_{fc}). Since vertical effective stress is typically closer to the maximum principal stress, this results in a higher shear strength for the same USR if vertical versus normal stress is used.

In an isotropically consolidated triaxial test, the confining pressures (σ'_1 and σ'_3) at the time of consolidation are equal such that the vertical consolidation stress (σ'_{vc}), the normal consolidation pressure on failure plane (σ'_{fc}), and maximum principal stresses are all equal. Therefore, for a CIU test, the same

normalization stress is used regardless of definitions, but in slope stability analyses depending on the angle at the base of the slice, σ'_{vc} and σ'_{fc} may not be equal. σ'_{fc} can be significantly less than σ'_{vc} if the failure plane is steep. Clearly, the impact of strength normalization is dependent on the shape of the failure surface. Table 3 provides an example of the effect of this variable on Site 2, discussed above. As shown in this table, assignment of shear strength properties based on vertical stresses is 5 to 13 percent, depending on what variables are compared.

Table 3: Effect of vertical stress or normal stress

Site	Selected sections	CIU FOS τ_{ff}		CIU FOS q_f		% Increase
		Assigned based on normal stress	Assigned based on vertical stress	Assigned based on normal stress	Assigned based on vertical stress	
2	Section E	1.28	1.34	1.43	1.45	5% (due to just normal stress vs. vertical stress) to 13% (due to τ_{ff} vs. q_f and vertical stress vs. normal stress)

Stress anisotropy

There are two types of anisotropy that are typically considered in shear strength selection; the structural anisotropy (due to the orientation of the failure plane related to bedding planes) and stress anisotropy (soil strength is a function of stress history, and stress paths). Structural anisotropy is typically addressed by conducting laboratory tests that match the anticipated mode of failure using CIU or DSS laboratory results. Incorporating stress history anisotropy (approximating the in-situ consolidation stresses) for tailings material is more challenging as horizontal in-situ stresses are typically unknown.

It is common practice to perform CIU (isotropic consolidation stress) tests instead of CAU (anisotropic consolidation stress), as they are easier and faster to set up and run. There are several published methods to convert CIU to approximate CAU strengths. Based on how stress anisotropy is accounted in the analysis, it results in a different FOS, as shown in Table 4 for Site 2.

Table 4: Effect of stress anisotropy

Site	Selected sections	No stress anisotropy	Kulhawy and Mayne (1990)/ Mayne (1985)[1]	% Decrease
CIU FOS τ_{ff}, Assigned based on normal stress				
2	Section E	1.28	1.25	3 (due to stress anisotropy)
CIU FOS q_f, Assigned based on vertical stress				
2	Section E	1.45	1.38	5 (due to stress anisotropy)

1) For site 2 fine tailings, Kulhaway and Mayne (1990) and Mayne (1985) result in similar Su/p' ratios

The authors conducted a limited laboratory testing program to quantify the effects of stress anisotropy and compare the laboratory test results to published methods to account for stress anisotropy when using CIU tests (Mayne, 1985; Wong et al., 1983). The laboratory testing program included five CAU and two CIU tests conducted on undisturbed Shelby tube samples of a uniform fine-grained low plasticity tailing material.

Table 5 summarizes the shear strength test results for the maximum principal stress ratio (PSR) failure criteria, shown in Figure 3, for three strength normalizations, and presents the CIU strengths converted to CAU using the methodology proposed by Wong et al. (1983) and Mayne (1985). The Mayne (1985) estimated strengths from the CIU tests are presented for both q_f and τ_{ff} . The following paragraphs discuss the observations from the test data. This discussion is grouped by the shear strength normalization to the vertical effective stress, and effective consolidation stress on the failure plane.

Table 5: Summary of test results from Site 2

Sample Depth (ft)	Test	σ'_{1c} (psi)	K_c	σ'_{fc} (psi)	Consol. Void Ratio	$\frac{T_{ff}}{\sigma'_{fc}}$	$\frac{q_f}{\sigma'_{vc}}$	$\frac{T_{ff}}{\sigma'_{vc}}$	$\frac{T_{ff}}{\sigma'_{fc}}$ Wong (1983) Estimate	$\frac{q_f}{\sigma'_{vc}}$ Mayne (1985) Estimate	$\frac{T_{ff}}{\sigma'_{vc}}$ Mayne (1985) Estimate
35–37	CAU	50	1.5	37	0.74	0.49	0.42	0.36	0.36	0.29	0.25
	CAU	50	2	30	0.71	0.54	0.39	0.33	0.44	0.29	0.25
	CAU	75	2	46	0.70	0.57	0.40	0.34	0.44	0.29	0.25
24–26	CIU'	50	1	50	0.70	0.29	0.34	0.29	–	–	–
80–82	CAU	85	2	52	0.81	0.46	0.33	0.28	0.44	0.28	0.24
	CAU	132	2	79	0.67	0.51	0.35	0.30	0.44	0.28	0.24
	CIU'	85	1	85	0.82	0.28	0.33	0.28	–	–	–

Figure 2 presents a summary of the test data shear strength (using max PSR failure criteria) normalized to the vertical effective stress versus Kc ($\sigma'_{1c}/\sigma'_{3c}$), along with the Mayne (1985) estimated anisotropic strength ratios for the CIU tests for both q_f and τ_{ff} . For each test, the consolidated vertical effective stress in psi is listed along with the consolidated void ratio. No apparent trend of strength ratio with Kc was observed when strength was normalized to σ'_{vc}. Note, the CIU strength when reduced to τ_{ff} is essentially equivalent to the strength reduction on q_f suggested by Mayne (1985) (~13%) for anisotropic conditions. All the anisotropic strength data points are essentially equal to or above the CIU strength and the Mayne (1985) anisotropic strength estimate using q_f.

Figure 3 presents the laboratory test data normalized to the effective consolidation stress on the failure plane (σ'_{fc}) along with the Wong et al. (1983) undrained shear strength estimates. The correlation is shown to be conservative when using the PSR failure criteria except for the purely contractive sample, which plots below the correlation but above the CIU′ (Kc=1) strength ratio.

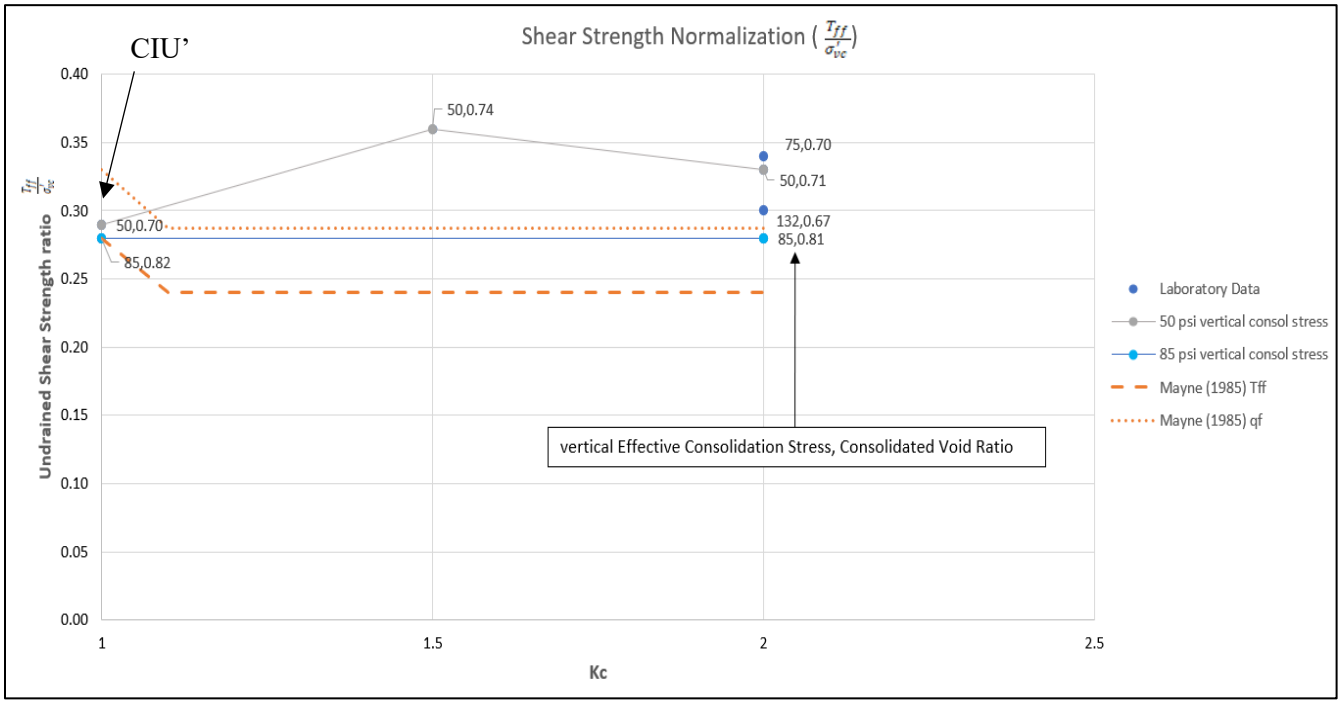

Figure 2: Laboratory data normalized to σ'_{vc} versus Mayne (1985) using Max PSR failure criteria. Lines drawn between similar σ'_{vc} to evaluate data trends

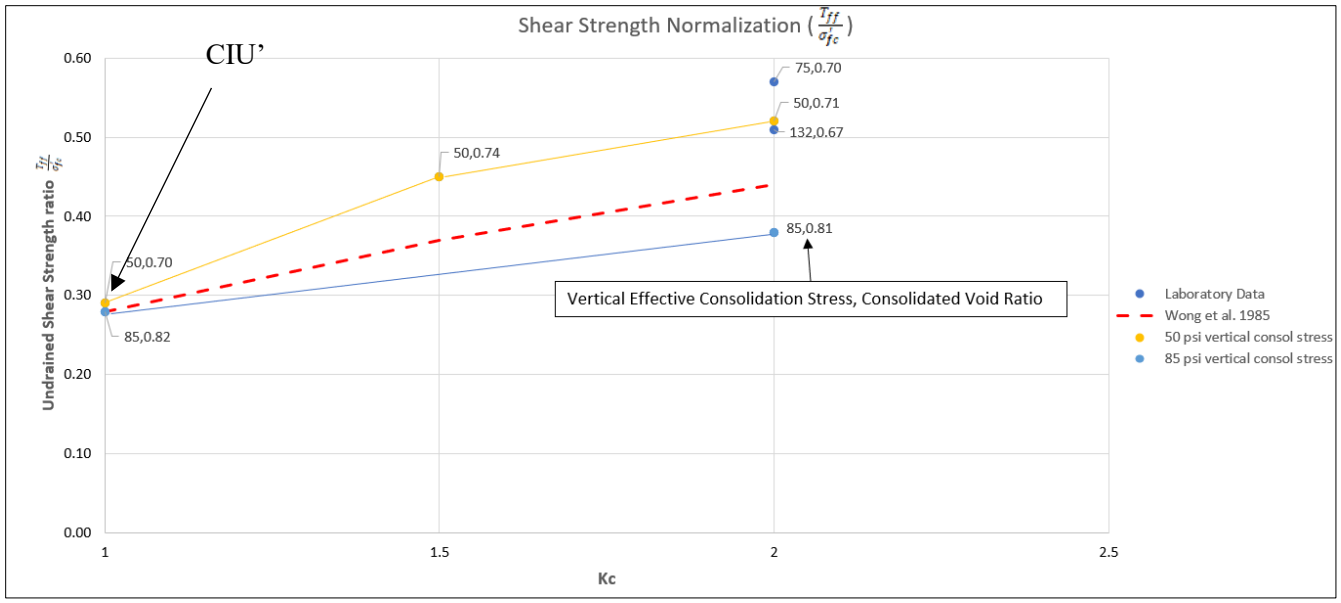

Figure 3: Laboratory data normalized to σ'_{fc} versus Wong et al. (1983) using max PSR failure criteria. Lines drawn between similar σ'_{fc} to evaluate data trends

The results of the laboratory testing program show that normalizing shear strength to either the vertical effective stress or the effective confining pressure on the failure plane are both reasonable options so long as the appropriate strength adjustments are taken, as suggested by Mayne (1985) and Wong et al. (1983), and the appropriate failure criteria is selected. The results also highlight that if τ_{ff} is used to reduce CIU test data, taking further reduction in strength (as suggested by Mayne) could compound conservatisms.

Summary of limit equilibrium analysis results

The author's survey asked five geotechnical engineering consultants about their practice for the selection of undrained shear strength from undrained triaxial testing (q_f vs. τ_{ff}), how strengths are normalized and input into the geotechnical model (effective vertical or normal stress), and how anisotropic consolidation is included in the strength assignment. Table 5 provides a summary of the results of the survey, and for one example, how the FOS is impacted by the approach selected. This small study highlighted that for the same set of laboratory results, the reported FOS for one section could vary by up to 16 percent, depending on how the data was reduced and applied in the LE stability analysis. Clearly the discrepancies in results can vary based on the actual problem being analyzed, based both on the factors discussed and other parameters involved in design that may have a higher impact on the calculated FOS. The designer needs to select the parameters and approach that best fit the project's level of uncertainty and risk.

Table 6: Summary of survey results and effect on FOS

Source	q_f vss t_{ff}	Common terminology	Assignment of shear strength on LE analysis	Stress anisotropy	Example of FOS:	% Change in comparison to Consultant #1
# 1	t_{ff}	Su/p', t_{ff} /s'$_{fc}$	Normal stress	No additional reduction on CIU strength taken for anisotropic in-situ stresses	1.28 (no stress anisotropy)	NA
# 2	q_f	Su/p'$_c$ for laboratory strengths, Su/s'$_{vc}$ for field strengths	Vertical stress	Mayne (1985) 13% drop from peak	1.38 (13% drop from stress anisotropy)	+8%
# 3	t_{ff}	Su/p' for laboratory tests and interpretations, Su/s'$_{vc}$ for the analyses	Based on selected model	Lab based	1.28 (assuming no stress Anisotropy, normal stress) 1.34 (assuming no stress Anisotropy, vertical stress)	0% +5%
# 4	q_f	Su/s'$_{vc}$ or Su/p'	Vertical stress	Lab based	1.45 (assuming no stress Anisotropy)	+13%
# 5	t_{ff}	Su/p'	Both, project specific basis	Kulhawy and Mayne (1990) $\left(\frac{Su}{\sigma'_{v0}}\right)_{CAUC} = 0.15 + 0.49\left(\frac{Su}{\sigma'_{v0}}\right)_{CIUC}$,	1.25 (K&M 1990 stress anisotropy and normal stress) 1.33 (K&M 1990 stress anisotropy and vertical stress)	-3% +4%

Conclusion

Laboratory testing is critical for understanding material behavior and for developing tailings shear strength characterization. Various methods have been proposed to reduce laboratory testing results, specifically triaxial testing, for application in geotechnical analyses. Each method has strong proponents, and no consensus in North America has been reached to set a standard of geotechnical practice. The survey results summarized in this paper highlight the differences in engineering practice among geotechnical engineering consultants and the impact of these discrepancies on the reported FOS for slope stability.

This study showed that for the same set of laboratory results, the reported FOS can vary by up to 16 percent, depending on how the data are reduced and applied in the analysis. This paper aims to help engineers, reviewers, and owners understand the impact of design parameter selection on FOS that should be factored in when developing recommendations from the slope stability analysis.

Recent failures of tailings embankments across the world have shown that precautionary limit equilibrium analyses alone are not sufficient for a robust design, considering their limitations and uncertainties as discussed above. It is recommended that designers consider this variability in design and

initiate a decision-making process that considers factors such as level of knowledge about the site, level of knowledge of material characterization, and performance of the structure, potentially enhancing the design through Performance-Based Design (Kafash et al., 2022).

Notation

CIU	isotropically consolidated-undrained shear test
CAU	anisotropically consolidated-undrained shear test
DSS	direct simple shear
K_c	ratio of horizontal to vertical consolidation stress
q	$0.5(\sigma'_v - \sigma'_h)$ or $0.5(\sigma'_1 - \sigma'_3)$
q_f	q at failure
Su	undrained shear strength
USA	undrained strength analysis
USR	undrained shear strength ratio
σ'_c	isotropic consolidation stress
σ'_{fc}	consolidation stress on failure plane
σ'_{ff}	effective stress on failure plane at failure
σ'_n	effective normal stress
σ'_v	vertical effective stress
σ'_{vc}	vertical consolidation stress
τ_{ff}	τ on failure plane a failure

A Critical Review of the Residual Pore Pressure Generation during Cyclic Loading

David Espinoza, Geosyntec Consultants, USA
Jenny Ramirez, Geosyntec Consultants, USA

Abstract

Recent notable catastrophic failures of mine tailing containment structures, often followed by mudflows, have exposed tailings facility's vulnerability to slope instability. The physical characteristics and current understanding of these types of failures have led engineers to evaluate liquefaction as a critical failure mode. Since excess pore pressures and liquefaction are related, seismic liquefaction potential is typically evaluated in the laboratory under cyclic undrained conditions, where excess pore pressures are measured. In cyclic undrained triaxial tests, a fraction of the transient excess pore water pressures remains locked-in, resulting in residual excess pore water pressures that do not dissipate at the end of a stress (or strain) cycle. Residual pore pressure continues to gradually increase until the total pore water pressure equals the confining cell pressure, resulting in partial or complete liquefaction.

This paper presents a critical review of the mechanisms that trigger the generation of residual excess pore pressure in cyclic triaxial undrained tests on completion of loading cycles and postulates an alternative mechanism. This paper argues that residual pore water pressure is the result of the testing boundary conditions, which are not representative of the field conditions. Because of the large extent and the sheer number of tailing storage facilities worldwide, attaining a solid understanding of how excess pore pressure builds up is paramount to avoid unnecessary multimillion-dollar retrofits when less costly remedies would be more appropriate to reduce liquefaction potential to tolerable levels.

Introduction

When a mine tailing storage facility (TSF) fails, it often has catastrophic consequences (Zhu et al., 2024). These failures have led the mining industry to develop the Global Industry Standards on Tailings Management (ICMM, 2020), which suggests evaluating credible failure modes affecting TSFs and the extent of their impact. Because TSFs often store saturated loose materials, and subsequent raises of the TSF using the upstream method result in berm construction over saturated material, liquefaction is often

considered a credible failure mode. Liquefaction can be caused by rapid loading (e.g., earthquakes, rapid construction).

The earliest seismic-induced liquefaction research studies took place following the catastrophic liquefaction-induced failures of the 1964 Niigata and 1964 Alaska earthquakes and focused on saturated granular soils. Since then, to understand the mechanisms that trigger liquefaction, researchers have performed numerous laboratory tests using commercially available clean sands with well-known geotechnical properties (e.g., Lee and Seed, 1967; Castro, 1969; Shibata et al., 1972). In addition to sands, materials with yet higher permeability coefficients (e.g., gravels) have also been tested to study liquefaction (e.g., Evans and Seed, 1987; Nicholson et al., 1989). In all these tests, it was observed that a fraction of the transient excess pore water pressures (PWPs) remained locked-in in undrained triaxial cyclic tests and accumulated with each load cycle. Based on the results of these tests, researchers developed constitutive models describing how excess PWPs are generated in granular materials (e.g., Beaty and Byrne, 1998; Elgamal, et al., 2002; Chen and Arduino, 2021) to capture this feature observed in the laboratory, and then implemented these PWP-generation models in commercially available numerical codes. As the use of numerical codes for evaluation of liquefaction has become more widespread in engineering, the economic impact associated with model assumptions can be significant when designing new TSFs or retrofitting existing ones.

Pore pressure generation during rapid loading under drained conditions in the field

Before postulating the potential mechanism of the observed residual excess PWP generation in undrained cyclic triaxial tests, the authors present a qualitative description of how excess PWP develops in the field for a hypothetical saturated soil deposit in response to specific loading and boundary conditions (Figure 1). The transient nature of excess PWP can be attributed to two distinct mechanisms: (i) consolidation following load application that leads to a gradual decrease (dissipation) of PWPs over time; and (ii) the variation (increasing or decreasing) of applied loads themselves over time. To describe the transient nature of consolidation following instantaneous loading (q) of saturated soil deposits, Terzaghi developed the theoretical framework of the excess PWP (Δu) dissipation process based on force equilibrium and Darcy's law (Terzaghi, 1943). Figure 1a shows the consolidation model for a double drained boundary condition and the corresponding PWP isochrones at multiple times. As shown in Figure 1a, when a load increment is applied instantly, the entire load is transferred to the PWP (i.e., $\Delta u = q$) at the time of load application ($t = t_o$), before dissipation starts. On the contrary, the effective stress increment ($\Delta\sigma'$) is 0 at t_o and reaches q at the end of the consolidation process (t_f), at a rate that depends on soil permeability. Figure 1b illustrates the variation with time of PWP and the effective stresses $\Delta\sigma'$ for a given depth z (the dashed lines illustrate the expected paths for a typical consolidation process, that is, q is not removed).

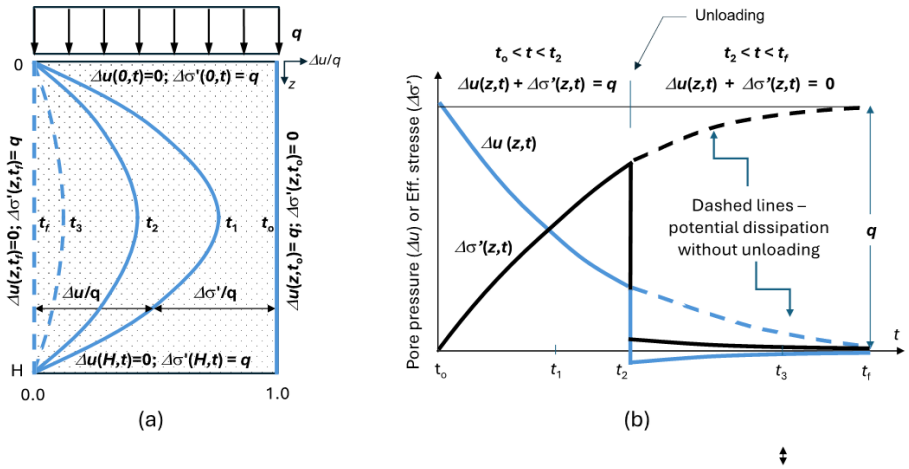

Figure 1: Excess PWP of a saturated soil layer following instantaneous loading and unloading: (a) PWP isochrones; (b) PWP dissipation with time at a given depth z after loading and unloading

In this hypothetical example, the excess PWP variation with time (t) due to changes in loading is clearly illustrated in Figure 1b (solid lines) when the layer is instantly loaded at $t = t_o$ ($\Delta u + \Delta\sigma' = q$) and instantly fully unloaded at $t = t_2$ ($\Delta u + \Delta\sigma' = 0$).[1] In both cases, equilibrium conditions are maintained. The instantaneous removal of q is used to facilitate the subsequent discussion because it avoids the commingling of the unloading and consolidation processes. Although the instantaneous loading and unloading illustrated in Figure 1b are extreme cases, they illustrate how excess PWPs are connected to load patterns and permeability (consolidation).

The study of excess PWP increase/decrease during one-dimensional consolidation due to intermittent cyclic rectangular loading/unloading has been analyzed using closed form solutions, numerical analysis and laboratory testing by multiple researchers (e.g., Wilson and Elgohary, 1974; Kim et al., 2021; Chai et al., 2022). The most salient feature of these studies is the fact that, independently of the soil permeability, pore pressures follow the loading/unloading patterns very closely. In other words, as illustrated in Figure 1b, an instantaneous load removal is followed by an instantaneous pore pressure reduction, that is, independent of permeability, PWPs instantly equilibrate with the new loading condition. If the soil was mostly gravel, negative PWP would not be generated and, therefore, PWP "dissipation" taking place upon unloading would not be observed either.

[1] Note that the figure shows realistically negative PWPs upon unloading, which dissipate towards zero as water flows back into the sample. In reality, trapped air within the voids may prevent full dissipation of negative pressures as samples may not be able to reach saturation. The negative PWPs are generated due to the tendency of soils to rebound, inducing volume expansion. The negative PWP magnitude will depend on suction characteristics of the soil matrix. Coarse particles generate smaller negative PWPs than finer particles.

To further illustrate the point, Figure 2 shows the excess PWP development with time in response to applying four equal loads instantaneously at different times to our hypothetical saturated soil deposit.

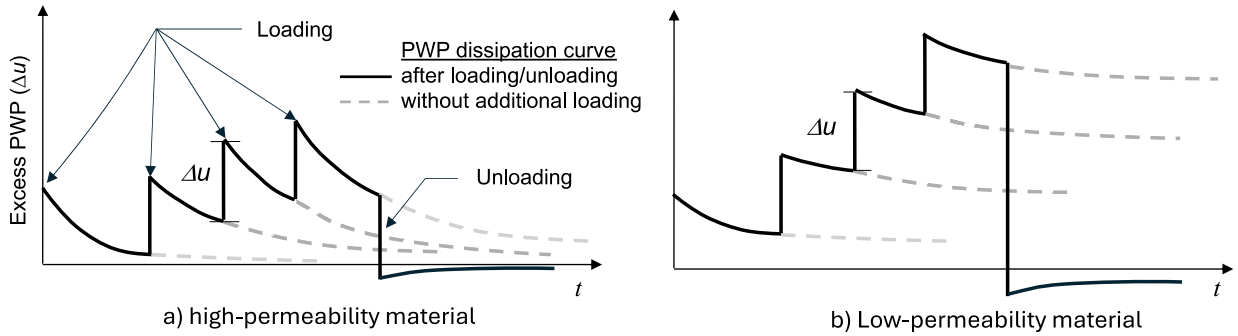

Figure 2: Schematic of PWP generation during incremental loading followed by instant unloading

As shown, each load generates an additional excess PWP (i.e., Δu) that is added to the remanent[2] excess PWP that has yet to dissipate, indicating that the previous applied loads have not been fully transferred to soil particles and the pore water is carrying a fraction of the applied stresses (Figure 2). In this hypothetical example, because the load is applied instantly, the magnitude of each increment of excess PWP (i.e., Δu) depends only on the magnitude of the applied loads regardless of the soil permeability. However, for the consolidation process, the remanent excess pore pressure at a given time will be higher for low-permeability soils than for high-permeability ones. If at any point during consolidation all the cumulative applied load is removed at once, the new equilibrium condition would require that the excess PWP be less than or equal to zero, regardless of the soil permeability at the time of load removal, and dissipating as water is drawn into the soil matrix (the total stress change would be zero throughout this process).

The magnitude of the accumulated excess PWP must be assessed to appropriately analyze the stability of earthen structures using effective stress (drained) or total stress (undrained) analyses. For slope stability calculations using effective stress analysis, the maximum excess PWP is an essential input parameter to calculate the critical failure surfaces. Although excess PWPs are not needed directly in stability calculations when a total stress analysis is used, they are needed to select representative stress paths to obtain appropriate undrained shear strength parameters.

Generation of residual pore water pressures in cyclic undrained tests

Typically, undrained laboratory tests are performed to mimic the condition of PWP build-up due to loads applied sufficiently rapidly that there is no time to dissipate the generated excess PWP. Excess PWPs

[2] The word remanent is synonymous of residual but it is purposely selected to avoid confusion with the term found in the literature to describe the residual PWP measured in undrained tests.

generated during undrained conditions should theoretically mimic the pattern of applied loads. As the load is gradually removed, the excess PWP should also approach zero (or become negative) to satisfy equilibrium conditions (i.e., change in total stresses equal to zero).

However, results from cyclic undrained triaxial tests show that when applied loads are momentarily at a zero load, a fraction of the excess PWP from the previous cycle remains. Figure 3 shows a typical PWP development due to applied cyclic stresses applied at 1 hertz (Hz). As shown by the black dots in this figure, the residual PWP increases with each cycle and gradually accumulates, reducing the confining stresses until eventually reaching failure (Shibata et al., 1972). Ishihara et al. (1975) attributed the generation of residual PWP measured in undrained triaxial tests of saturated sands to the development of irrecoverable plastic deformations during loading. Multiple researchers have reported similar results (e.g., Seed et al., 1976; Lee and Seed, 1967; Dobry et al., 1982; Sakai and Ochiai, 1986; Shoaei and Kassa, 1996; Tabata and Vucetic, 2010; Chen et al., 2019; Do et al., 2023).

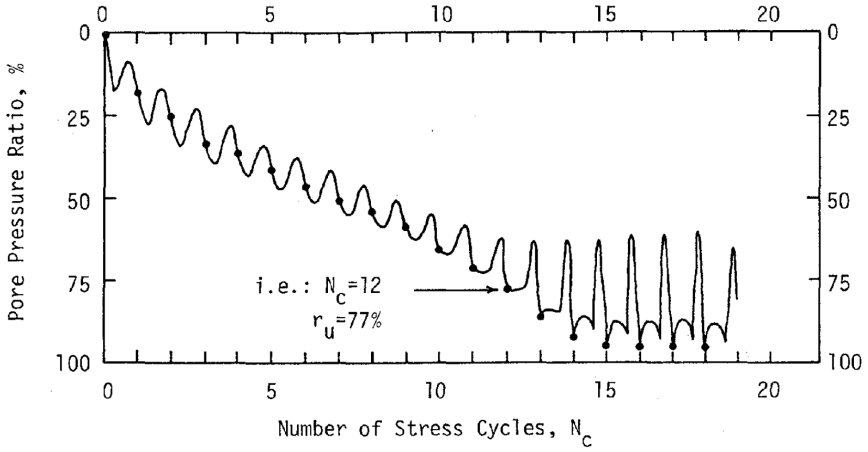

Figure 3: Residual PWP ration vs. number of cycles for 1 Hz load cycle (from Evans and Seed, 1987)

However, despite the reported results, it is hard to envision residual PWPs generating and accumulating in such highly permeable materials. To reiterate, in order to satisfy equilibrium conditions, excess pore pressures generated during undrained tests should theoretically track the applied loads (i.e., the PWP should be highest when the applied load is highest and then should be at zero or negative at the end of a load cycle). Because residual PWPs are detected at the end of a load cycle in granular materials, the origin and meaning of such pressures must be examined. Are they a real phenomenon (i.e., the result of plastic yielding during loading) or are they the result of the boundary conditions introduced by the test to simulate undrained conditions?

Because soil samples are the real-world representation of mathematical entities described by differential volumes elements with single values representing its state of stresses, it is implicitly assumed

that the stress field (including PWP) within the soil sample is homogeneous and that data collected on the sample periphery is representative of what exists inside it. On the contrary, excess PWP is not uniform within the sample. Despite its name, undrained testing conditions only means that the test is set up to prevent water draining out of the initial space delimited by the plates and the membrane encapsulating the soil sample. But, in order for contraction to occur during loading, pore water must flow out of the initial voids. A qualitative description of the water flow within a sample during undrained loading is shown in Figure 4.

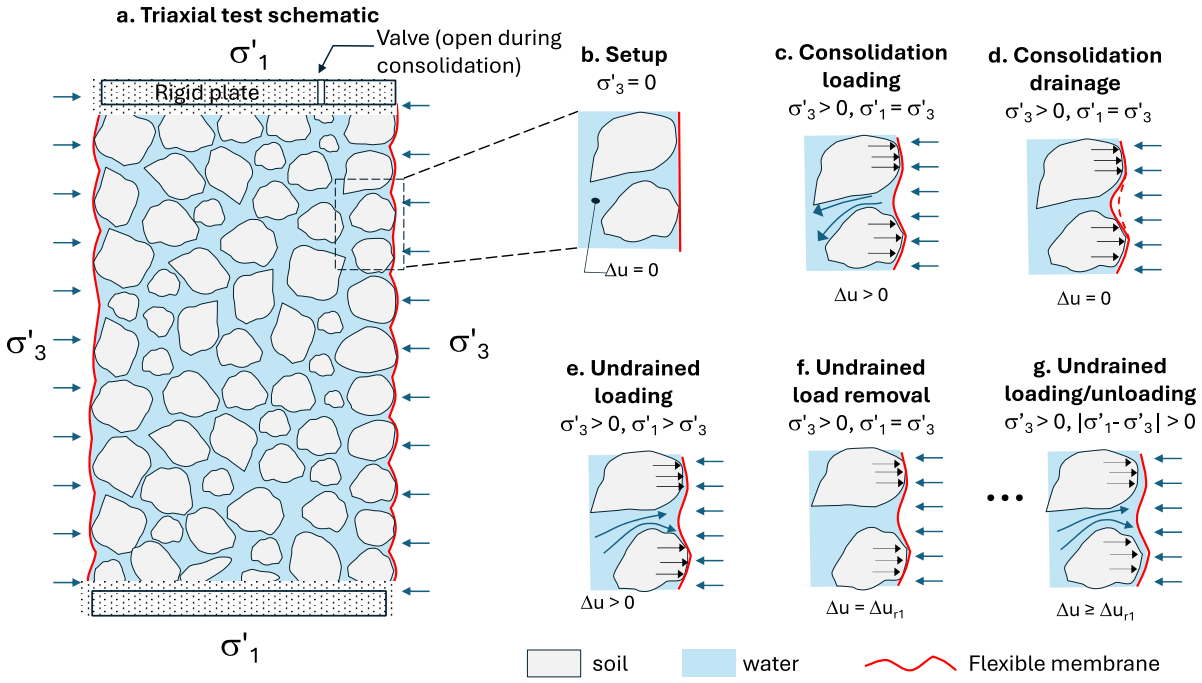

Figure 4: Schematic representation of the drainage process and residual PWP generation in triaxial tests

Similarly to the consolidation process described above, the boundary conditions imposed by the testing setup could induce a variation in the excess PWP within the sample ranging from a maximum at the sample axis to a minimum at the interface between the membrane and the soil (i.e., the boundaries) where it is zero at the beginning of the test (Figure 4a). Since the sample volume must remain constant to satisfy the undrained conditions, in contractive soils, pore water must flow from the center toward the interface, separating the soil from the membrane at some locations. As water relocates to the soil–membrane interface, a fraction of the confining cell pressure is transferred to the interstitial pore water rather than the soil particles.

The drainage process and PWP variation during the test are illustrated in Figure 4:

a. Saturated sample sketch.

b. Sample saturation begins; no excess PWP is generated.

c. Sample consolidation begins, application of a confining pressure generates excess PWP.

d. Sample consolidation continues, since valves are open, water drains out of the sample until excess PWP reduces to zero, sample is consolidated, soil/membrane contact area is maximized and 100% of cell pressure is applied to soil particles.

e. Undrained loading begins, valves are closed, excess PWP is generated, water flows towards soil/membrane/interface, contact area decreases, a fraction of cell pressure is applied to the sample water.

f. Removal of deviatoric load induces a reduction of excess PWP; since water at the interface cannot be pushed back into the sample, residual PWP (Δu_{r1}) begins to generate.

g. Residual PWP increases proportionally with additional loading/unloading cycles as the contact area between soil and membrane is reduced (i.e., the fraction of cell pressure applied directly to sample water is increased).

With increasing loading cycles (i.e., time), this fraction gradually increases until the residual PWP equals the confining pressure, which is the opposite of the consolidation process where the effective stresses gradually increases with time. Since soils are mostly inelastic, a reduction of voids during loading is typically larger than the increase in voids during unloading. Thus, in undrained tests of contractive soils, the amount of water trapped at the soil/membrane interface will increase with each load cycle, leading to the observed monotonic increase of residual excess PWP. The unique setup of the cyclic triaxial undrained test creates a variable boundary condition (i.e., decreasing confining effective pressure). The PWP at the interface is not 0 throughout the test as in the hypothetical example of the saturated layer above. As pore water flows toward the boundary (soil-membrane interface) during loading, PWP seeks equilibrium with the cell pressure.

Generation of residual pore water pressures in cyclic drained tests

Since an undrained test condition is only a representation of the extreme case of rapidly applied loads where consolidation does not affect the generated excess PWP, to complement the hypothesis that observed residual excess PWP is simply a result of the boundary conditions of undrained cyclic triaxial tests, the results of drained cyclic triaxial tests are discussed next. If residual PWPs in soils were indeed the results of plastic deformations during loading, such a phenomenon should not be limited to undrained tests. In drained conditions, the authors contend that PWPs should follow the same transient pattern of the applied loads, although at a reduced magnitude because a fraction of the PWPs would dissipate during loading as drainage takes place.

Chen et al. (2019) performed 12 strain-controlled cyclic-triaxial drained tests on Nanjing fine sand using (i) four relative densities (D_r) ranging from loose to dense sands; and (ii) three axial strains (ε_a). The soils were consolidated with a cell pressure of 100 kilopascals (kPa) and then the pressure remained constant throughout the tests. During the tests, excess PWP generated within specimens was dissipated by controlling back-pressure at a constant value of 400 kPa. Each test applied 250 cycles of axial strains with a sinusoidal wave shape characterized by a constant frequency of 1 Hz for a given strain amplitude. The results of four of the twelve tests are presented in Figure 5.

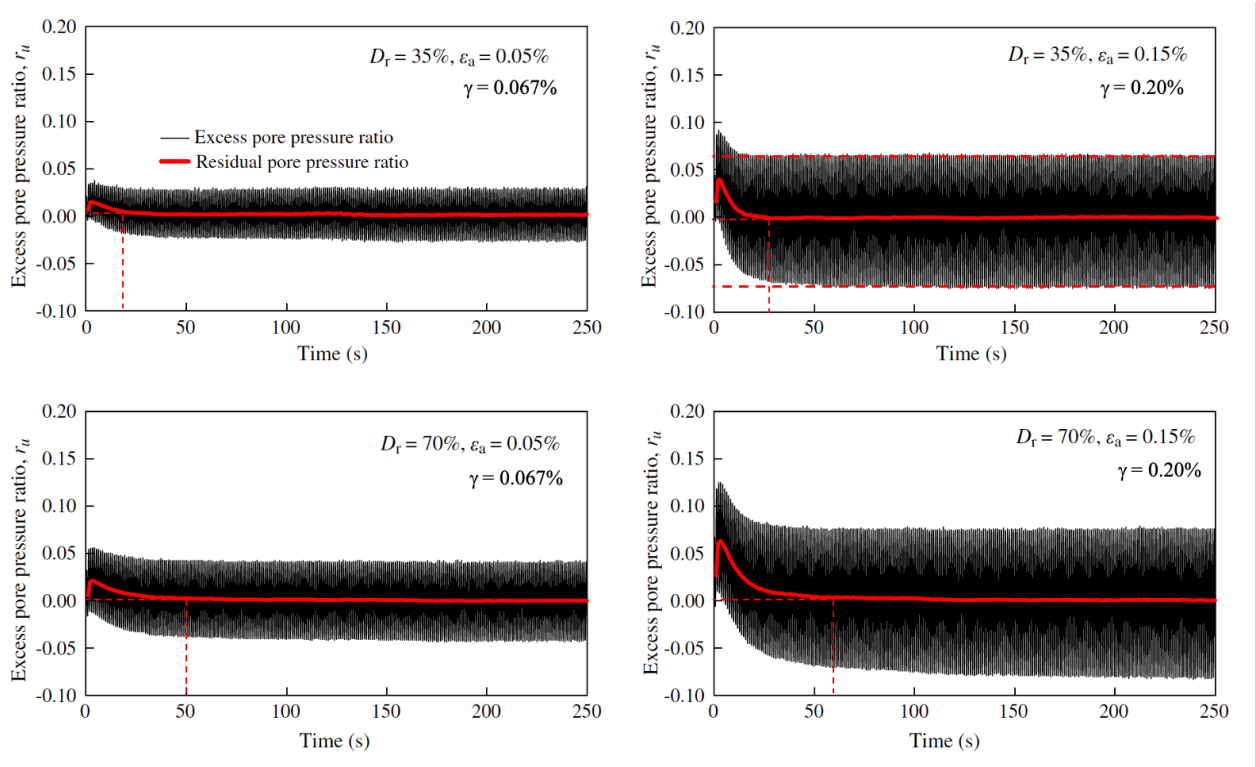

Figure 5: Pore water pressures during drained cyclic triaxial drained tests (Chen et al., 2019)

As shown in the figure, the maximum residual and transient PWPs in all tests initially increase but level off after a few cycles. This might be the result of delayed transducer measurements during unloading that may impact the accuracy of the initial readings when water flow within the soil sample is the largest. But after a few cycles and when the transducer readings become more stable, the transient excess PWP mimics the sinusoidal loading. As hypothesized, the resulting transient excess PWPs (black line) largely follow the sinusoidal shape of the axial loading, although at a fraction of the maximum applied axial load[3], whereas the residual excess PWP (red line) is zero except for the initial few cycles. The results indicate that drained cyclic tests on typical sands with loads applied at a frequency of 1 Hz are rapid enough to generate

[3] The axial loads were estimated from the plot of drained Young modulus as a function of vertical strain (Figure 8) reported by Chen et al (2019).

excess PWP that mimics the applied load. More importantly, for all practical purposes, the results indicate that no residual excess PWPs are generated. Since water is allowed to drain out of the sample, the tests boundary effect described in the previous section is not a factor that results in the artificial generation of "residual" PWP. In summary, since the generated residual PWP generated in undrained tests appears to be an artifact of the testing conditions, the validity of selecting undrained tests to perform stability analysis using total stresses in particular for liquefaction analysis is seriously questioned.

Conclusion

In this paper, the authors propose that the development of residual excess PWP observed in undrained cyclic triaxial tests is more likely a result of the test boundary conditions and the non-homogeneous conditions within the sample than the results of permanent plastic deformations. These deformations can only account for the difference in the amount of water expelled out and drawn into the sample. Considering the pore water flow that occurs in contractive samples during loading and unloading, the authors present a potential alternative mechanism that could explain why excess residual PWP is recorded during undrained tests.

Since the sample volume must remain constant, contraction (i.e., reduction in voids) can only occur if the membrane separates from the soil sample and the pore water expelled from the voids flows toward the space created at the soil/membrane interface. As water migrates toward this interface, a fraction of the confining cell pressure directly contacts the pore water through the membrane. As a result, the recorded residual excess PWP does not represent the process of liquefaction, but is simply a proxy for the fraction of the surface area that is no longer in contact with the soil particles.

It is also argued that if residual excess PWPs were indeed the results of plastic deformations during loading, they should not be limited to undrained tests; they should also manifest, at a reduced magnitude, in drained tests. Therefore, the authors presented the results of drained tests obtained for loading conditions similar to the undrained test. The results of drained triaxial tests support PWPs following the same transient pattern of the applied loads (i.e., PWPs mimic the shape of the applied loads). These results are in agreement with the theoretical and experimental results obtained in a one-dimensional consolidation test under cyclic loads (i.e., PWPs mimic the applied loads), which contest the wide-spread belief that it takes time for excess PWPs to equilibrate following removal of the load that generated such PWPs.

Although this paper focuses on the results of undrained cyclic triaxial tests, the influence of testing boundary conditions and pore water flow within the sample during testing should not be unique to these types of tests. Other popular cyclic tests may exhibit more or less pronounced effects on water flow to/from the membrane interface. Furthermore, the effect of boundary conditions is very likely an important issue in the interpretation of undrained monotonic triaxial tests where soils are typically tested to reach strains well over 20%. The authors recommend further research to investigate the potential boundary effects of cyclic

tests commonly used to evaluate liquefaction potential. Likewise, it is also recommended to evaluate potential modifications of existing testing apparatus to reduce/eliminate the described boundary effects.

Finally, the widespread use of undrained tests (monotonic and cyclic) to calibrate numerical codes to assess the liquefaction potential of existing and new TSFs makes the verification, implementation, and validation of accurate material constitutive models (e.g., PM4Sand, UBCSand, SANISAND) of upmost importance. Since most of these calibrations assume that residual excess PWPs generated in undrained cyclic tests are a naturally occurring phenomenon that should hold in the field, subsequent modeling using these assumptions will inexorably lead to developing fictitious PWPs that are the result of laboratory testing boundary conditions that do not replicate field conditions.

Numerical Modeling Comparison of Large-strain Tailings Consolidation

Daniel Pham, WSP, Australia

Abstract

Consolidation of mine tailings can take extended periods of time due to their high water content and relatively low permeability, which can affect the storage capacity of the tailings storage facilities (TSFs) during the Life of Mine (LoM), and the timeline to start their rehabilitation at closure. An understanding of the tailings consolidation behavior during TSF planning stages is therefore critical to achieve efficient and sustainable mine waste management during operations and prior to closure. This can be accomplished by a combination of laboratory testing and numerical modeling prior to the commencement of tailings deposition.

A numerical modeling comparison of large-strain tailings consolidation was undertaken with three software, Plaxis LE, FSConsol and MinTaCo, which are commonly used by tailings practitioners. The objectives of the study were to find the advantages and limitations for each software to assist with selecting the appropriate numerical modeling program corresponding to the project budget, complexity, anticipated effort, and outputs required. This paper presents a multicriteria assessment and a case study involving consolidation modeling undertaking on an in-pit tailings storage facility based on laboratory testing results using the software considered for both single and multiple filling scenarios, as well as with and without the effects of evaporation.

Introduction

Tailings have been generated in large volumes worldwide as byproducts of ore beneficiation from the process plants in the mine sites. Tailings are generally deposited in the form of slurry either on perimeter dykes constructed from their coarser fraction, i.e., waste rock above ground, or within the inactive open pits. These structures are called tailings storage facilities (TSFs). Settling and consolidation processes of mine tailings can take a long time, which reduces the storage capacity of the TSFs due to the conventional tailings characteristics of high water content and low hydraulic conductivity. As such, a combination of laboratory testing and numerical modeling is usually required prior to the commencement of tailings deposition to achieve effective planning and management during TSF operations and prior to closure.

Numerical modeling on tailings consolidation has evolved over the years, with multiple software available both commercially and for educational purposes, focusing on one-dimensional configuration. Each software has its own advantages, limitations, and functions, as well as variability in costs and model configurations. This study presents a comparison between three modeling software that have been used by tailings practitioners to model large-strain tailings consolidation, namely, Plaxis LE, FSConsol and MinTaCo.

It is acknowledged that there is other modeling software available on the market that can model large-strain consolidation such as Finite Strain Consolidation Analysis (FSCA), and the Norwegian Geotechnical Institute (NGI) approach to model tailings deposition and consolidation in FLAC. Due to access constraint to FSCA and the complexity of using FLAC, they have not been included in the scope of this study.

Background

Finite-strain consolidation

The consolidation of tailings can be broken down into three components:

1. Self-weight consolidation occurs following deposition and is the result of the settling of the tailings solid particles without additional loading.
2. Primary consolidation follows self-weight consolidation and is the result of the dissipation of pore-water pressure generated by an increase in vertical effective stress.
3. Secondary consolidation (or creep deformation) continues in the long term following primary consolidation and under a state of relatively constant stress. Note that secondary consolidation was not considered in the study presented herein due to its limited settlement magnitude in comparison to self-weight and primary consolidation.

During self-weight consolidation, tailings will undergo large deformations due to low effective stress and high void ratio in the early stage of tailings matrix (i.e., particle fabric) development. The hydraulic conductivity of tailings decreases as the density changes with increased thickness of the deposit during tailings deposition. Therefore, the conventional Terzaghi consolidation theory becomes invalid due to the inherent assumptions of infinitesimal strains and constant hydraulic conductivity. To capture the high nonlinearity due to initial large volume change at a high void ratio of tailings, a finite-strain consolidation theory for self-weight consolidation involving large-strain deformation must be adopted.

Numerical modeling software considered

Plaxis LE

Plaxis LE is a software for limit equilibrium slope stability analysis and finite element analysis of

groundwater seepage. Consolidation is a module within Plaxis LE that solves coupled hydro-mechanical processes that are available separately in the Groundwater and Stress software packages. The large-strain consolidation is modeled following the non-continuum mechanics in the Lagrangian coordinate system developed by Bonet (2008). The software has the capability to model both small-strain (constant soil properties) and large-strain (nonlinear soil properties) consolidation problems in both 1D and pseudo-3D (i.e., coupled 3D slurried tailings deposition scenario with the effects of saturated 1D columns) configurations. Note that the software was originally developed by SoilVision, a geotechnical engineering software provider that was acquired together with Plaxis by Bentley Systems in 2018.

FSConsol

FSConsol is a 1D consolidation program that uses the Finite Strain Consolidation Theory developed by Gibson et al. (1967) to determine the rate and magnitude of consolidation of soil slurries such as mine tailings, deltaic deposits, and other soft soils. The software can model a variety of consolidation problems ranging from a step-loaded laboratory consolidation test to a complex mine tailings pond scenario with varying filling rates, changing pond areas, and changing soil properties.

MinTaCo

MinTaCo is a 1D numerical modeling program developed by the University of Western Australia (UWA) in 1996. MinTaCo has the capability to incorporate the effects of drying on the conventional large-strain consolidation process (Seneviratne et al., 1996). It iteratively applies different suction values to the surface of the tailings to achieve a specific evaporation rate for the material. This iterative adjustment in suction continues until the layers reach the shrinkage limit density that is assessed by laboratory consolidation testing.

Multi criteria assessment

A basic multicriteria assessment (MCA) was conducted with the key criteria summarized in Table 1, while Table 2 presents a summary of the key advantages and disadvantages of the three software.

The main advantage of MinTaCo in comparison to the other two software is the ability to model unsaturated conditions such as the inclusion of evaporation during consolidation. Its major drawback is the lack of a functional graphical user interface (GUI), which can create many difficulties for first time users. Plaxis LE has the benefit of having the ability to do 3D modeling, which is more suitable for data visualization, and a well and fully developed GUI, which is more appealing to users.

Table 1: Summary of key outcomes from the multi criteria comparison

Criteria	Plaxis LE	FSConsol	MinTaCo
Ease of use	Advanced graphical user interface (GUI)	Basic GUI	No GUI available
Model configuration	1D and Pseudo-3D	1D	1D
Available license	Network	USB dongle	License is not required
Soil saturation conditions	Saturated only	Saturated only	Saturated & unsaturated

Table 2: Summary of advantages and limitations of each software considered

Software	Advantages	Limitations
Plaxis LE	Soil parameters required for constitutive models can be generated within the software using the "Apply fit" function. Multiple functions available for nonlinear compressibility. Ability to do pseudo-3D modeling in 3D based on aerial survey of site topography or using 3D models created in Plaxis Designer. GUI is easy to use and follow. The outputs are easy to process and understand with plots provided.	Only two settings for top and bottom boundary conditions regarding drainage: with and without drainage. There are no options available for other modeling scenarios such as decant pond at the top and partial drainage at the bottom. Stage settings during model set up can be time consuming and repetitive if significant numbers of stages are required. Results from deposition modeling using a 3D modeling software are required to inform the stages for 1D consolidation modeling.
FSConsol	Software is relatively easy to use with basic GUI. The outputs are relatively easy to process and understand with plots provided. Pond filling function adopting progressive filling based on various pond areas which can be considered as pseudo-3D. Ability to model creep deformation.	USB dongle is required to run the software. Soil parameters required for the compressibility and permeability functions need to be assessed separately using Excel. Inability to model unsaturated conditions. Outputs do not have flux rates of consolidated water at the top and bottom. Model solver can be unstable when dealing with more than one material.
MinTaCo	Ability to incorporate evaporation in consolidation modeling. Ability to consider multiple drainage conditions at the top and bottom. Output of the shear strength at the surface can be generated from the model. License is not required. Ability to set target height for deposition and consolidation, especially useful for multiple fillings.	Inability to model pseudo-3D. Soil parameters required for the compressibility and permeability functions need to be assessed separately using Excel. It takes longer for new users to be familiar with the software due to the lack of GUI. Outputs are not user-friendly. Plots are required to be drawn manually in Excel which requires significant effort and therefore is time-consuming. However, VBA can be used to automate this process, which requires programming skill. Results from deposition modeling using a 3D modeling software are required to inform the stages for 1D consolidation modeling.

Case study

Background

Consolidation modeling has been undertaken using the three software mentioned herein on an in-pit TSF (IPTSF) called De Grey pit that is located in Western Australia (WA) as a case study. De Grey is an inactive open pit and is part of the Shovelanna complex. The pits are located approximately 35 km east of Newman within the Pilbara region of Western Australia. The Hamersley Range and Fortescue Plains subregions (where the pits are located) are typified by an arid and tropical climate, with hot wet summers and cool dry winters. Average annual rainfall is typically 300 mm, most of which falls during the summer because of rain depressions and cyclones. Hot, dry, and sunny conditions in the Pilbara lead to an average annual evaporation rate of 3,200 mm.

Consolidation modeling

Design basis

De Grey and Swan pits have been identified as the candidates for a short-term tailings management solution, with tailings deposition planned to commence in mid-2026 when the process plant is commissioned. The tailings deposition strategy selected was two weekly rotated deposition cycles between the two pits to improve consolidation during the operational periods. Table 3 presents the design inputs and assumptions adopted in relation to the IPTSF operations for the deposition and consolidation modeling. Note that only the consolidation modeling for the De Grey pit is presented in this paper.

Table 3: Design basis of the IPTSF operations

Design Parameter	Design Input
Life of asset	Utilize full pit capacity.
Available capacity in pit	De Grey – 13.78 Mm^3 at maximum tailings elevation. Swan – 10.80 Mm^3 at maximum tailings elevation.
Commencement of tailings generation	1 August 2026 (FY27).
Tailings solids generated	5.89 Mtpa on average from FY27 to FY51
Deposition approach	Slurry deposition by spigots. Two deposition point locations adopted in Swan and De Grey pits.
Tailings deposition strategy	Multiple filling phases over the LoM and 2 weekly rotated deposition cycles between De Grey and Swan pits.
Representative tailings samples	Average Blend for the first three years of operations followed by High Dales during the LoM.
Beach slope	Assumed to be 0.5%, with no change in beach slope beneath the pond.
TSF decant pond depth throughout deposition	Minimum 1 m.

Laboratory testing

Multiple laboratory tests were conducted on the representative tailings samples to assess their classification and to characterize their consolidation behavior. A summary of the tests undertaken and their corresponding results that were considered to assist in establishing the model input parameters for consolidation is presented in Table 4.

Table 4: Summary of geotechnical laboratory test results for the representative tailings samples

Test	Parameters	Measurement for tailings samples prepared at 45% solids concentration	
		Average Blend	High Dales
Density bottle	Particle density (t/m^3)	3.99	4.02
e_0 beaker test	Solids concentration at e_0 (%)	49.4	47.1
	Initial void ratio e_0	4.09	4.52
	Dry density at e_0 (t/m^3)	0.78	0.73
Settling column with top drainage	Final settled dry density (t/m^3)	0.90	0.86
	Time to achieve final settled dry density (days)	20	19
Air drying test	Final air-dried density (t/m^3)	1.85	1.92
	Time to reach final air-dried density (days)	28	34
One-dimensional slurry consolidation	Pressure range tested (kPa)	10 to 1600	
	Void ratio, e	1.97 to 0.97	2.08 to 1.02
	Dry density (t/m^3)	1.34 to 2.03	1.31 to 1.99
	Hydraulic conductivity (m/s)	1.01×10^{-8} to 1.13×10^{-9}	5.4×10^{-9} to 9.17×10^{-10}
	Coefficient of consolidation ($m^2/year$)	4.5 to 170	5.2 to 82.9

Material input parameters

Plaxis LE and FSConsol

Tailings parameters for input to the model in Plaxis LE and FSConsol were estimated based on laboratory classification and consolidation testing of Average Blend and High Dales samples as summarized in the above section. They were used to establish the following:

- The relationship between void ratio and effective stress (fitted extended power function as presented in Figure 1)

Equation 1 (Average Blend): $e = 2.954(\sigma'_v + 0.11)^{-0.155}$ $(\sigma'_v \; in \; kPa)$

Equation 2 (High Dales): $e = 3.006(\sigma'_v + 0.051)^{-0.149}$ $(\sigma'_v \; in \; kPa)$

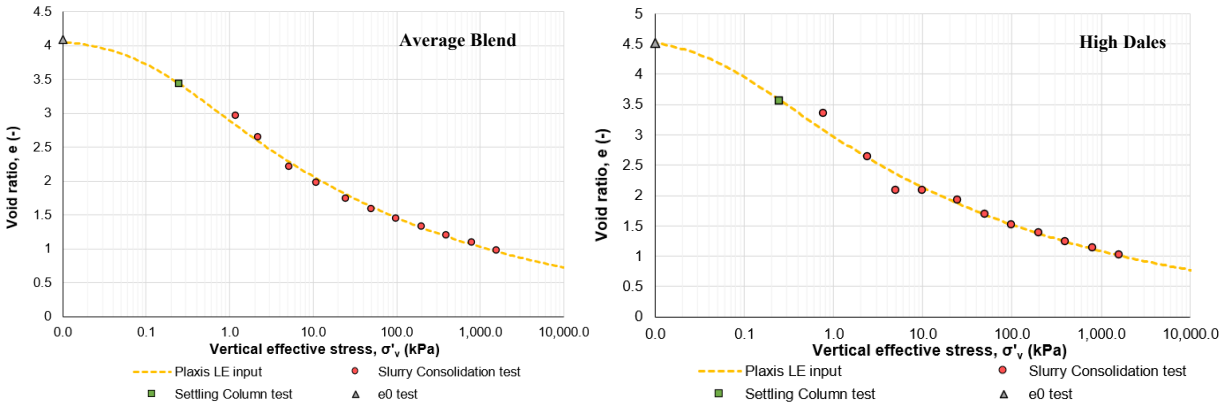

Figure 1: Functions adopted for void ratio (e) vs. vertical effective stress (σ'v)

- The relationship between permeability and void ratio (fitted power function as presented in Figure 2)

Equation 3 (Average Blend): $k_v = 1.0 \times 10^{-9}(e)^{3.047}$

Equation 4 (High Dales): $k_v = 9.0 \times 10^{-10}(e)^{2.806}$

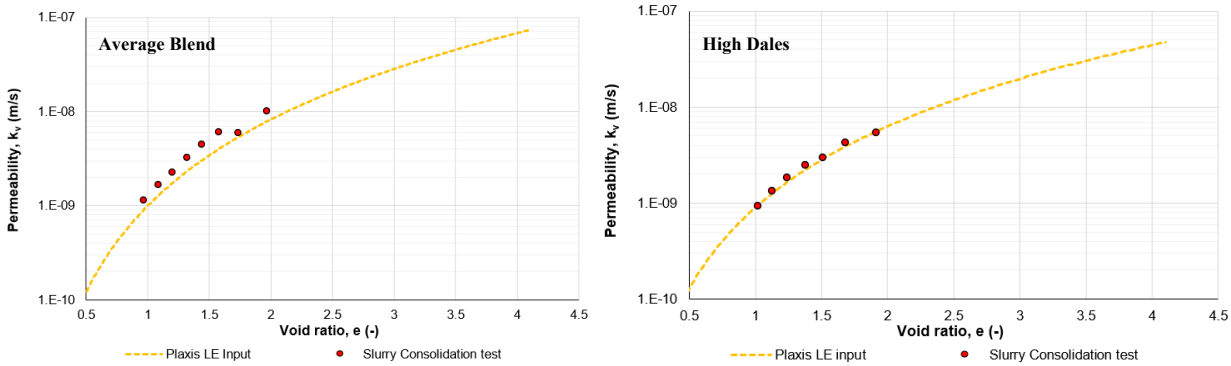

Figure 2: Functions adopted for permeability (kv) vs. void ratio (e)

Note that only Average Blend parameters were used in FSConsol due to the software being unstable when processing two tailings materials in the assessment.

MinTaCo

Tailings parameters for input to the model are summarized in Table 5. They were estimated based on laboratory classification and consolidation testing results of Average Blend and High Dales samples, as summarized in the Laboratory Testing Section.

Equation 5: $e = c(\sigma'_v)^d \ (\sigma'_v \ in \ kPa)$

Equation 6: $k_v = \frac{a(e)^b}{1+e} \ (k_v \ in \frac{m}{day})$

Table 5: Input parameters used to simulate Average Blend and High Dales tailings samples

Parameter		Tailings sample	
		Average Blend	High Dales
Specific gravity		3.99	4.02
Permeability constants	a*	2.16 × 10-4	1.56 × 10-4
	b*	3.6	3.55
Compressibility constants	c*	2.87	2.96
	d*	-0.148	-0.15
Void ratio at sedimentation		4.09	4.52
Shrinkage limit void ratio		1.16	1.09
Air entry suction at shrinkage limit (kPa)		430	890

Note: *estimated by curve fitting the consolidation test results

The shrinkage limit void ratios and the corresponding estimated air-entry suction values for both tailings samples are presented in Figure 3.

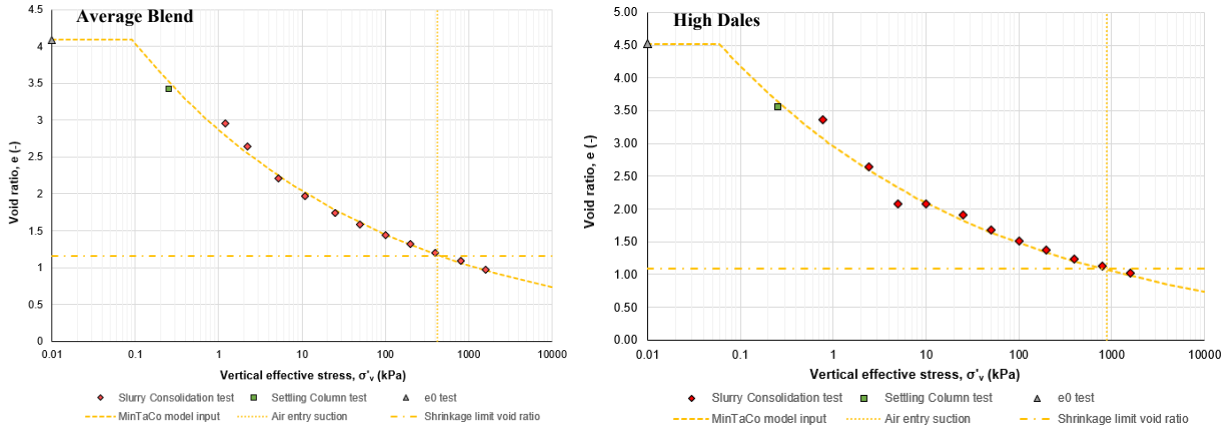

Figure 3: Laboratory test results and functions adopted for void ratio (e) vs. vertical effective stress (σ'v)

The relationship between void ratio and effective stress adopted in the models is presented in Figure 3, while Figure 4 shows the relationship between void ratio and hydraulic conductivity.

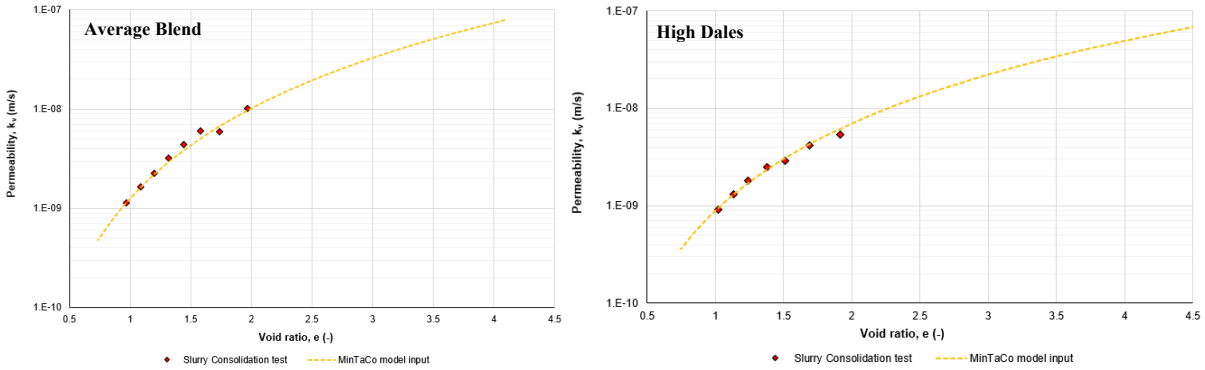

Figure 4: Laboratory test results and functions adopted for permeability (kv) vs. void ratio (e)

Modeling assumptions

The following inputs were incorporated and assumed in the models:

- A Poisson's Ratio of 0.3 is assumed for both Average Blend and High Dales tailings. This is considered appropriate for iron ore tailings as suggested by Priestley (2011).
- Decanting is operational at both pits during the deposition periods. A maximum pond depth of 1 m has been assumed to be developed within the depositional area.
- Freeboard requirements have been adopted in the consolidation modeling following the outcomes of overtopping assessment in conjunction with deposition modeling.
- An average annual lake evaporation rate of 5.9 mm/day (or 2.2 m/year) was adopted to simulate evaporation in the models. This is equivalent to a coefficient of conversion between A-Pan and the lake evaporation of 0.65. The data was extracted from SILO using Morton's shallow lake evaporation rates at the stations where the De Grey and Swan pits are located.
- Boundary conditions:
    - A conservative assumption of no flux at the lower boundary of the models (i.e., zero seepage with only upward drainage allowed).
    - Zero excess pore water pressure at the upper boundary to allow for water to drain at the surface. Tailings are assumed to remain fully saturated, which is representative of supernatant pond removal through decanting.
    - These boundary conditions are considered appropriate given the high rate of rise and low permeability of the tailings materials and pit base, as well as the likelihood that a supernatant pond will be allowed to form on the tailings surface.

Modeling results

1D modeling

Single filling phase

Consolidation modeling for the single filling was undertaken adopting the following scenarios and software: Plaxis LE, FSConsol, MinTaCo without evaporation and MinTaCo with evaporation.

The results are summarized in Table 6 and indicate the following:

- A storage life of 3.5 – 3.7 is achieved consistently in the scenario without evaporation using the three software. This is further illustrated in the output profiles in Appendix A.
- The incorporation of evaporation increases the storage life slightly to 3.9 years.
- The expected settlement within De Grey pit is approximately 55 – 58 m. Note that due to only one tailings sample being adopted for FSConsol, the results of settlement post deposition are not included for comparison purposes.

Table 6: Modeling results of De Grey pit for single filling phase

Parameters	Plaxis LE	FSConsol	MinTaCo (without evaporation)	MinTaCo (with evaporation)
Estimated storage life (years)	3.6	3.45	3.7	3.9
Total estimated settlement post-deposition (m)	55	N/A	54	58
Approximate time to reach 90% settlement from end of deposition (years)	47	N/A	44	44
Approximate tailings elevation at the end of settlement (RL m)	514	N/A	515	511
Average void ratio at the end of deposition	3.97	3.95	3.89	3.71
Average stored dry density at the end of deposition (t/m^3)	0.83	0.83	0.84	0.85

Multiple filling phases

Consolidation modeling for the multiple fillings was undertaken adopting the following scenarios and software: Plaxis LE (without evaporation) and MinTaCo (with evaporation).

An average tailings settlement magnitude of 5 m is assumed to be the target for tailings deposition restart following the fallow periods. Assessment in FSConsol was not included due to the maximum limit of 61 filling rates that can be inserted within the software, and the instability when handling more than one tailings material type.

The results are summarized in Table 7 and presented graphically in Figure 5. The results indicate the following:

- An overall storage life of ~9.4 years is anticipated to be achieved by incorporating evaporation in MinTaCo in comparison to ~5.2 years in Plaxis LE without evaporation, which is an increase of ~81% in storage life during operations.
- A reduction in total tailings settlement is anticipated when evaporation is considered, from 48 m to 39 m.
- MinTaCo takes longer to reach 90% settlement in approximately 80 years from FY51 in comparison to 51 years using Plaxis LE.

Table 7: Modeling results of De Grey pit for multiple filling phases

Parameters	MinTaCo	Plaxis LE
Estimated storage life at the end of the initial deposition phase (years)	3.9	3.6
Estimated total storage life at the end of the final deposition phase (years)	9.4	5.2
Total estimated settlement post-operations (m)	39	48
Settlement ratio (%)	37	46
Approximate time to reach 90% settlement from FY51 (years)	80	51
Approximate tailings elevation at the end of settlement (RL m)	525	516

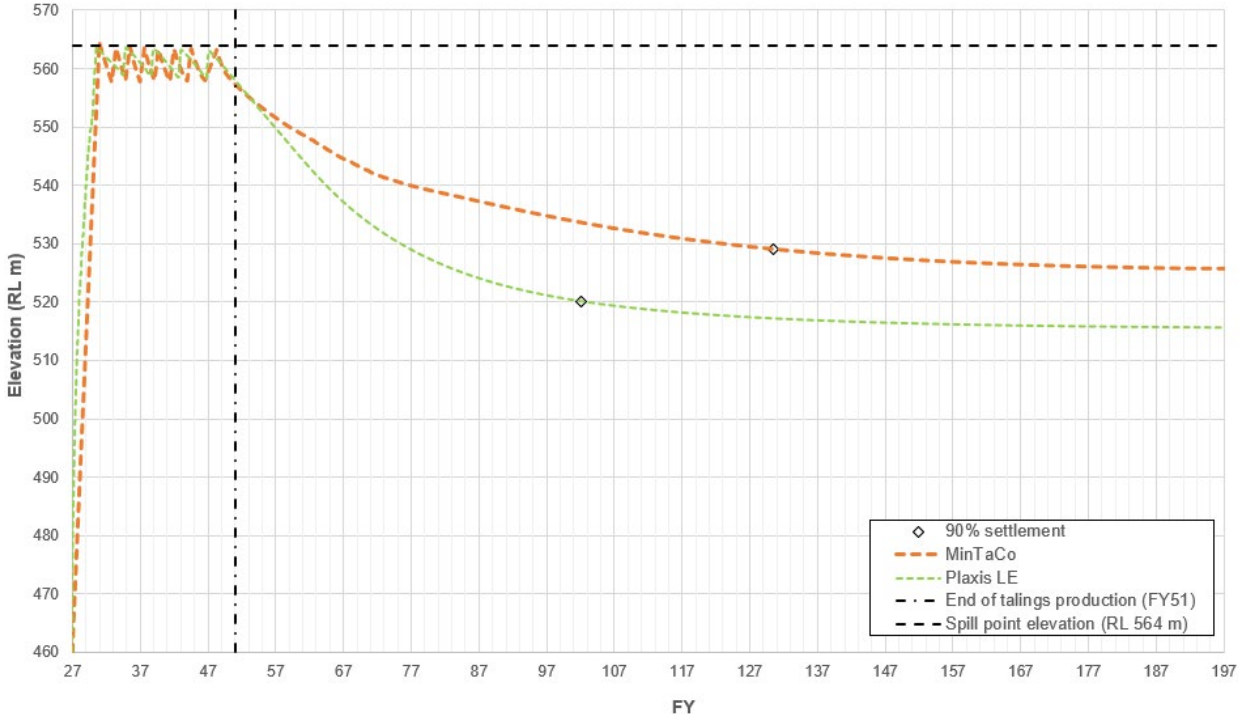

Figure 5: Settlement of software considered for the multiple filling phases

Pseudo-3D modeling

The results of 1D modeling are representative for a single location within the pit, where settlements are expected to be the greatest. It is expected that the average settlement across the pits' area will be less due to changes in the pit geometry. Pseudo-3D consolidation modeling has been undertaken to provide a better understanding of the tailings settlement profile in three-dimensional configuration. Note that pseudo-3D does not consider horizontal dissipation of pore pressure, lateral deformation, and the effects of evaporative desiccation.

The results of pseudo-3D consolidation modeling are presented in Figure 6, showing the estimated final tailings surfaces at the end of consolidation. 3D outputs showing void ratio and effective stress profiles at various timeframes in both pits are included in Appendix B. The results of the pseudo-3D modeling indicate that:

- The settlement profiles at the deepest locations within the two pits are aligned with the 1D modeling results with a total estimated post-deposition settlement of ~50 m in De Grey pit. The estimated final tailings elevation at those locations at the end of settlement are within RL 510 m and RL 520 m.
- The magnitude of settlement reduces with reducing pit depth/height of tailings column. As such there is likely to be less settlement around the edges of the pits than in the center, creating a dished tailings surface profile.

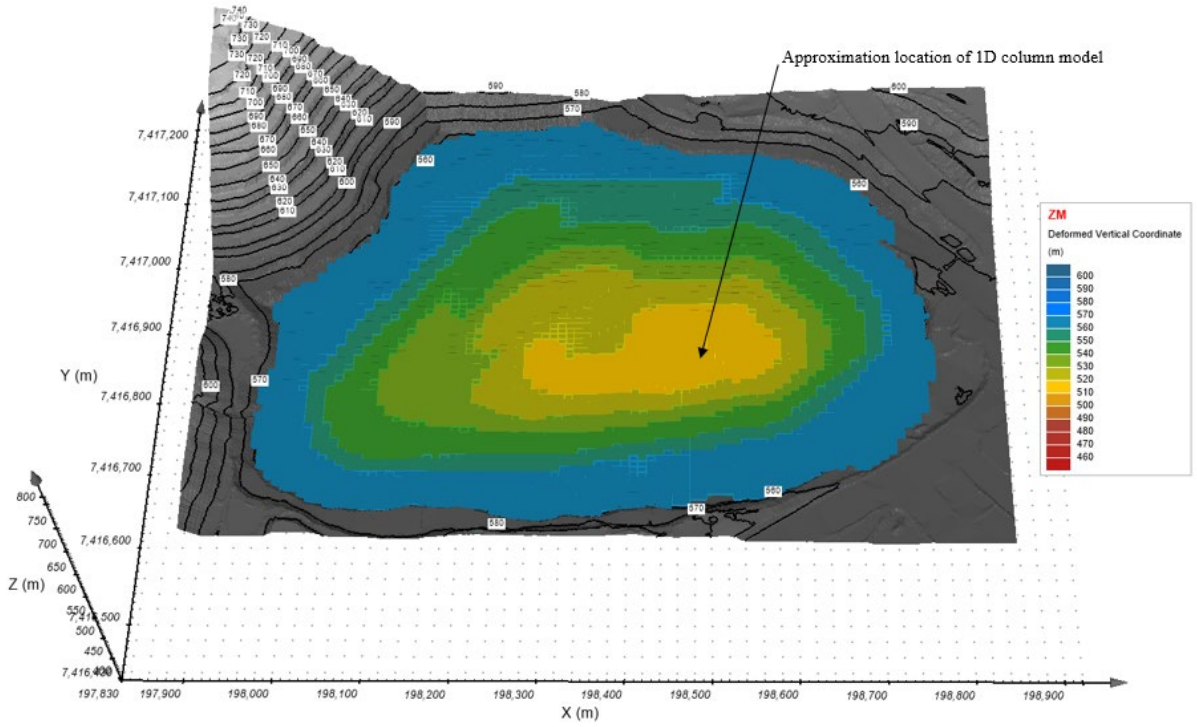

Figure 6: Pseudo-3D surface of total estimated tailings settlement in the De Grey pit

Conclusion

The numerical modeling comparison of large-strain tailings consolidation undertaken indicates the following:

- FSConsol has been primarily used by tailings practitioners in the industry for consolidation modeling due to its relatively basic GUI and the ability to model creep deformation. This is suitable for 1D consolidation models, having simple TSF geometry with limited inputs required. Plaxis LE has a more sophisticated GUI and advanced functions that allow users to model complex TSF geometry based on the actual site topography in both 1D and pseudo-3D configurations. However, this will normally require users to have relatively advanced modeling skills, with some background knowledge in 3D modeling. In comparison to Plaxis LE and FSConsol, MinTaCo has the advantage of being able to incorporate climatic conditions such as evaporation. The major drawback with MinTaCo is the lack of a user-friendly GUI and the ability to model pseudo-3D.
- The case study showed a consistent similarity between the outputs of settlement magnitude, profiles of void ratio, dry density, effective stress, and hydraulic conductivity from the three software. FSConsol showed instability in its model solver as it was not able to handle two tailings materials in comparison to Plaxis LE and MinTaCo, even though FSConsol allows the user to enter over 30 different material types. The results of pseudo-3D modeling in Plaxis LE were consistent with the 1D outcomes. When incorporating evaporation in a multiple filling scenario, MinTaCo showed a significant increase in the storage life of the TSF, which emphasizes the importance of climatic conditions to tailings consolidation process.

Enhancing Data Management and Analysis for Mine Waste and Tailings Dam Design through Modern Data-Analytics Dashboards

Ela Talebi, Stantec, USA
Fariba Yavari, Canada
Kris Hojka, Worley Consulting Ltd, Canada

Abstract

In mine waste and tailings dam design and risk management, the mining industry has relied on traditional spreadsheet software for compiling essential data sets from field investigations, laboratory results, instrumentation, and sensor readings. While spreadsheets have been a staple due to their widespread availability and fundamental analytical capabilities, their usage has significant drawbacks and limitations. For large projects, the static nature of spreadsheets makes them inefficient for dynamic data management and highly prone to data loss and corruption. Additionally, these isolated data silos make it exceedingly difficult to perform comparative analyses against other data sources. Analyzing data within these limitations often leads to errors and challenges in correlating with historical data. This may result in a fragmented understanding of foundation conditions, leading to not well-informed decisions in tailings dam designs and their risk management.

In response to these challenges, we propose an innovative workflow that leverages the advanced capabilities of Power BI. This methodology enables a comprehensive representation of data in 2D and 3D formats, integrating information from diverse sources for multi-faceted analysis. The seamless real-time interoperability between data and visualization tools ensures continuous support throughout the project's life cycle. We provide practical examples to address visualization limitations for geotechnical engineers, and demonstrate how this technology enables a more informed and flexible response to design and risk management challenges. This improvement marks a significant enhancement in efficiency for all phases of tailings and mine waste projects, from inception to closure.

Introduction

In the field of mining waste and tailings dams design, the importance of robust data processing cannot be overstated. Traditionally, the mining industry relies on critical data sets derived from field surveys and

investigations, laboratory results, and monitoring data. However, the limitations inherent in traditional spreadsheets, such as their static nature, susceptibility to errors, and potential for data loss, impede comprehensive data management. These shortcomings pose significant challenges in addressing environmental concerns, assessing the risks of dam failure, and ensuring the long-term safety of mining operations.

Monitoring data plays a crucial role in this context, as it provides real-time insights into the behavior and performance of tailings dams. Effective monitoring can detect early signs of instability, such as changes in pore pressure, seepage, or structural deformation, allowing for timely interventions that mitigate risks. However, the vast amount of monitoring data generated can be difficult to manage and interpret using traditional methods, further complicating the ability to respond to potential issues quickly.

To overcome these obstacles, we advocate for using advanced data analysis and visualization tools, such as Power BI. Power BI's capabilities enable the integration of diverse data sources, allowing for dynamic and comprehensive analyses that surpass the static constraints of traditional spreadsheets. This innovative approach enhances decision-making processes, improves risk management strategies, and provides a deeper understanding of geotechnical and environmental conditions. By leveraging Power BI, stakeholders can gain real-time insights and a more nuanced understanding of the data, leading to more informed and proactive management of tailings dams.

Through practical examples and demonstrations, we aim to showcase the transformative potential of this method in enhancing tailings dam design and risk management practices. The integration of advanced data analytics and visualization not only streamlines data management but also fosters a culture of continuous improvement and proactive risk mitigation. By adopting these technologies, the mining industry can significantly enhance its ability to address environmental challenges, improve the safety of tailings dams, and protect both human lives and the environment.

Empowering mining projects with advanced data insights: the role of Power BI

In the field of large-scale data analysis, particularly in mining projects that deal with significant data sets, Power BI stands out as a pivotal tool for effective data exploration and decision making. Unlike Excel, which often struggles with the volume and complexity of data, Power BI excels in managing large datasets seamlessly. Modern dashboards' powerful data modeling capabilities enable the efficient storage and retrieval of various data types, ensuring that mining professionals can access and analyze critical information quickly and accurately. In addition, Power BI's dynamic visualization features enable users to create interactive dashboards and reports that provide deep insights into geological surveys, designs, and production metrics and operational efficiency.

Using Power BI's coding capabilities and advanced processing power, mining engineers can overcome the limitations of traditional spreadsheet applications and empower them to make informed decisions based on comprehensive data analysis. Additionally, Power BI's ability to create dynamic groups and hierarchies is crucial for data lifecycle analysis. In mining projects characterized by extensive data sets including investigation stages, tests, designs, and resource extraction and management, the ability to segment and visualize data dynamically is vital.

To understand operational trends and identify potential efficiencies, it facilitates this task by allowing users to define and modify dynamic groups, adapting to evolving landscapes and project requirements, from correlations and patterns that may influence decision-making processes. Using integrated data search and transformation tools, design flows can be more accurate and reduce risks associated with data management, thereby optimizing project outcomes, and ensuring sustainable resource management practices.

The role of geotechnical investigations in tailings dam design

The design of tailings dams has become critically important due to the increasing frequency of tailings dam failures, which pose severe risks to human life and cause significant environmental damage. Such incidents highlight the necessity for geotechnical engineers to meticulously attend to design details and implement rigorous safety controls. Ensuring the structural integrity and safety of tailings dams requires a comprehensive approach rooted in precise geotechnical investigations and comprehensive data processing and interpretation.

Comprehensive and detailed geotechnical investigations are essential for the design, and stability assessment of tailings dams. This process involves several key activities: drilling boreholes to obtain soil and rock samples, conducting geological profiling to understand the subsurface conditions, performing various geotechnical tests to determine material properties, and analyzing large volumes of data collected throughout different project stages. These steps are crucial for identifying vulnerable sections, potential failure modes and designing dams that can withstand both expected and extreme loading conditions.

Moreover, the data obtained from these investigations inform critical design decisions, such as selecting appropriate construction materials, determining dam geometry, and designing effective drainage and reinforcement systems. Continuous monitoring and assessment throughout the lifecycle of the dam, from construction through operation to closure, are also imperative to detect and address any emerging issues promptly. By adhering to these detailed and data-driven approaches, geotechnical engineers can significantly enhance the safety and reliability of tailings dams. Geotechnical testing is essential for ensuring the stability and safety of structures like tailings dams, encompassing a wide range of assessments on soil, rock, groundwater, and other geologic materials. In-situ soil testing methods will determine the soil strength, compactness, and consistency. Laboratory soil tests focus on parameters such as grain size

distribution, Atterberg limits, moisture content, and additional special loading tests to evaluate soil behavior under various loading conditions. These tests are crucial for predicting how soil will behave under various load conditions and environmental factors, ensuring stable foundations for tailings dams (Das, 2021).

Rock testing determines the strength and durability of rock materials, which are critical for the integrity of dam foundations and structural supports. Important parameters include compressive strength, tensile strength, and durability assessments. These parameters measured by various tests provide insights into the mechanical behavior of rock masses, ensuring they can support the construction and long-term stability of tailings dams.

Spoils permeability and pore pressure testing is used to understand seepage characteristics and potential liquefaction hazards. This information is vital for designing effective drainage systems and control of water pressures within the dam. By integrating the results of soil, rock, and groundwater tests, engineers can make informed design decisions, ensuring that tailings dams are robust, stable, and capable of withstanding both normal and extreme conditions, thereby minimizing the risk of catastrophic failures.

In addition, geotechnical research starts to use advanced methods of data analysis, including artificial intelligence algorithms and numerical simulations (Gao, 2024). These technologies enhance decision making by providing more accurate predictions of dam behavior under various loading conditions and environmental scenarios. Integrating this geotechnical research will ensure that tailings dams are designed with greater robustness, and reliability, reducing risks, and protecting human communities and natural ecosystems.

Integrating monitoring techniques with Power BI

In the field of mining waste and tailings dams design, the importance of robust data processing cannot be overstated. Traditionally, the mining industry relies on critical data sets derived from field surveys and investigations, laboratory results, and monitoring data. However, the limitations inherent in traditional spreadsheets, such as their static nature, susceptibility to errors, and potential for data loss, impede comprehensive data management. These shortcomings pose significant challenges in addressing environmental concerns, assessing the risks of dam failure, and ensuring the long-term safety of mining operations.

Monitoring is a vital component of tailings dam management, providing essential data on the dam's structural integrity and environmental impact. Common monitoring techniques include in-situ instrumentation, such as piezometers for measuring pore pressure, inclinometers for detecting slope movement, and seepage monitoring systems. Remote sensing technologies, like satellite imagery and drone surveys, are also used to monitor surface deformations and water levels. These techniques generate vast

amounts of data that are crucial for assessing the real-time condition of tailings dams and can send real time alarm, warning messages, in the event TARPs (Trigger Action Response Plan) levels are triggered.

To maximize the effectiveness of these monitoring techniques, the data they generate can be integrated into Power BI dashboards. Power BI offers a platform for real-time data visualization, enabling engineers and decision-makers to monitor the status of tailings dams continuously. By connecting monitoring instruments directly to Power BI, data such as pore pressure readings, slope stability metrics, and seepage rates can be displayed on interactive dashboards. These dashboards allow for the visualization of trends over time, alert generation when critical thresholds (TARPs) are exceeded, and the ability to perform predictive analytics. This integration empowers stakeholders to respond swiftly to emerging risks, improving safety and reducing the likelihood of catastrophic failures.

The real-time monitoring capabilities provided by integrating monitoring data with Power BI offer significant advantages. They enable proactive management by facilitating early issue detection, thus preventing them from developing into larger problems. The ability to visualize all relevant data in one platform enhances decision-making and provides a comprehensive understanding of the tailings dam's condition. This approach not only improves safety but also supports compliance with regulatory requirements and fosters a culture of continuous monitoring and improvement.

Through practical examples and demonstrations, we aim to display the transformative potential of this method in enhancing tailings dam design and risk management practices. The integration of advanced data analytics, visualization, and monitoring not only streamlines data management but also fosters a culture of continuous improvement and proactive risk mitigation. By adopting these technologies, the mining industry can significantly enhance its ability to address environmental challenges, improve the safety of tailings dams, and protect both human lives and the environment.

Ultimately, adoption of these innovations will lead to more flexible and safer tailings dam management practices, ensuring long-term sustainability and operational excellence.

Case study

A Power BI dashboard has been meticulously developed for a tailing dam geotechnical investigation project, serving as a robust tool for data analysis and visualization. This comprehensive dashboard comprises multiple pages, each dedicated to different aspects of the investigation, featuring a variety of visualizations and statistical analyses designed to present data in an intuitive and accessible manner.

The dashboard provides in-depth information on lithology, presenting intervals and classifications of different geological formations encountered during the investigation. Users can view detailed descriptions of the lithology, including rock and soil classifications, which are essential for understanding the

composition and characteristics of the subsurface materials. The location of each borehole is precisely mapped, allowing users to correlate geological data with specific geographical points.

Figure 1 exemplifies one of the pages of the report, highlighting the intricate details of lithology. This page includes rock and soil classifications along with comprehensive test results. It allows geotechnical engineers and project stakeholders to examine the properties and behaviors of various geological materials encountered.

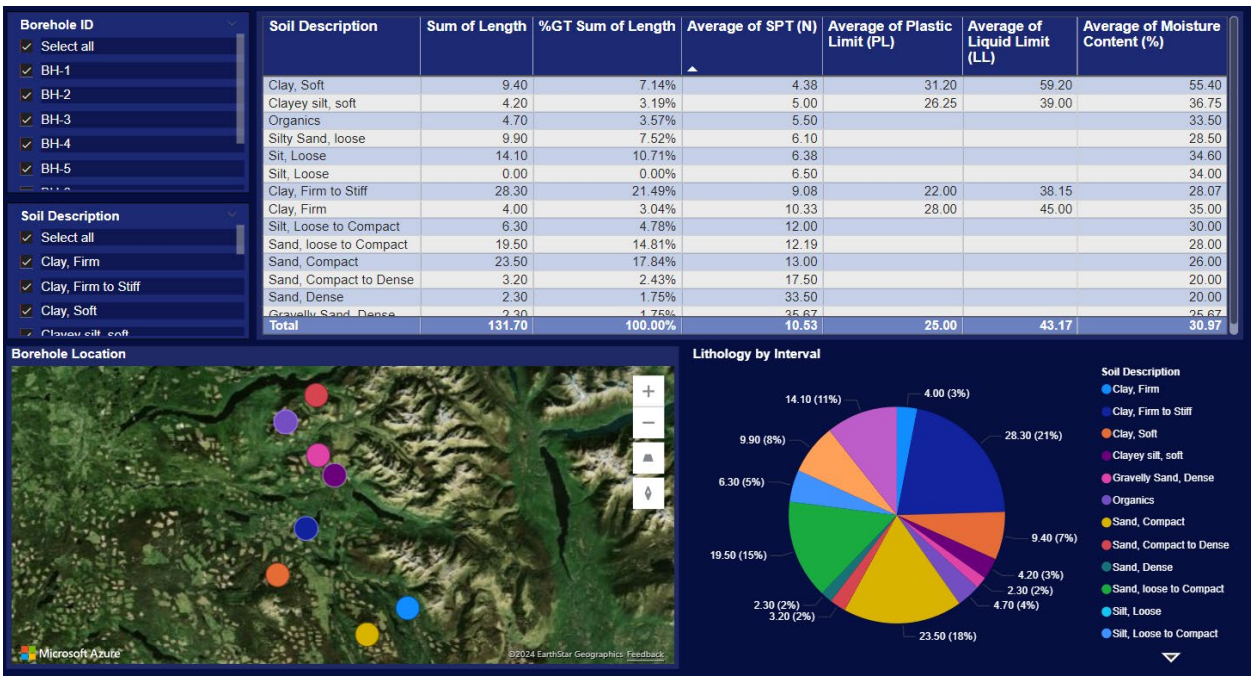

Figure 1: Detailed and dynamic lithology analysis of boreholes

The dashboard is equipped with advanced filtering capabilities, enabling users to apply various criteria and parameters to their analysis. Filters such as location, lithology, and borehole ID allow users to customize their view and focus on specific data subsets. This interactivity makes the dashboard a dynamic tool, facilitating tailored analysis and quick data retrieval based on user-defined parameters.

Figure 2 presents a borehole log, offering a thorough examination of the lithology throughout the borehole depths. This includes Standard Penetration Test (SPT) results, moisture content measurements, liquid limit, and plastic limit results. These logs are essential for understanding the mechanical properties of the soil and rock layers, which are crucial for assessing the stability and integrity of the tailing dam.

Figure 3 features an advanced 3D visualization of borehole logs, providing a spatial representation of the lithology layers across multiple boreholes. This three-dimensional perspective enables users to grasp the spatial relationships and orientations of different geological layers, enhancing their understanding of the subsurface profile. It aids in identifying weak spots, patterns, and correlations between boreholes, which can be critical for designing and implementing geotechnical solutions.

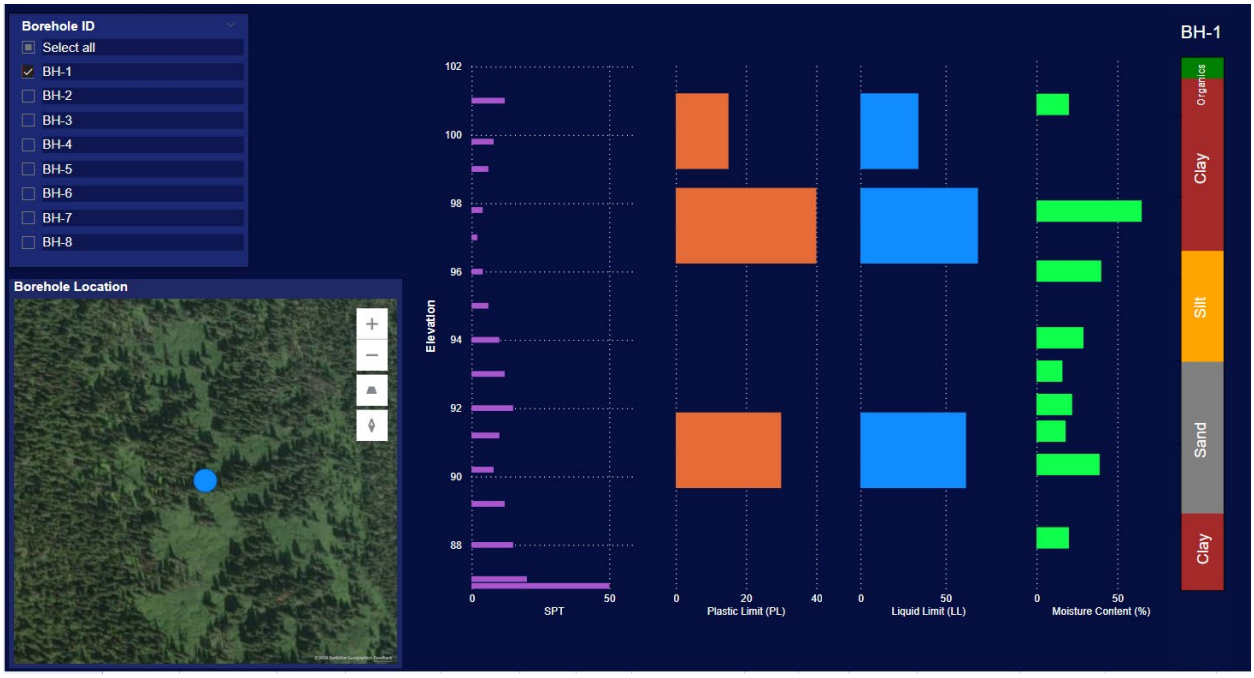

Figure 2: Detailed and dynamic analysis of borehole logs

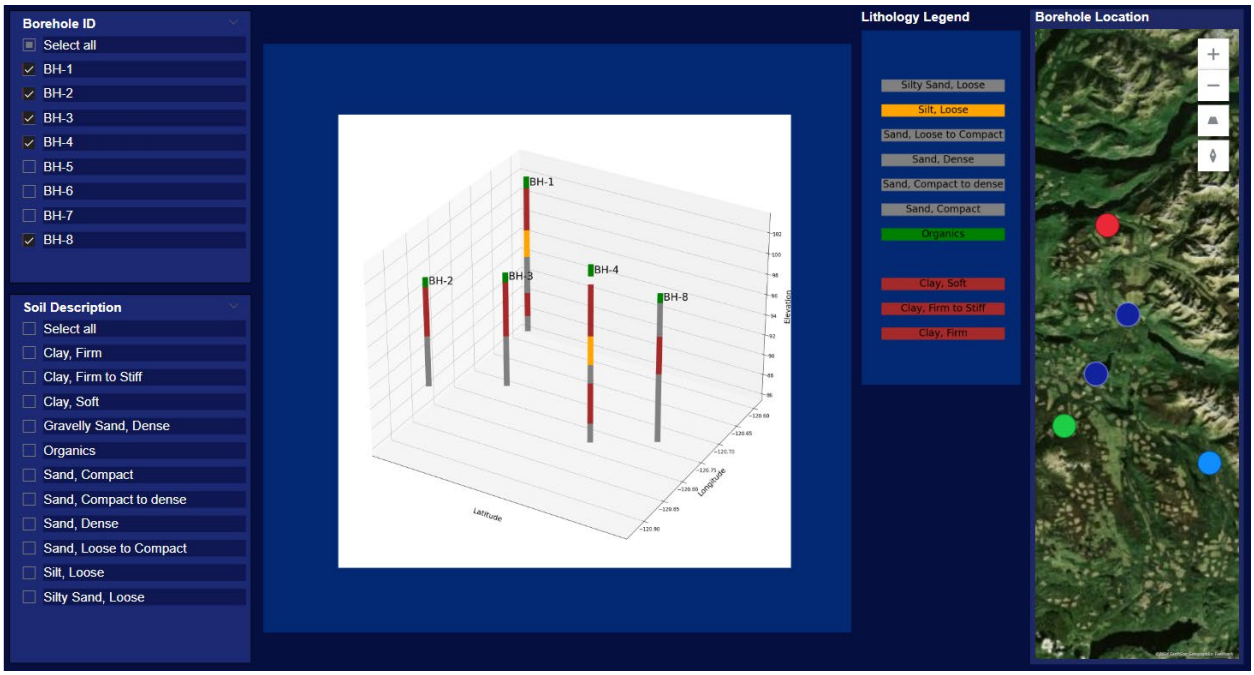

Figure 3: Detailed and dynamic 3D analysis borehole log

This Power BI dashboard features several advanced analytical tools:

- Trend analysis: Users can track changes in geological properties and test results over time or across different boreholes, enabling the identification of trends and anomalies.

- Comparative analysis: The dashboard allows for side-by-side comparisons of different boreholes or lithology layers, providing a more comprehensive understanding of the data, and
- Predictive modeling: Integrating predictive models can help forecast geological behaviors and identify potential risks associated with the tailing dam.

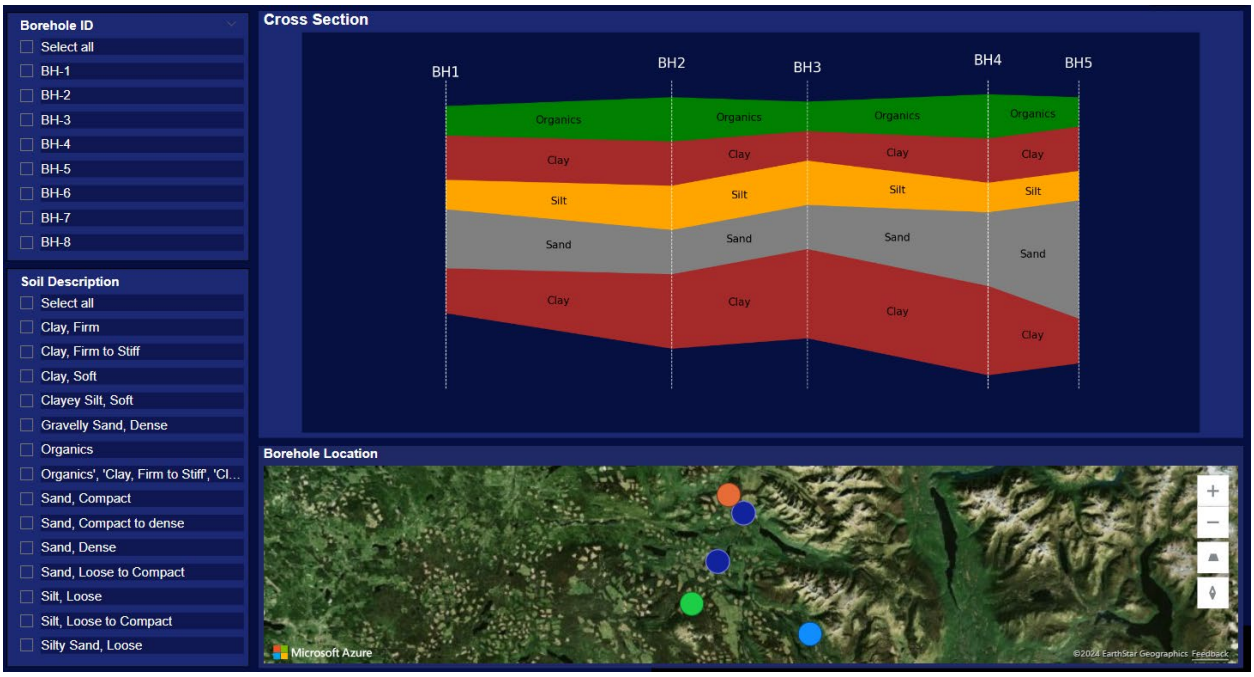

Figure 4: Cross-section of the borehole logs

In Figure 4, the geotechnical cross-sections developed in Power BI for the tailing dam design provides a comprehensive visualization of the subsurface conditions, enhancing the analysis and interpretation of geotechnical data. By plotting borehole data along a cross-section line, this tool allows for an in-depth examination of the spatial distribution and continuity of various soil layers between boreholes. The vertical lines marking each borehole location, combined with the color-coded soil layers, create a clear and intuitive representation of the subsurface profile. This detailed visualization is essential for identifying the characteristics and extent of different soil and rock formations, aiding in the design and construction of a stable tailing dam.

Furthermore, the dynamic and interactive capabilities of Power BI enhance the usability of the geotechnical cross-section. Users can filter and adjust the displayed data based on specific criteria such as borehole locations, soil types, and depth intervals, providing a tailored view of the geotechnical information relevant to their needs. This interactivity, combined with the ability to annotate and highlight key features, ensures that engineers and decision-makers can quickly and accurately assess the conditions at the tailing dam site. This tool supports more informed decision-making, contributing to the effective planning, design, and implementation of tailing dam projects.

During the presentation of this paper at the conference, we will explore how video dynamic charts improve analytical capabilities, such that these analyses lead to a broader and more accurate understanding of geotechnical information compared to traditional formats. Data storage is similar to Excel spreadsheets. This approach facilitates easy identification of missing or anomalous data and ensures comprehensive data coverage for improved design results and more reliable results.

Enhanced geotechnical data analysis for tailings dam design: mitigating liquefaction risks

Liquefaction assessment is one of the most important steps in tailings dam design and its stability assessment. Tailings dams are designed to contain safely tailings from mining processes, and their sustainability is highly dependent on accurate geotechnical analyses, including liquefaction assessment.

Liquefaction is a phenomenon in which saturated soil loses its strength and stiffness under cyclic loading such as earthquake or rapid loading during static conditions. In the field of tailings dam design, liquefaction potential evaluations are crucial to understand how dam materials behave in seismic conditions. This analysis includes a detailed evaluation of factors such as soil properties, seismic hazard levels, and dam geometry (Idriss and Boulanger, 1982).

Advanced tools like Power BI are increasingly used in these analyses due to their ability to manage large data sets and perform complex calculations efficiently. By leveraging Power BI's analytical capabilities, engineers can achieve more reliable results and more precise design adjustments. These tools enable comprehensive data analysis, including the identification of anomalies or missing data points, which are critical for sensitivity analysis and simulation of liquefaction scenarios.

The importance of data analysis in geotechnical investigations of tailings dams cannot be ignored. Accurate data analysis enables engineers to assess potential liquefaction hazards more comprehensively, thereby informing design decisions that enhance the long-term safety and sustainability of these critical structures. By integrating detailed geotechnical data analysis into the design process, it is possible to reduce the risks of missing data gaps and make more accurate interpretation of data, aiding in detection of most vulnerable zones susceptible to liquefaction.

Conclusion

A comprehensive review and comparison of traditional tailings dam design systems, including conventional geotechnical analyses and traditional databases such as Excel, reveals inherent limitations and challenges. These traditional methods often struggle with managing large volumes of data and may miss important insights due to their manual and less adaptive nature. In contrast, advances in artificial intelligence (AI) and machine learning (ML) present promising alternatives for enhancing data analysis capabilities in tailings

dam design. AI and ML algorithms can efficiently process enormous amounts of geotechnical data and identify patterns and anomalies that may not be easily visible through traditional methods. This capability enables engineers to perform more thorough sensitivity liquefaction assessments and optimize dam design to reduce risks associated with seismic events and other potential hazards.

Furthermore, the integration of AI and ML into geotechnical engineering practices promotes iterative improvements in design methods and ensures that tailings dams are not only safer, but also more resilient throughout their operational lifetimes. Using these technologies, mining companies can achieve stronger and more reliable designs for tailings dams, thereby increasing environmental sustainability and safety standards in mining operations. Continued research and implementation of AI and ML in geotechnical engineering promises more innovation and efficiency in tailings dam design, and the setting of new standards for safety and reliability in the mining industry.

The proposed methods of AI and ML play a key role in data analysis and graphs of geotechnical results, but the noteworthy point is that the experience of engineers plays a significant role in design, and a qualified, experienced engineer should be making final interpretations of geotechnical information and decisions.

Abstract

The current state of practice in liquefaction studies involves analyzing this phenomenon through numerical models. In these simulations, it is often necessary to use constitutive models capable of capturing nonlinear behavior, pore pressure generation, and strength loss. The Clay and Sand Model (CASM) is one such model that can represent all these phenomena. CASM has the advantage of being applicable to both fine and granular materials, ranging from ductile to brittle behavior, and is based on a robust formulation that incorporates critical state concepts. CASM is not yet available in commercial codes, thus its application is not yet common practice. However, its potential has been confirmed through retro-analyses of recent tailings dam failure cases, such as the Brumadinho Dam collapse. In this work, we discuss CASM's formulation and present its implementation in the commercial finite element software Plaxis using its user-defined soil models functionality. The implementation is then verified through a series of numerical tests and a parametric analysis is conducted to evaluate the model's response to different input parameters. Results show that CASM is able to model important critical state mechanisms in both fine- and coarse-grained soils, such as volumetric changes, and showcase its potential for application in complex geomechanics problems, such as tailings dam failures.

Introduction

Granular and transitional soils, such as sand or silty soils, tend to contract when loosely packed and subjected to shearing. When these loose soils are saturated and rapidly loaded, their contractive tendency generates excess pore water pressures, leading the soil to behave in an undrained fashion. This process

decreases effective stress, and consequently, the soil particles lose contact with each other, reducing the soil's strength and stiffness, and causing it to behave like a fluid. This phenomenon is known as static liquefaction (Jefferies and Been, 2016).

Tailing dams constructed using the upstream method are found to be more vulnerable to failure and highly susceptible to static liquefaction (Piciullo et al., 2022). The geotechnical community has placed significant focus on the failure of upstream raised tailings dams due to static liquefaction, driven by recent incidents such as the Fundão collapse in 2015 (Morgenstern et al., 2016), the Cadia failure in 2018 (Jefferies et al., 2019), and the Brumadinho tragedy in 2019 (Arroyo and Gens, 2021), Figure 1.

Figure 1: Brumadinho tailings dam collapse snapshots

Tailings dam failures result in significant economic and environmental harm, so in order to better understand the safety and behavior of such structures, the use of numerical modeling to address the onset of flow liquefaction is increasing (Jefferies and Been, 2016). Therefore, these numerical models demand constitutive models capable of simulating the liquefaction phenomenon.

In this context, this paper addresses the constitutive model known as the Clay and Sand Model (CASM), which was first proposed by Yu (1998), and recently modified by Mánica et al. (2021). CASM was developed to represent the behavior of both sands and clays, so it is a good candidate for modeling the behavior of tailings, which encompass a wide range of grain sizes. This constitutive model has been used to retro-analyze historical tailings dam liquefaction cases, such as the Merriespruit Dam (Mánica et al., 2021) and the Brumadinho Dam (Arroyo and Gens, 2021). However, it is not currently available in commercial software, and its implementation requires a custom process.

Hence, this paper presents the CASM formulation and its implementation using an explicit integration scheme as a user-defined model in Plaxis (Brinkgreve et al. 2020). It includes a procedure to validate the implementation, along with additional parametric analyses based on a series of numerical laboratory tests. Validation results demonstrate the consistency and robustness of the formulation proposed, and the procedure described will serve as a methodology to validate future implementations.

Formulation

A description of CASM's formulation is provided in this section. For standardization purposes, the equations are written in terms of the Cambridge invariants: mean effective stress (p'), Von Mises deviatoric stress (q), and Lode angle (θ) (Wood, 2004). The parameters and main equations of the CASM model are presented in Tables 1 and 2, respectively.

Table 1: Parameters of the CASM model

Component	Parameters	
Critical State Line - CSL	Γ	CSL void ratio (e) at p' = 1 kPa, in e-ln(p') plane;
	λ	slope of CSL in e-ln(p') plane;
	M_{TC}	slope of CSL in q-p' space for triaxial compression condition;
Elasticity	ν	Poisson ratio
	κ	slope of elastic line in a e-ln(p') space
Plasticity	n	Parameter that controls the yield function shape;
	r	spacing ratio;
	m	Parameter that controls the plastic potential shape;
State	$OCR = p'_0 / p'$	over-consolidation ratio;

Table 2: Main equations of the CASM model

Component	Equation		
CSL in e x *ln* p′ plane	$e = \Gamma - \lambda \, lnp'$		Equation 1
Slope of CSL in q x p′ plane	$M_\theta = M_{TC} \left(\frac{2\,\alpha^4}{1+\alpha^4+(1-\alpha^4)\,sen3\theta}\right)^{1/4}$;	$\alpha = \frac{3}{3 + M_{TC}}$	Equation 2
Yield function	$f = \left(\frac{q}{M_\theta p'}\right)^n + \frac{1}{\ln r} \ln\left(\frac{p'}{p'_0}\right)$		Equation 3
Hardening rule	$\frac{\partial p'_0}{\partial \varepsilon_p^p} = \frac{(1+e)\,p'_0}{\lambda - \kappa}$		Equation 4
Plastic Potential	$g = \left(\frac{q}{M_\theta p'}\right)^m + \mathrm{m} - 1 - \frac{p_c\,(m-1)}{p'}$;	$p_c = \frac{p}{m-1}\left[\left(\frac{q}{M_\theta p'}\right)^m - 1\right]$	Equation 5
Elasticity	$K = \frac{(1+e)\,p'}{k}$		Equation 6

CASM is based on critical state theory and adopts an approach similar to the Cam-Clay constitutive model (Wood, 1990). It postulates a linear relationship for the critical state line in the *e* (void ratio)- *ln(p')* plane (Equation 1), with consolidation lines assumed to run parallel to the CSL.

In contrast to the Cam-Clay model, CASM replaces the normal consolidation line with the reference compression line, representing the loosest state the material might experience. According to Yu (1998), this change was made because the normal compression line of sands, unlike clays, is only reached under high stresses, uncommon in engineering problems. The position of the reference consolidation line in CASM is determined by the spatial ratio (*r*, refer to Table 1), a parameter used to measure the distance between the critical state line and the reference line.

The slightly modified version of CASM proposed by Mánica et al. (2021) is employed in this work. Mánica et al. (2021) modified the original version proposed by Yu (1998) by integrating the effect of the intermediate principal stress, captured by the change in Lode's angle on the CSL, in the *p'-q* plane. In order to account for Lode's angle changes, the authors applied the relationship presented in Equation 2, proposed by Sheng et al. (2000).

The yield function adopted in the model is presented in Equation 3, where the elastic domain is controlled by the pre-consolidation stress (p'_0). On the other hand, the hardening law (Equation 4) is based on plastic volumetric strain, similar to the Cam-Clay model.

The plastic potential function adopted by Mánica et al. (2021) was also modified from the original formulation by Yu (1998). The plastic potential employed is presented in Equation 5, where p_c must be solved for the current stress state. Notably, the plastic potential function exhibits a distinct form from the yield surface. Consequently, the CASM model incorporates non-associated flow. The parameter *m* offers flexibility in adjusting the model's response along oedometric paths, ensuring that the coefficient of at-rest lateral earth pressure (K_0) remains constant at a specified value, unaffected by plastic strains.

Finally, the elastic behavior in the CASM model is defined by constant Poisson ratio (ν), and by the bulk modulus (K). The bulk modulus is related to the slope of the unloading line (κ) and also varies with stress level and void ratio, as depicted in Equation 6.

Implementation

CASM was implemented in the finite element software Plaxis, which allows for the incorporation of new constitutive models through its "User Defined Soil Model" functionality. To integrate a user-defined constitutive model into the software, the code, written in Fortran, must be compiled into a Dynamic-link library (DLL) file and added to the program's directories.

The constitutive model will be invoked at each Gauss point, and Plaxis will provide preliminary information such as stress state, pore pressures, and state variables, along with strain increments as input

data to the user-defined script. The constitutive model will then compute stress increments according to the defined formulation, and, subsequently, Plaxis will solve the equilibrium equations using the finite element method and will pass new strains back to the constitutive model. This cycle repeats until convergence is achieved.

To make the DLL functional within the main Plaxis program, it is necessary to develop a code that communicates with specific subroutines:

1. Initialization of state variables: At this stage, initial values of user-supplied properties and state variables are defined.
2. Integration of constitutive relations: During these steps, calculations are performed to determine new stresses based on strain increments.
3. Creation of the elastoplastic stiffness matrix: This involves creating the matrix that describes the relationship between stresses and strains for elastoplastic material behavior.
4. Creation of the elastic stiffness matrix: Here, the matrix describing the relationship between stresses and strains for purely elastic material behavior is created.

The main code of the constitutive model implementation involves integrating the constitutive relations. During the integration process, an elastic prediction is first made. If it is determined that the new stress state lies outside the yield surface, a plastic correction is performed, which is necessary to ensure consistency. The generalized elastoplastic constitutive relation is presented in Equations 7 and 8.

$$\begin{Bmatrix} dp' \\ dq \end{Bmatrix} = [D] \begin{Bmatrix} d\varepsilon_p \\ d\varepsilon_q \end{Bmatrix} \quad \text{Equation 7}$$

$$[D]^{-1} = \left\{ \begin{bmatrix} {}^{1}/_{K} & 0 \\ 0 & {}^{1}/_{3G} \end{bmatrix} - \frac{1}{\frac{\partial f}{\partial s}\left(\frac{\partial s}{\partial h}\frac{\partial g}{\partial p'} + \frac{\partial s}{\partial h}\frac{\partial g}{\partial q}\right)} \begin{bmatrix} \frac{\partial f}{\partial p'}\frac{\partial g}{\partial p'} & \frac{\partial f}{\partial q}\frac{\partial g}{\partial p'} \\ \frac{\partial f}{\partial p'}\frac{\partial g}{\partial q} & \frac{\partial f}{\partial q}\frac{\partial g}{\partial q} \end{bmatrix} \right\} \quad \text{Equation 8}$$

where $d\varepsilon$ is the strain increment, with subscripts q and p representing the shear and volumetric components, respectively; *[D]* is the elastoplastic stiffness matrix; s is the hardening parameter controlling the elastic domain variation; and h is the plastic strain parameter related to s, i.e., $ds = f(dh)$.

In the CASM, the hardening parameter controlling the variation of the elastic domain is the pre-consolidation stress p_0, thus $s = p_0$. Since hardening is governed by volumetric plastic deformations, $h = \varepsilon_{vp}$. Considering that the yield function and the plastic potential function adopted in CASM are given by

Equations 3 and 5, respectively, and that the hardening law is defined by Equation 4, the following derivatives can be defined as presented in Equations 9 to 14.

$$\frac{\partial f}{\partial p'} = \left(\frac{q}{M_\theta}\right)^n \left(\frac{-n}{p'^{n+1}}\right) + \frac{1}{p' \ln r} \quad \text{Equation 9}$$

$$\frac{\partial f}{\partial q} = \left(\frac{1}{M_\theta p'}\right)^n (nq^{n-1}) \quad \text{Equation 10}$$

$$\frac{\partial g}{\partial p'} = \left(\frac{q}{M_\theta}\right)^m \left(\frac{-m}{p'^{m+1}}\right) + \frac{p' c(m-1)}{p'^2} \quad \text{Equation 11}$$

$$\frac{\partial g}{\partial q} = \left(\frac{1}{M_\theta p'}\right)^m (mq^{m-1}) \quad \text{Equation 12}$$

$$\frac{\partial f}{\partial s} = \frac{\partial f}{\partial p'_o} = \frac{-1}{ln\, r}\left(\frac{1}{p0'}\right) \quad \text{Equation 13}$$

$$\frac{\partial s}{\partial h} = \frac{\partial p'_o}{\partial \varepsilon_v^p} = \frac{(1+e0)p'_o}{\lambda - \kappa} \quad \text{Equation 14}$$

During the plastic correction process, the initial attempt is to apply the entire strain increment to integrate stresses and hardening parameters. To ensure numerical stability in this process, an explicit algorithm of automatic sub-incrementation, proposed by Sloan et al. (2001), has been adopted. If integration fails to meet the specified error level, the strain increment is reduced. This process continues until all strain is applied while respecting the specified error level.

Verification

To validate the numerical implementation of CASM, a series of numerical tests were conducted. The model developed for this stage consists of a sample under axisymmetric conditions with regular geometry, as shown in Figure 2. The parameters used in these simulations are presented in Table 3, which were defined by Arroyo and Gens (2021) to represent the fine tailings of the Brumadinho Dam.

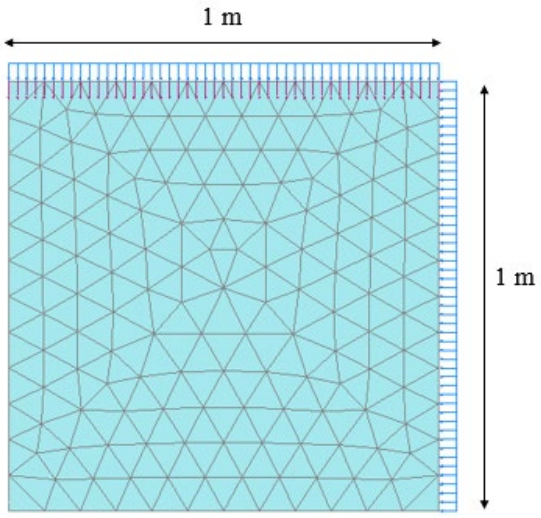

Figure 2: Boundary condition and problem setup used for CASM implementation validation

Table 3: CASM parameters applied in the validation simulations

Critical State Line - CSL		Plasticity		Plasticity and State	
Value					
Γ	1.2	n	5	ν	0.3
λ	0.053	r	35	κ	0.007
M_{tc}	1.4	m	2.3	OCR	1

For a comprehensive validation, numerical drained and undrained triaxial tests were simulated under compression and extension conditions. The results are presented in Figure 3, demonstrating the CASM ability to represent varying strength values depending on the simulated path, the hardening process under drained conditions, and the generation of pore pressures and brittle behavior under undrained conditions.

Isotropic compression and oedometer tests were also conducted. The results are presented in Figure 4a, showing an increase in stiffness with increasing confinement in both tests. It is noteworthy that in the oedometer test, the sample was initially in an isotropic condition and as it was compressed, it approached a constant K_0 value, demonstrating the model's capability to control the coefficient of lateral earth pressure, which is crucial for applications involving staged construction simulations.

An unloading followed by an undrained loading test was conducted, and the result is presented in Figure 4b alongside the results of a numerical test on a normally consolidated sample. It is observed that the model successfully captures the increase in OCR induced by unloading, leading to elastic behavior at the beginning of reloading. Such scenarios are crucial for dam de-characterization involving excavation processes and subsequent unloading.

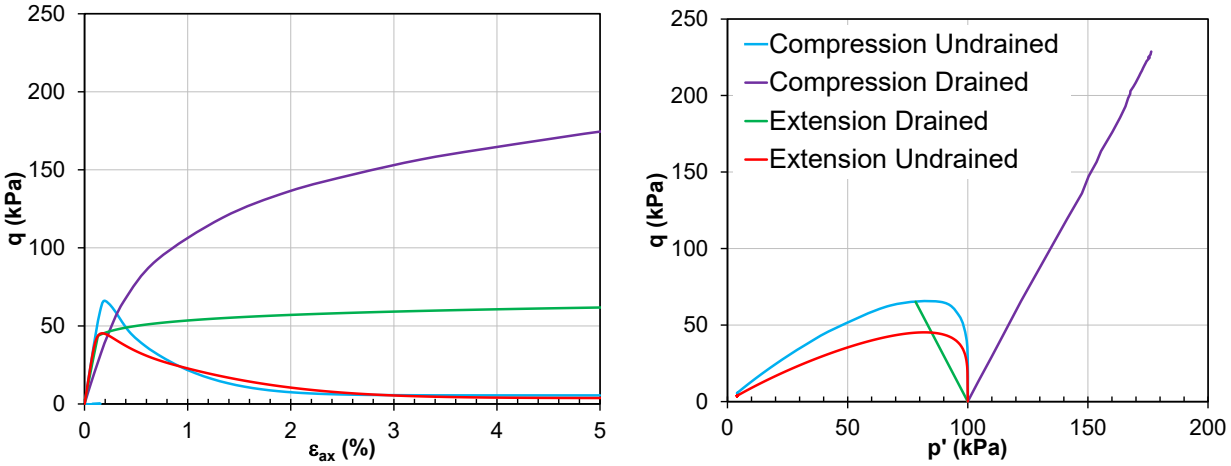

Figure 3: Validation of CASM implementation in conventional triaxial tests

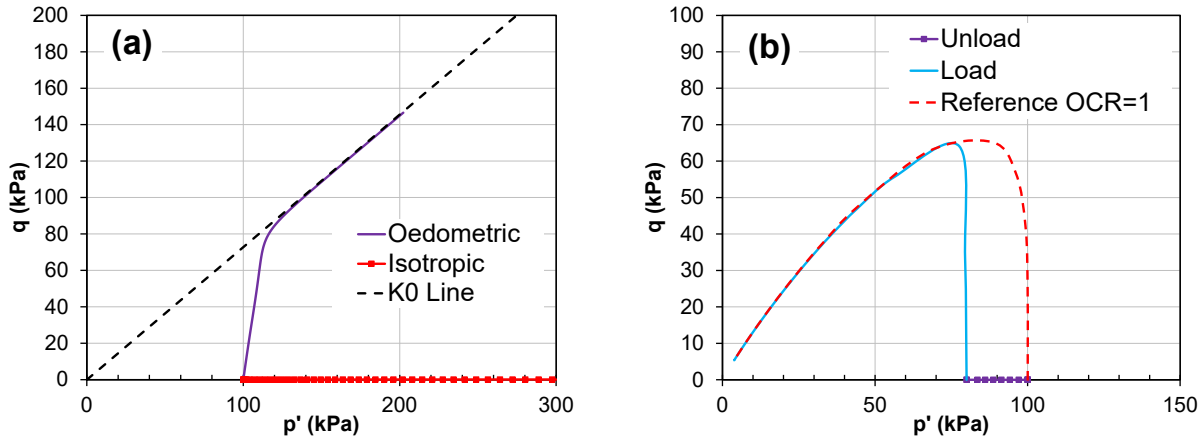

Figure 4: Validation of CASM implementation in: (a) isotropic compression and oedometer paths, and (b) unloading paths followed by undrained recompression

The numerical verification also included partially drained/undrained behavior through hydro-mechanical coupling approaches, where excess pore pressure generation is a function of strain rate, soil stiffness, and permeability. In this simulation, horizontal and vertical hydraulic conductivities of 1.00E-08 m/s and 2.00E-09 m/s, respectively, were applied, as presented by Arroyo and Gens (2021). The results obtained are shown in Figure 5, indicating that CASM can simulate partially drained behavior in triaxial compression tests by adjusting the strain rate, ranging from fully drained to undrained conditions.

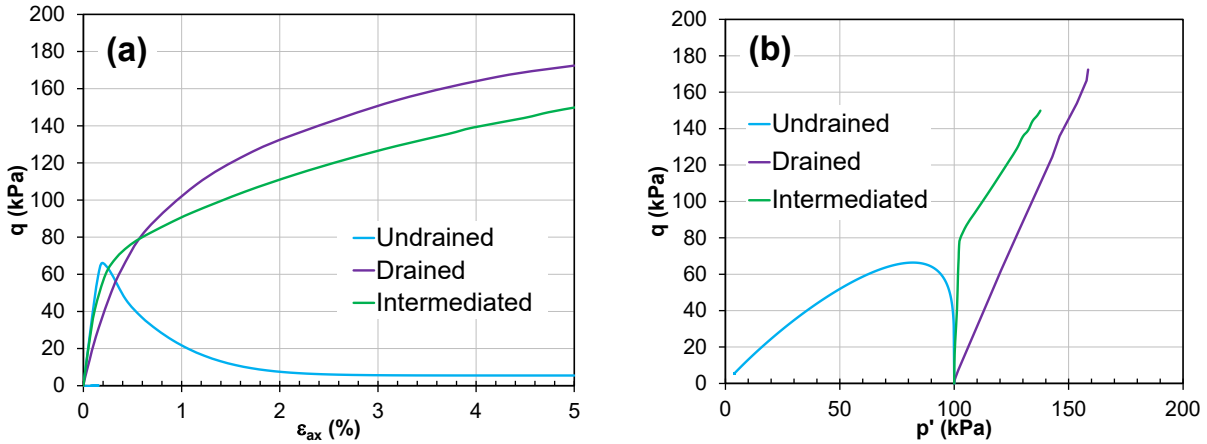

Figure 5: Validation of hydro-mechanically coupled triaxial tests using CASM

Parametric analysis

The main difference between CASM and Cam-Clay models lies in the addition of parameters n, r, and m. For instance, if $n = 2$, $r = 2$, and $m = 2$, CASM simulates behavior similar to that obtained with the Cam-Clay model, as shown in Figure 6 (Cam-Clay model parameters were extracted from Table 3). Therefore, sensitivity analyses focused on the effects of these parameters on the behavior represented in the CASM. These analyses were conducted starting from the parameters listed in Table 3.

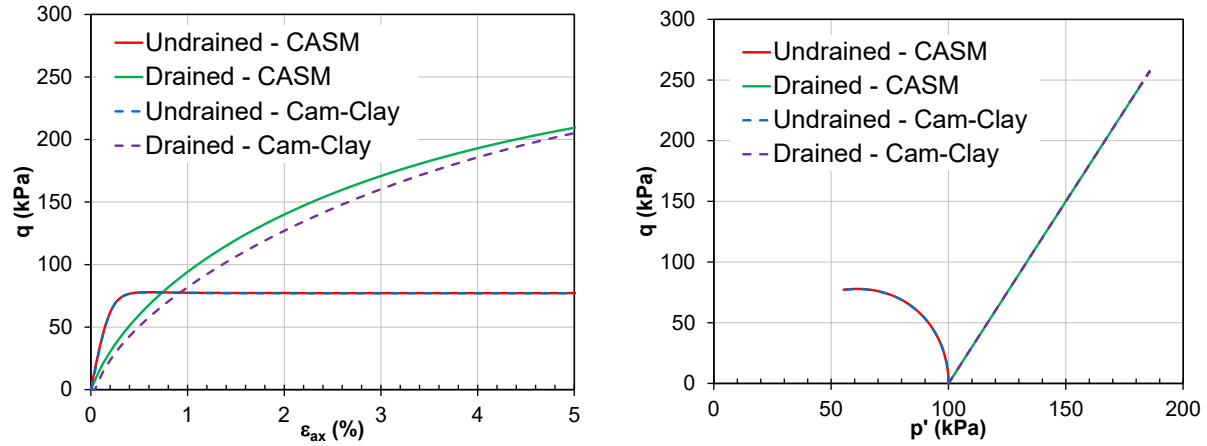

Figure 6: Comparison of triaxial compression test results using the Cam-Clay and CASM models with $r = 2$, $n = 2$, and $m = 2$

Mánica et al. (2021) presented analytically derived equations considering normally consolidated material, which establish relationships between the parameters n and r with peak undrained strengths (S_{up}) and residual strengths (S_{ur}), as shown in Equations 15 and 16. They also established a relationship between the parameters m and K_0, as given by Equation 17.

$$\exp\left[\left(\frac{1}{\sqrt[n]{n\ln r}}\right)^{n}\ln r\right]=\frac{M_{TC}}{2\frac{\sigma'_v}{S_{up}}\sqrt[n]{n\ln r}}\exp\left[\left(\frac{q_{ini}/p'_{ini}}{M_{TC}}\right)^{n}\ln r\right]\exp\left[\frac{\lambda-\kappa}{\kappa}\ln\left(\frac{M_{TC}}{2\frac{\sigma'_v}{S_{up}}\sqrt[n]{n\ln r}}\right)\right] \quad \text{Equation 15}$$

$$r=\left[\frac{M_{TC}}{6}\,(1+2K_0)\left(\frac{\sigma'_{vini}}{S_{ur}}\right)\right]^{\frac{\lambda-\kappa}{\kappa}} \quad \text{Equation 16}$$

$$\frac{3\,(\lambda-\kappa)}{2\,\lambda}=\left[\frac{M_{TC}}{m}-M_{TC}\right]\left[\left(\frac{1}{M_{TC}}\frac{3(1-K_0)}{1+2K_0}\right)-\left(\frac{1}{M_{TC}}\frac{3(1-K_0)}{1+2K_0}\right)^{1-m}\right] \quad \text{Equation 17}$$

where σ_v' is the initial vertical stress, and the subscript "ini" refers to the initial state of the material.

The parameter n modifies the shape of the yield surface, as shown in Figure 7a. It is evident that a higher n expands the elastic domain, thereby increasing the peak undrained strength, as demonstrated by Equation 17 and the parametric analyses depicted in Figure 8a and 8b.

The parameter r also influences the shape of the yield surface, as shown in Figure 8b, but its primary role is to separate the reference compression line from the critical state line. Thus, an increase in the parameter r indirectly promotes an increase in the state parameter, consequently reducing the residual undrained strength, as observed in both Equation 16 and Figure 8c and 8d.

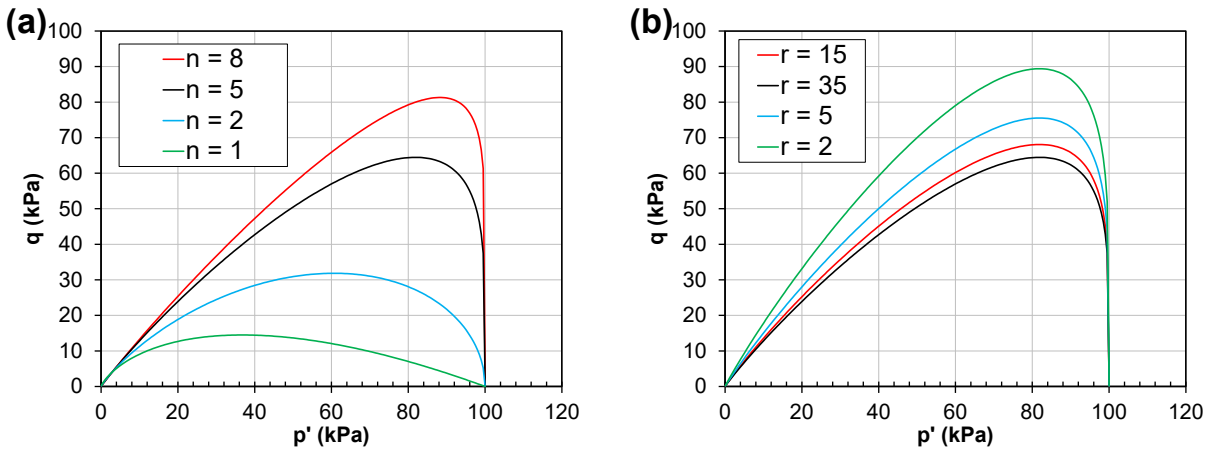

Figure 7: Changes in the yield surface shape due to variations of parameters: (a) n, and (b) r

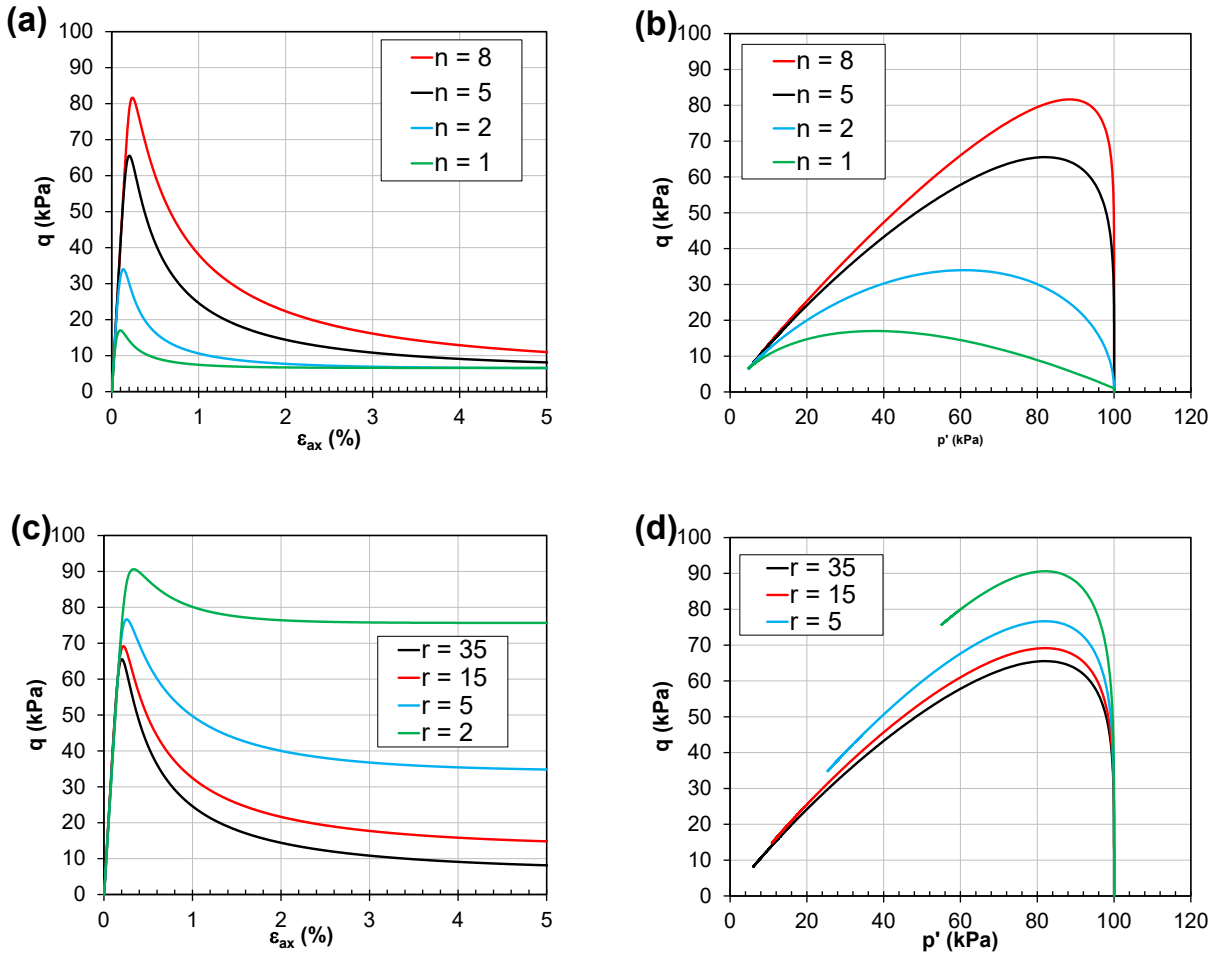

Figure 8: Sensitivity of CASM in undrained triaxial compression tests to variations of parameters: (a) and (b) n, (c) and (d) r

Given the non-associated flow rule adopted in the CASM model, the parameter m solely influences the plastic potential function. Thus, in shear loading conditions, such as in triaxial tests, this parameter affects only the deformations, while stress paths remain unchanged (Figures 9a and 9b). On the other hand, in oedometer compression conditions, m directly controls the value of the coefficient of at-rest lateral earth pressure, i.e., the slope of the K_0 line simulated in the model, as seen in Equation 17.

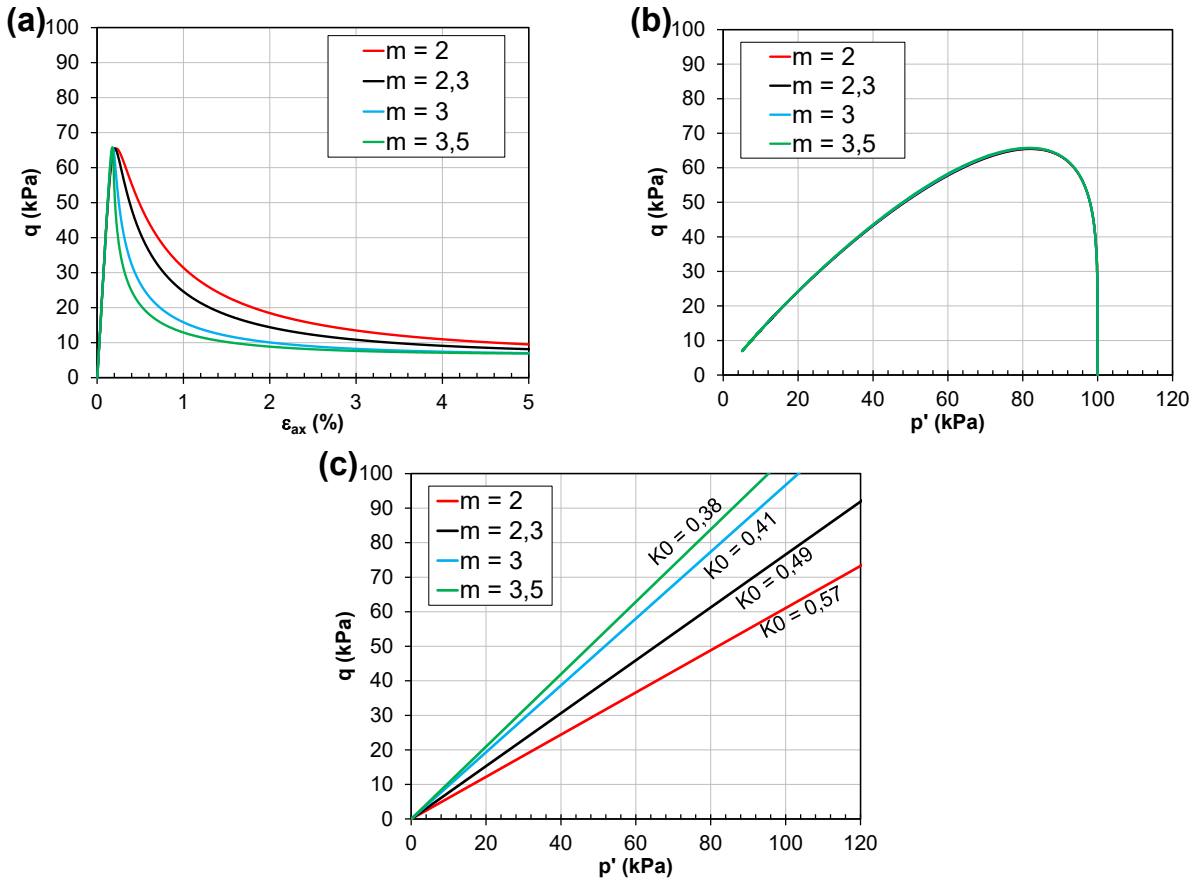

Figure 9: Sensitivity of CASM to variations of the parameter *m* in: (a) and (b) undrained triaxial compression tests, and (c) oedometer compression tests

Conclusion

Using numerical modeling to address the onset of flow liquefaction is becoming more prevalent. Consequently, there is a growing demand from the industry for constitutive models capable of simulating liquefaction phenomena. In this context, this paper focuses on the CASM model, which was developed to represent the behavior of sands and clays alike, making it a suitable candidate for characterizing tailings behavior.

The CASM formulation and its implementation using an explicit integration scheme as a user-defined model in Plaxis were presented. A validation procedure based on a series of numerical laboratory tests is also included. This procedure encompasses analyses in different stress paths and drainage conditions, demonstrating CASM's capability for transient simulations with hydro-mechanical coupling.

Additional sensitivity analyses were performed, demonstrating the relationship between CASM's parameters *n* and *r* with peak and residual undrained strength. Furthermore, CASM's ability to control the coefficient of at-rest lateral earth pressure during oedometer compression simulations was highlighted, which is crucial for applications in construction simulations.

The results of the numerical models presented in this work demonstrate the consistency and robustness of the formulation, serving as a methodology for validating future implementations. This marks the initial phase of a project aiming to utilize CASM for simulating real large-scale problems.

A Comparison of Different Methods Used to Estimate the State Parameter to Assess the Static Liquefaction of Tailings

Fahimeh Mahdavi Naftchali, WSP Canada Inc., Canada
Mathan V. Manmatharajan, WSP Canada Inc., Canada
Hamed Behzadipour, WSP Canada Inc., Canada
Michael Etezad, WSP Canada Inc., Canada

Abstract

Static liquefaction has been one of the leading causes for the failures of tailings dam constructed using the upstream dam raise method. Cone penetration tests (CPTs) are widely used to characterize the tailings and to assess the liquefaction potential of tailings. In this study, site investigations were carried out at a mine site in Canada, which included CPTs, drilling boreholes, and index and advanced laboratory tests. CPTs were pushed to determine the in-situ characteristics of the tailings, and disturbed samples were collected to perform laboratory testing on tailings. The advanced tests included a series of triaxial compression tests to determine the tailings critical state line (CSL).

The state parameter is widely used to assess the flow liquefaction of tailings in the mining industry. In the literature, various methods have been developed to assess the flow liquefaction of natural soils and tailings based on the state parameter. The state parameter can be determined using the CSL to identify the contractive and dilative behavior of tailings. This study examines five different methods developed for the CPT to assess the flow liquefaction of tailings. The methods include those developed to determine the state parameter using the CSL and NorSand constitutive model calibration. The state parameter was calculated for each CPT using five methods. A comparison of the results obtained among different methods is provided, and the accuracy of the state parameter is determined based on these methods is discussed.

Introduction

Static liquefaction has been one of the leading causes of the failures of tailings dam constructed using the upstream dam raise method. Tailings are generally hydraulically transferred to storage facilities and deposited in a loose saturated condition within storage dams. The loosely deposited tailings are normally prone to liquefaction, posing a significant dam breach risk, where the dam is constructed on loose saturated

or near saturated tailings. Liquefaction assessment is carried out using in-situ tests (e.g., CPT) and advanced laboratory tests (e.g., triaxial tests, simple shear tests). Understanding the tailings state and behavior through in-situ tests, advanced laboratory tests, and advanced constitutive models is crucial in the current practice of tailings characterization and liquefaction assessment.

Critical state soil mechanics captures a wide range of soil behavior in a logical and quantifiable way, providing a mechanistic framework to understand soil behavior. Static liquefaction potential can be predicted under the critical state soil mechanics framework. The state parameter (ψ) introduced by Been and Jefferies (1985) was used to determine the flow (static) liquefaction susceptibility of the soils and tailings using critical state soil mechanics. The state parameter is a density index used to understand the state of the soil and is defined as the difference between void ratios at the current state and the critical state at a given stress level, and it captures the effect of both void ratio and effective stress. Soils at the same state (ψ) express similar responses and tend to have the same liquefaction potential (Manmatharajan et al., 2023). Generally, soils with a state looser than critical state ($\psi > 0$, above the critical state line) are contractive in drained shearing, and are strain softening in the deviator stress path against mean effective stress during undrained shearing; whereas soils with a state denser than critical state ($\psi < 0$, below the critical state line) are dilative in drained shearing and are strain hardening in the deviator stress path against mean effective stress during undrained shearing. Jefferies and Been (2006) suggested that soils with a state parameter higher than -0.05 ($\psi > -0.05$) will contract and will undergo strength loss during undrained shearing.

Cone penetration tests (CPTs) are widely used to characterize tailings and to assess the liquefaction potential of tailings. The CPT is one of the most reliable in-situ tests for silt-sized particles, offering accurate and repeatable data. Various methods proposed in the literature suggest correlations between the state parameter and CPT resistance (e.g., Plewes et al., 1992; Ghafghazi and Shuttle, 2008; Shuttle and Jefferies, 2016; Robertson, 2022; Ayala et al., 2023). However, these methods require some level of in-situ approximation, different levels of information on soil properties, various interpretation procedures, and some accompanying triaxial tests to determine the critical state line. This paper evaluates the estimation of state parameter from CPT resistance using five independent methods and discusses the variation in the estimated state parameter among the methods.

Laboratory testing program

Material

Two types of gold mine tailings (Tailings 1 and Tailings 2) were collected from a mine site located in Canada. The tailings were predominantly comprised of non-plastic silt-sized particles. The tailings were

deposited along the perimeter dams of the tailings storage facility with a pond maintained in the interior of the basin. Thus, the tailings were generally characterized as "saturated, non-plastic" tailings and susceptible to liquefaction under both static and dynamic loading. Figure 1 depicts the Particle Size Distributions (PSD) of the two tailings. The PSDs of the two tailings are very close and hence the two tailings are expected to yield the same CSL. Accordingly, they are considered as one material in determination of the CSL.

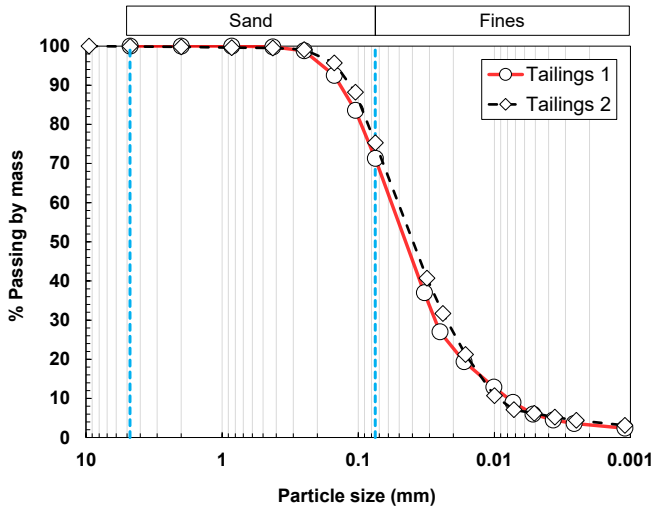

Figure 1: Particle size distribution of the Tailing 1 and Tailing 2

Triaxial test, critical state line (CSL) determination and NorSand calibration

A series of isotopically consolidated triaxial compression tests were carried out on the tailings and a CSL was determined in both e-log p' space and q-p' space. The triaxial tests were carried out following the Bishop and Henkel (1969), Jefferies and Been (2016) and ASTM D7181 and ASTM D4767 recommendations. The triaxial test specimens were reconstituted using the moist tamping method to various densities and then isotopically consolidated to a range of initial confining stresses between 75 kPa and 400 kPa. Once consolidated, the specimens were sheared at a constant rate (1% to 2% per hour) under either drained or undrained conditions until a minimum axial strain of about 20% was reached.

The tailings were initially dried in an oven at a temperature of about 60°C. Sub-samples of the oven-dried tailings were placed in plastic bags after splitting the original sample into approximately equal portions. Water was added to the sub-samples in the plastic bags to bring the moisture content to approximately 5%. The testing procedure is based on reconstituting samples, typically by placing six layers of moist soils in a reconstitution split mold. Initial densities in each layer are varied by changing the compaction effort to control how the samples are formed (trying to keep a uniform cylindrical shape) using a variation of the under-compaction method proposed by Ladd (1978) and the wet tamping technique (Ishihara, 1993). As soil properties at the critical state are assumed to be unaffected by initial fabric

(specimen reconstitution method) and density (Been et al., 1991), the choice of specimen preparation method (wet tamping) and void ratio are to obtain a set of data points to clearly define the CSL. The final moisture contents were determined by freezing the samples after concluding shearing. Figure 2 shows the CSLs in the void ratio versus *log (p')* space and in the q versus p' space. q and p'_c correspond to the deviator stress and mean effective stress at the critical state.

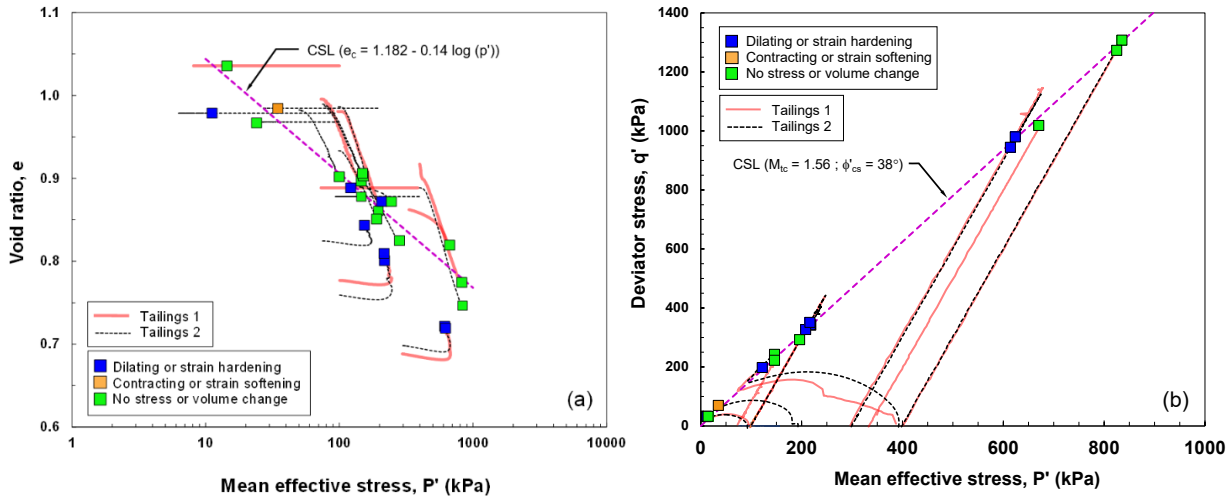

Figure 2: (a) Variation of void ratio against mean effective stress and CSL in e vs. *log (p')* (b) variation of deviator stress against mean effective stress and CSL in q vs. p'

In the void ratio *(e)* versus *log (p')* space, conventional semi-log linear CSL was considered as shown in Equation 1.

$$e_c = \Gamma - \lambda_{10} \log (p'_c) \qquad \text{(Equation 1)}$$

where e_c and p'_c correspond to the void ratio at the critical state, respectively.

Γ is the void ratio at the critical state at reference pressure of 1 kPa, and λ_{10} is the slope of the CSL in a semi-logarithm space (i.e., e vs. *log (p')*). In the q versus p' space, conventional linear CSL is defined by Equation 2.

$$q = M_{tc} p'_c \qquad \text{(Equation 2)}$$

M_{tc} is the stress ratio at critical state, where t_c refers to "triaxial compression". The stress ratio (friction angle) was estimated using dilatancy D, which is the ratio of volumetric strain to shear strain rate. The friction angle at the critical state can then be derived from the stress ratio defined by Equation 3.

$$M_{tc} = \frac{6 \sin \phi_c}{3 - \sin \phi_c} \qquad \text{(Equation 3)}$$

As shown in Figure 2, the end points denoted by green squares indicate that the tailings continue to deform under constant stresses and volumes (void ratios), which is a theoretical definition of critical state.

In practice, the tailings may not deform in such a manner due to limitations in the element tests. However, they will tend to reach the critical state. The end points denoted by orange squares indicate that the tailings are still contracting or strain softening. The end points denoted by blue squares indicate that the tailings are still dilating or strain hardening. Table 1 summarizes the CSL parameters, dilatancy, and plastic hardening parameters obtained from NorSand calibration using the triaxial test results. Figure 3 presents an example of curve fitting during NorSand calibration.

Table 1: Critical state parameters and calibrated NorSand parameters

Material	Γ	λ_{10}	M_{tc}	ϕ'_{cs} (°)	N	χ_{tc}	H	ν

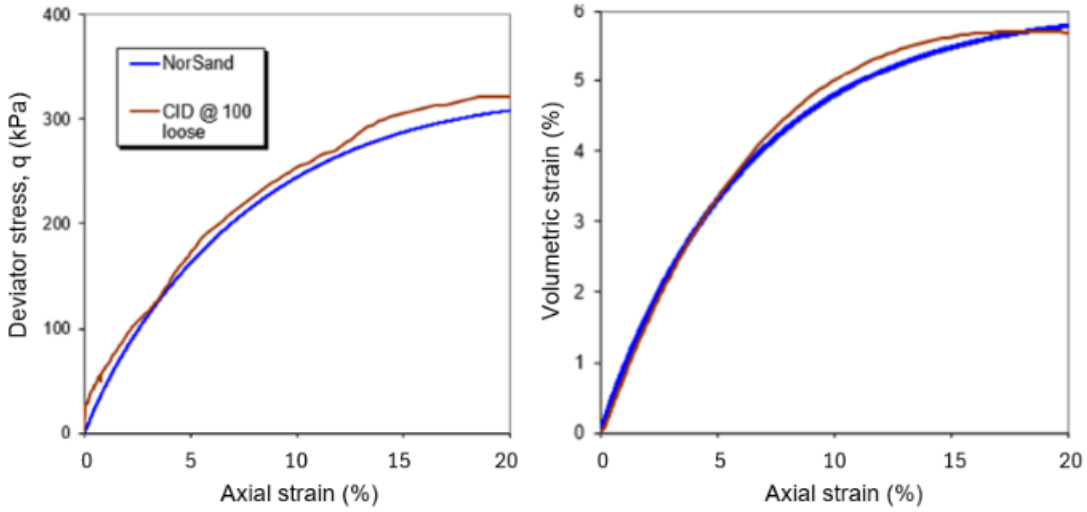

Figure 3: Example of NorSand calibration

Cone Penetration Testing (CPT) program

CPTs were advanced with a piezocone of 15 cm^2 at a standard penetration rate of 2 cm/s. The results of five CPTs are presented and discussed herein. The CPTs were performed in accordance with ASTM D5778. CPT based flow liquefaction assessment was carried out using the state parameter (Jefferies and Been, 1985). The state parameter was estimated using five independent methods proposed between the early 1990s and 2023. Some methods (empirical-based) estimate the state parameters using the CPT resistance; whereas some other methods (CSL-based) estimate the state parameter using the CPT resistance, and critical state parameters.

Methodology

Five independent methods (Plewes et al., 1992; Shuttle and Jefferies, 2016; Olaya and Bray, 2022; Robertson 2022; and Ayala et al., 2023) used in this study are discussed below. Table 2 summarizes the formulae used in the empirical-based and CSL-based methods. Details of each method can be found in the corresponding references. For the Plewes et al. (1992) method, in addition to the CSL-based method, the state parameter was determined using empirical correlation for the l_{10}. For the CSL-based methods, NorSand calibration and CPT widget were performed to get the calibrated dilatancy, elasticity, and plastic hardening parameters. Table 3 summarizes the computed coefficients. The undrained condition was considered for Shuttle and Jeffries (2016) and Ayala et al. (2023) methods.

Table 2: Methods used to estimate the state parameter (ψ)

Methods	Formula	Reference
Empirical based	$\psi = 0.56 - 0.33\ Log\ (Q_{\mathrm{tn,cs}})$	Robertson (2022)

Results and discussion

Figures 4 to 8 present the CPT measured data, interpreted using CPet-IT software (v. 3.9.2.19) developed by GEOLOGISMIKI, and the estimated state parameter for five CPTs (CPTs 21-03, -04, -05, -06, and -09), respectively. Each figure presents five plots to show the variation of (a) tip resistance, (b) sleeve friction, (c) dynamic pore pressure (u_2), (d) soil behavior type index (SBTn) (I_c), and (e) state parameter (ψ) of the corresponding CPT. The contractive-dilative boundary is marked by a red dashed line representing the state parameter of -0.05 (Jefferies and Been, 2006).

In Figure 4 (CPT21-03), for the depths between the phreatic surface and 10.8 m (sand mixtures and silt mixtures), tip resistance is generally less than 5 MPa and friction is less than 50 kPa. Dynamic pore pressure shows some positive pore water development from the hydrostatic pressure and the I_c plot indicates sand and silt mixtures ($2.05 < I_c < 2.95$). In general, all the methods shown in Figure 4(e) estimate the tailings to be contractive. Estimated state parameters vary between 0.15 and -0.05 ($\Delta\psi \sim 0.2$). Plewes et al.'s (1992) empirical method estimates the state parameters to be close to 0.15 while Olaya and Bray's (2022) method estimates the state parameters closer to -0.05. Results from the rest of the methods are in between. For depths between 10.8 m and 21.2 m (sand mixtures), dynamic pore pressure closely follows the hydrostatic pressure. The estimated state parameters vary between 0 and -0.15 ($\Delta\psi \sim 0.15$).

For these depths, Plewes et al.'s (1992) method estimates the state parameters to be close to -0.15, while Shuttle and Jefferies' (2016) method provides estimates close to 0. Results from the rest of the methods are in between. Shuttle and Jefferies' (2016), Robertson's (2022), and Ayala et al.'s (2023) methods predict some layers to be contractive, while Plewes et al.'s (1992) and Olaya and Bray's (2022) methods predict a complete dilative layer. At depths between 21.2 and 24 m (clay and silt mixtures), the estimated state parameters are more scattered, and the difference among the methods is more than 0.25.

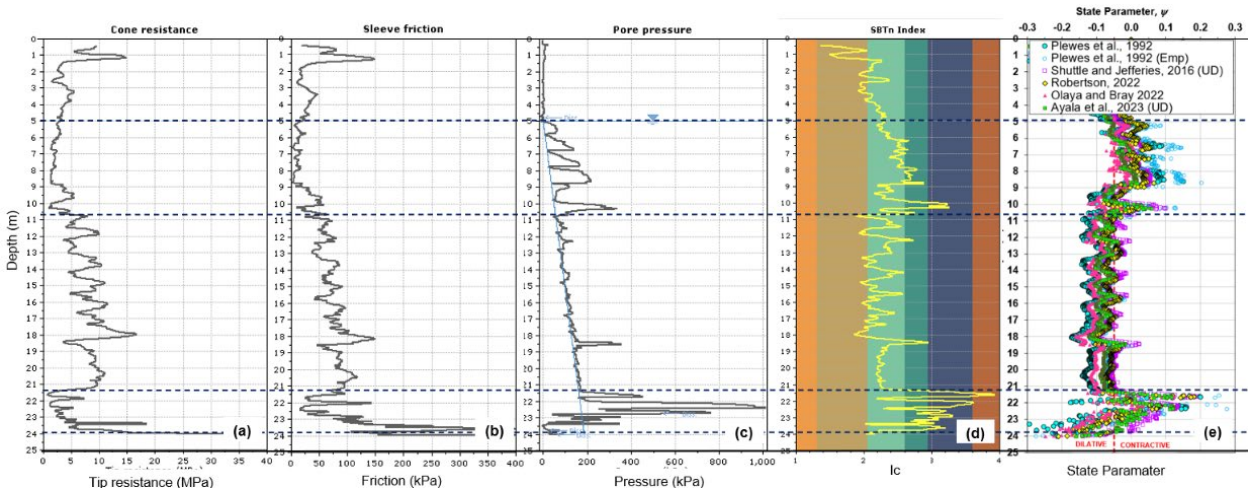

Figure 4: Results of CPT21-03 – (a) tip resistance, (b) sleeve friction, (c) dynamic pore pressure, (d) soil behavior type index, and (e) state parameter

In Figure 5 (CPT21-04), for depths between the phreatic surface and 10 m (sand mixture), all methods estimate the tailings as contractive. Estimated state parameters vary between 0.1 and 0. The estimates of Olaya and Bray's (2022) and Ayala et al.'s (2023) methods are close to 0, while the estimates of Plewes et al. (1992) empirical method are close to 0.1. Results from the rest of the methods are in between. For depths between 10 and 13.8 m (sand mixture), the estimated state parameters are very close (difference, $\Delta\psi \sim$ 0.05); However, Olaya and Bray (2022) estimate a complete dilative layer, while other methods estimate a thicker contractive layer. For depths between 13.8 and 16.3 m, the estimated state parameters are scattered.

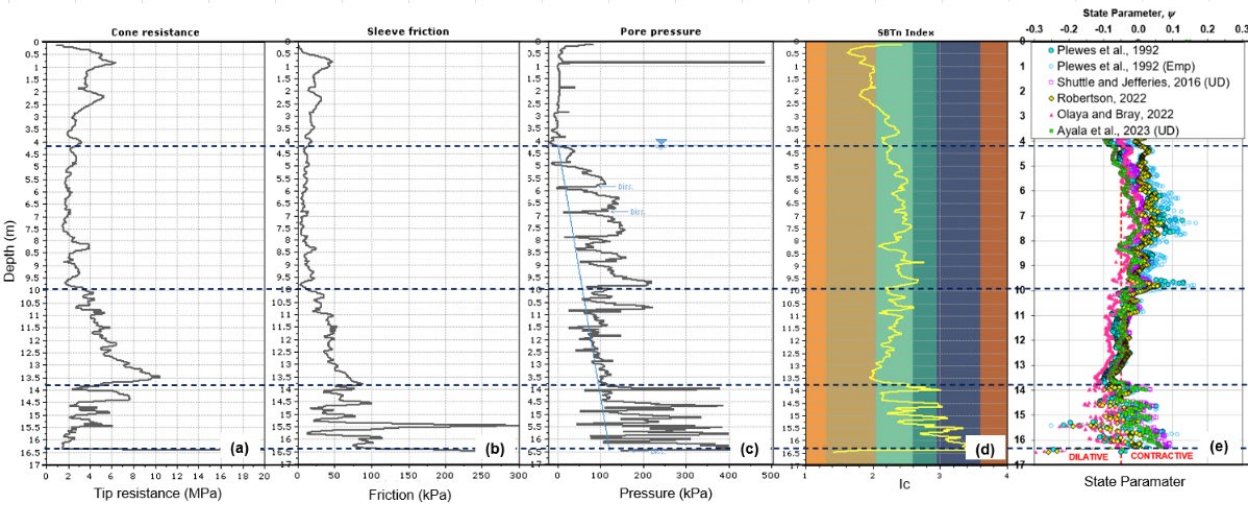

Figure 5: Results of CPT21-04 – (a) tip resistance, (b) sleeve friction, (c) dynamic pore pressure, (d) soil behavior type index, and (e) state parameter

In Figure 6 (CPT21-05), for the depths between phreatic surface and 7 m (sand mixture), three methods estimate the tailings to be contractive. The estimated state parameters vary between 0.05 and -0.06. The

methods of Olaya and Bray (2022) and Ayala et al. (2023) estimate a dilative response, while the rest of the methods estimate a contractive response. For depths between 7 and 11.5 m (sand mixture and silt mixture), the estimated state parameters vary between 0.15 and -0.05. The methods of Olaya and Bray (2022) and Ayala et al. (2023) estimate a state parameter of around 0, while the method of Plewes et al. (1992) yields estimates of around 0.15. For depths between 11.5 and 14 m (sand mixture and silt mixture), the estimated state parameters among the methods vary between 0.05 and -0.15, and they are on both sides of the contractive-dilative boundary, which is a concern for the design engineer.

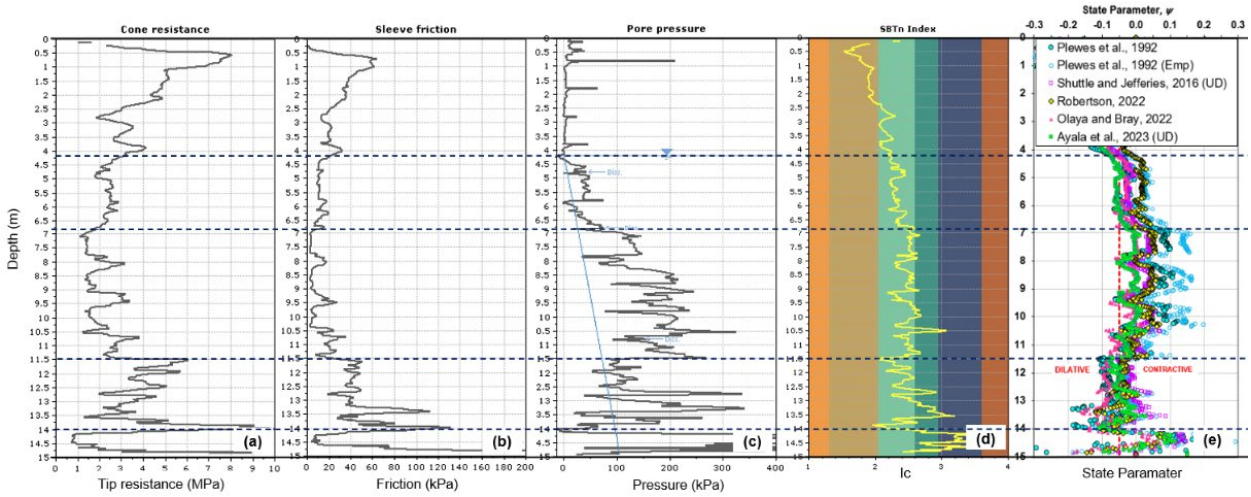

Figure 6: Results of CPT21-05 – (a) tip resistance, (b) sleeve friction, (c) dynamic pore pressure, (d) soil behavior type index, and (e) state parameter

In Figure 7 (CPT21-06), for depths between the phreatic surface and 3 m (sand mixture), a contradictive estimation of state parameter is observed. The estimated state parameters are between -0.1 and 0.05. The methods of Shuttle and Jefferies (2016) and Ayala et al. (2023) estimate a dilative response, while the other methods estimate a contractive response. For depths between 3 and 5 m (sand and silt mixtures), all methods estimate the tailings to be contractive and the estimated state parameters are between -0.03 and 0.13. For depths between 5 and 7.5 m (sand mixture), the estimated state parameters generally move from the contractive side to the dilative side with almost the same band width ($\Delta\psi \sim 0.13$). However, the Robertson (2022) method remains within the contractive side. For depths between 7.5 and 8.5 m (sand and sand mixture), all methods estimate a dilative response with about 0.1 difference in state parameter. Below 8.5 m depth (silt mixtures), the methods of Shuttle and Jefferies (2016) and Robertson (2022) estimate a contractive response, while other methods estimate a dilative response with about 0.1 difference in state parameter.

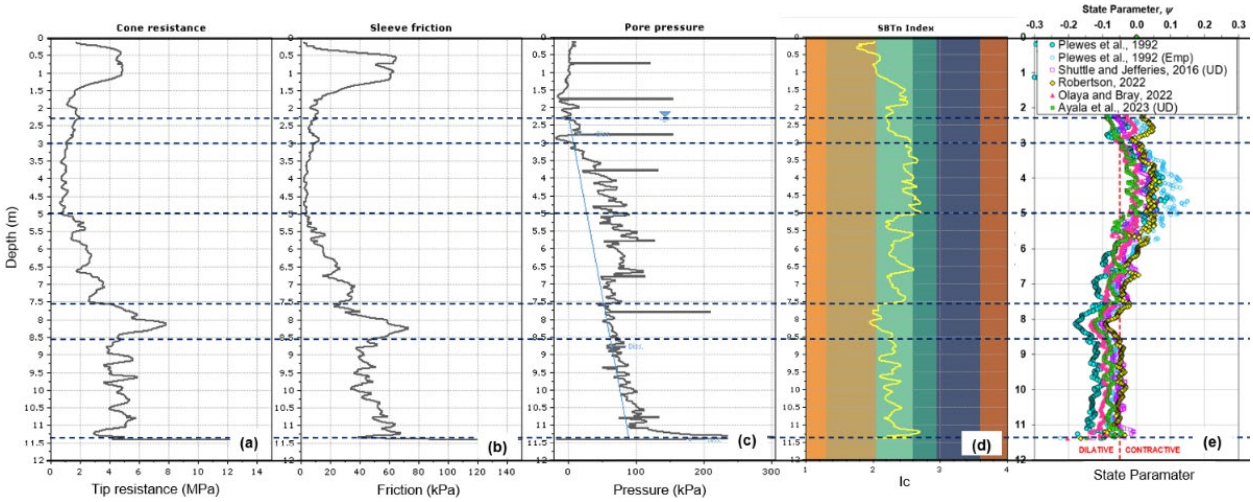

Figure 7: Results of CPT21-06 – (a) tip resistance, (b) sleeve friction, (c) dynamic pore pressure, (d) soil behavior type index, and (e) state parameter

In Figure 8 (CPT21-09), for depths between the phreatic surface (2.2 m) and 12 m (sand mixture and silt mixture), the estimated state parameters have about 0.15 difference among the methods. Plewes et al. (1992) and Olaya and Bray (2022) estimate a dilative response while Shuttle and Jefferies (2016) and Robertson (2022) estimate a contractive response. Below 12 m (silt mixtures and clay), all methods predicted a contractive response with a considerable difference in the state parameter.

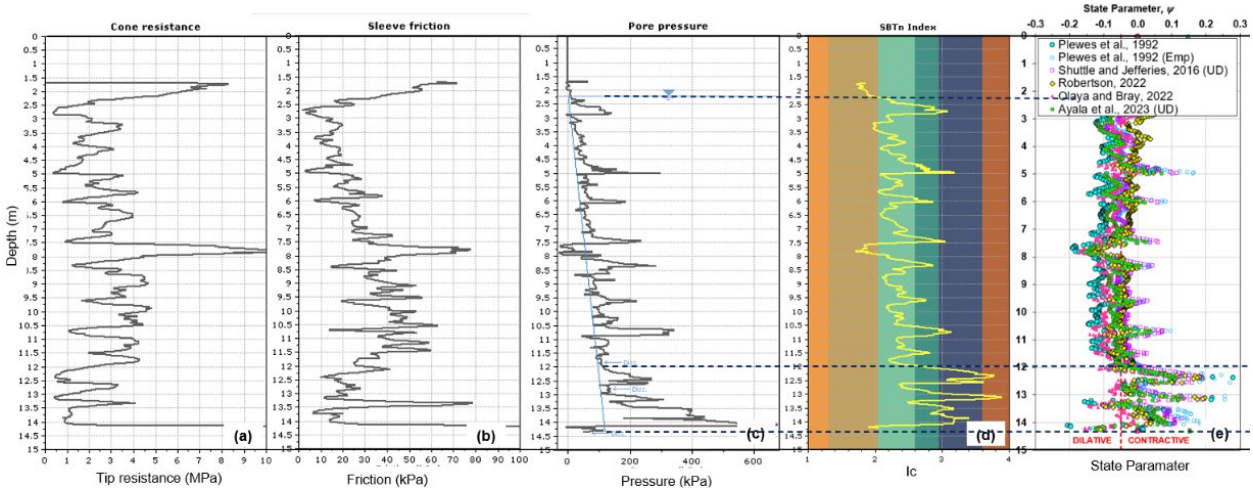

Figure 8: Results of CPT21-09 – (a) tip resistance, (b) sleeve friction, (c) dynamic pore pressure, (d) soil behavior type index, and (e) state parameter

As observed, there is a disagreement among the results obtained from the various methods in determining the state parameter of tailings. There are cases where one method indicates dilative tailings not susceptible to flow liquefaction, whereas the other method indicates contractive tailings susceptible to flow liquefaction.

Conclusion

In this study a CPT-based liquefaction susceptibility assessment of saturated, non-plastic tailings was evaluated using the state parameter approach. Five CPTs were advanced at a standard penetration rate of 2 cm/s and the CSL was determined using a series of isotopically consolidated triaxial compression tests on moist tamped tailings specimens. In total, five methods in the literature were used to determine the state parameter of tailings, and the state parameters were estimated using the CPT resistance and the combined CPT resistance, and critical state parameters. The following conclusions can be drawn from this assessment:

- Among the methods used, the difference in estimated state parameter ranges from 0.05 to 0.25.
- The greatest divergence was observed when the tailings contained finer particles (silt mixture, based on SBTn index).
- The methods exhibit less scatter for sand mixtures, based on the SBTn index.
- Based on the CPTs analyzed, no single method provides the highest (most conservative) or lowest state parameter estimates. There is not a universally accepted method available for estimating the state parameter. The state parameter, combined with the measured CPT parameters (e.g., excess pore water pressure response), should be considered in the flow liquefaction assessment.

In summary, the estimated state parameters show considerable disagreement depending on the methods used to analyze them. Without having a universally accepted and accurate method in the industry, this variation in results could lead to the adoption of a conservative approach by the design engineer to minimize the risk, which in turn may result in an overconservative design and increased cost for the project. On the other hand, if the design engineer selects a method that could result in an excessively conservative design, the risk of tailings dam instability will be increased.

Silty Sand Tailings Saturation and its Influence on Interpreted CPTu Soil Behavior Type

Abstract

Piezometric Cone Penetrometer (CPTu) testing is a widely used technique to investigate tailings deposits, aiding in the identification of contractive and potentially liquefiable material. Recent studies have identified a significant shift in the CPTu-interpreted behavior of silty sand tailings (from dilative to contractive / potentially liquefiable) depending on the saturation condition of the material (Russell and Reid, 2018). These findings may create uncertainty when characterizing unsaturated silty sand tailings that are expected to saturate in the future due to a rising groundwater table.

This paper investigates the effect of saturation and matric suction in the interpretation of CPTu tests conducted in an unsaturated iron ore silty sand tailings deposited at Germano Complex. The influence of suction hardening was estimated from Soil-Water Characteristic Curves determined for the tailings material. A framework was developed for characterizing the unsaturated silty sand tailings using Robertson's (2016) Modified Normalized Soil Behavior Type (Mod SBTn) that couples the saturation data with CPTu data interpretation. A protocol has been established for correcting the CPTu tip resistance to account for the influence of suction hardening as a function of overburden stress. The results show that suction hardening in the silty sand tailings at the site is significant at shallow depth (low overburden stresses) but negligible beyond ~10 m below ground surface. This provided confidence to the design team in the interpreted behavior of the tailings at depth considering closure conditions when the groundwater is expected to rise and saturate a portion of the tailings.

Introduction

Piezometric Cone Penetrometer (CPTu) testing is a common ground investigation technique that provides a continuous data profile through a deposit as a probe is advanced. CPTu testing is relatively quick and inexpensive when compared to other in-situ investigation techniques (i.e., boreholes) and has become a

preferred investigation method for tailings deposits and characterization. The continuous data profiles collected by CPTu probes include tip resistance (q_c), sleeve friction (f_s), and dynamic pore pressure (U2).

There are a range of CPTu-based semi-empirical relationships and interpretation techniques to characterize silty sand tailings. The methodology proposed by Robertson and Wride (1998) and Robertson (2010, 2016), which is based on the modified soil behavior type (Mod SBTn), has been widely used to assess the behavior and liquefaction potential of these materials. The Robertson (2016) methodology distinguishes three different soil behavior types (Sand-like, silt (Transitional) and Clay-like) but does not differentiate between saturated and unsaturated conditions.

Russell and Reid (2018) identified a significant shift in behavior (from Dilative to Contractive) of gold tailings when interpreting CPTu data when the deposit transitions from unsaturated to saturated conditions. This shift in behavior creates uncertainty associated with the characterization of unsaturated silty sand tailings using CPTu, i.e., where the data interpretation would change upon saturation (e.g., due to a rising groundwater table). Russell and Reid (2018) attributed the shift to suction hardening in the unsaturated regime, generating artificially high cone bearing resistance (q_c). The findings and the associated uncertainty led the project team to develop an in-situ and lab testing program to investigate these effects for Germano Complex's silty sand tailings.

Site characterization

The Germano Complex is a tailings storage facility located in Minas Gerais State, Brazil and comprises two primary tailings storage facilities: the Germano Pit (GP) and Germano Main Dam (GMD), both raised using the upstream construction method with hydraulically placed iron ore tailings. Constructed between 1976 and 2016, GP and GMD are approximately 55 m and 165 m high, respectively, with ~3H:1V downstream slopes. The combined tailings storage capacity of the Germano Complex is ~150 Mm^3 (Dawson et al., 2019).

Table 1: Silty sand tailings index test results

Percent Fines (<75µm)	D_{10} (mm)	Specific Gravity, G_s	Atterberg Limits	Typical Deposit (Bulk Unit Weight (kN/m^3)	Min.-Max. Void Ratio
ASTM D422	ASTM D422	ASTM D854	ASTM D4318	ASTM D7263	ASTMD4253 / ASTMD4254
45 – 55%	0.03 – 0.05	2.93	Non-Plastic	20	0.40 – 0.85

Table 1 summarizes representative index test results for the Germano silty sand tailings. According to the particle size distribution, this material classifies as a silty sand/sandy silt, denoted by the United Soil Classification System (USCS) as SM-ML, with ~50% fines (passing sieve No.200) and < 3% clay-size particles (2µm) (Dawson et al., 2019).

Methodology

The shear strength, τ, of an unsaturated soil can be described by the Bishop (1959) equation (Eq. 1) below:

$$\tau = c' + [(\sigma_n - u_a) + X(u_a - u_w)] \tan \phi' \quad \text{(Equation 1)}$$

where, c' is effective cohesion, (σ_n-u_a) is net normal stress, (u_a-u_w) is matric suction, also denoted by the symbol "s", and ϕ' is effective friction angle. X is the effective stress parameter and ranges from 0 to 1. For X = 1, reflecting fully saturated, and X = 0, effectively dry conditions, this equation reduces to the familiar Mohr-Coulomb failure criterion. X is related to the degree of saturation, S, and the saturation is related to the matric suction through the Soil-Water Characteristic Curve (SWCC). Figure 1 shows the SWCC for the Germano silty sand tailings, derived using a Tempe cell. The degree of saturation of the tailings was calculated based on an average porosity of 0.42 (e = 0.72). The residual volumetric water content, Θ_r, is estimated at 0.02.

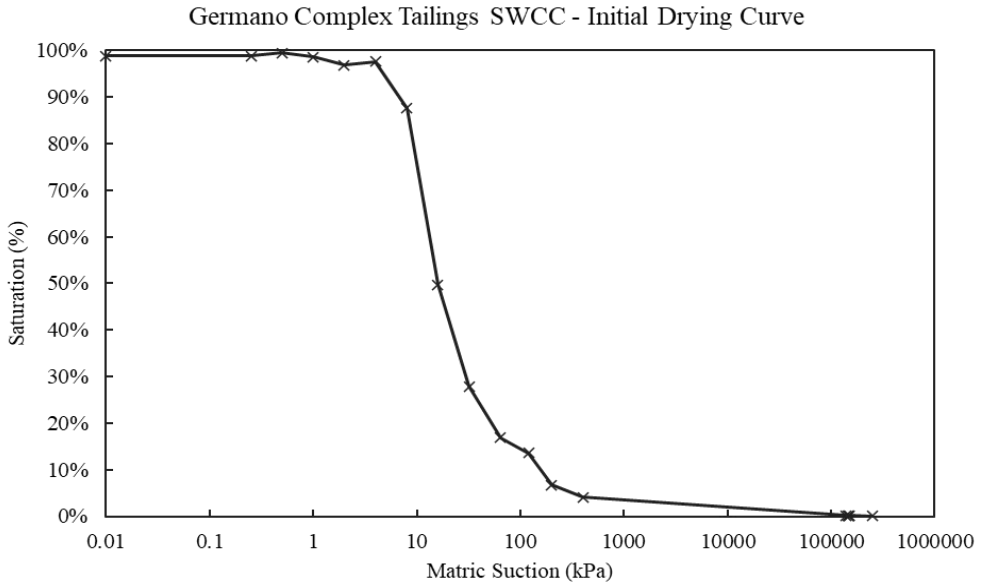

Figure 1: Germano Complex SWCC for silty sand tailings

According to Vanapalli (2009), for cohesionless materials, the additional shear strength due to matric suction is more or less parabolic when plotted against matric suction. It is null when s = 0 kPa (full saturation) and is very small beyond the residual moisture content. A peak unsaturated shear strength is reached at some intermediate matric suction. This cohesionless strength behavior model is considered representative of Germano Complex silty sand tailings behavior in the unsaturated regime.

This study is split into two phases based on the type of site investigation and data collection method, and the subsequent data analyses and interpretation, as follows:

Phase 1 – Comparison of Twinned CPTu. One (1) CPTu sounding advanced at the GMD facility, twinning a sounding advanced at the same location several years prior with a well-delineated phreatic surface. Nearby piezometers indicate a 5 to 10 m drop in the phreatic surface between the dates in which the soundings were advanced. A Fringe Zone was created where the tailings transitioned from saturated to unsaturated conditions, following cessation of tailings deposition in 2013. The data signatures of the two (2) CPTu soundings were compared for this Fringe Zone, and data profiles developed to characterize the behavior of the tailings in this zone using the Mod SBT_n framework, to identify variations between the saturated and unsaturated regime. This phase is discussed in detail in Burgin et al. (2021).

Phase 2 – Saturation Profiles. Boreholes advanced into tailings at both GP and GMD facilities, with samples collected at regular intervals for laboratory testing to characterize moisture content and specific gravity (G_s). The lab information was combined with existing oedometer test data from a previous tailings behavior characterization study of Germano silty sand tailings (Dawson et al., 2019) to estimate the degree of saturation with depth (saturation profiles), then further processed with the SWCC to develop profiles of X·s by assuming X equals the normalized volumetric water content, θ_n, calculated using the equation below (Eq. 2) (Vanapalli et al., 1996).

$$\theta_n = \frac{\theta_w - \theta_r}{\theta_{sat} - \theta_r} \quad \text{(Equation 2)}$$

where, θ_w is the volumetric water content, θ_r is the residual water content, and θ_{sat} is the saturated volumetric water content (equivalent to porosity).

Pournaghiazar et al. (2013) developed a relationship (Eq. 3) between unsaturated and saturated cone bearing, q_{cxs} and q_{c0} respectively, as a function of mean total stress, p_{no}, and X·s. A ratio approaching unity indicates similar cone bearing, while increasing values indicate the beneficial influence of suction hardening in the unsaturated regime.

$$\frac{q_{cxs}}{q_{co}} = \left(\frac{p_{n0} + X \cdot s}{p_{n0} - u_w}\right)^{0.85} \quad \text{(Equation 3)}$$

The ratio can be calculated for the full range of collected tailings samples to estimate the effect of suction hardening on CPTu data with depth.

Site data and analysis

Table 2 summarizes the site investigation activities carried out as part of the study. A total of two CPTu soundings and 14 boreholes were advanced at GP and GMD, and 229 samples were collected for moisture content and G_s testing. Samples were collected above the established groundwater table at each borehole location (i.e., sample collection was limited to the unsaturated zone). The CPTus were advanced in 2017

and 2021 at roughly the same coordinates on GMD. The unsaturated samples allowed for development of saturation profiles with depth at each borehole location.

Table 2: Summary of Site Investigation Activities

Phase	Structure	In-Situ Investigation Method	Location Count	Unsaturated Sample Count
Phase 1	GMD	CPTu	2	N/A
Phase 2	GMD	Borehole	3	46
	GP	Borehole	11	183
		Subtotal	16	229

Figure 2 compares the 2017 and 2021 CPTu datasets. The Fringe Zone, delineated by Burgin et al. (2021), is denoted as a yellow rectangle in this figure. The upper bound is about 25 m below ground surface and corresponds to the water level in 2017. The q_c profiles are generally similar although it appears the 2021 probe may be more sensitive with higher peaks and troughs. The f_s profiles appear to shift slightly right (increase) in 2021, again with higher peaks and troughs. U2 profiles bound the Fringe Zone, with (near) hydrostatic phreatic surfaces of 865 m El. and 860m El. in 2017 and 2021, respectively.

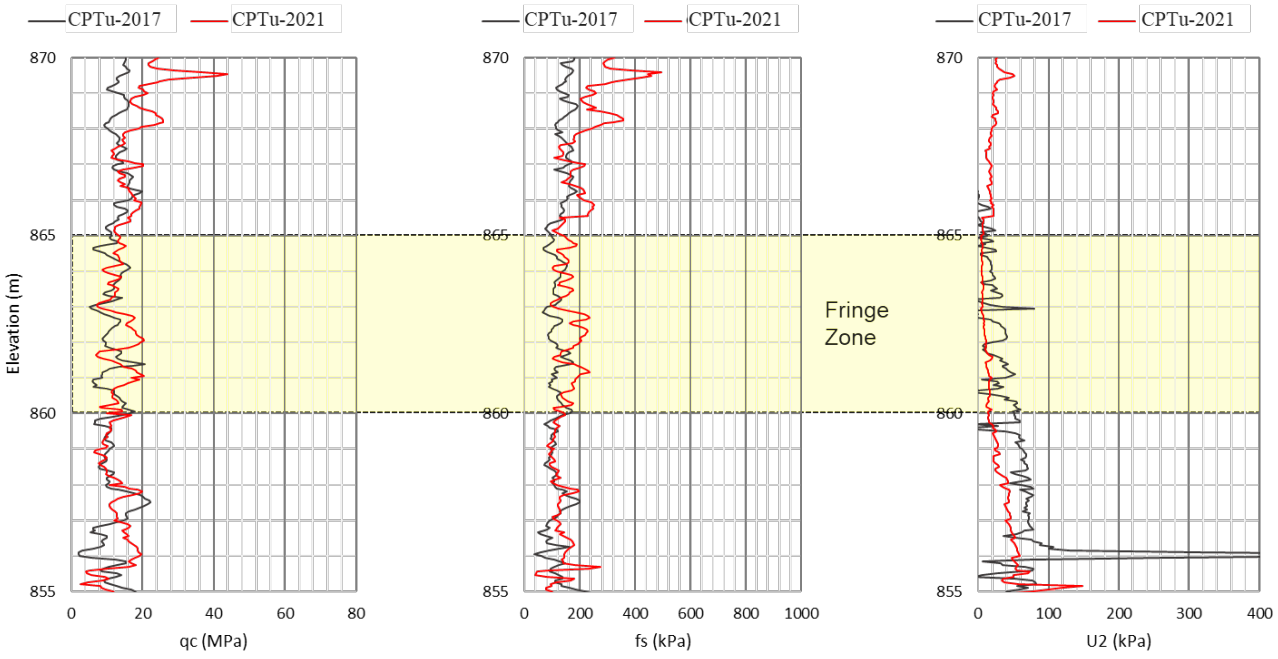

Figure 2: Phase 1 CPTu sounding data profiles, adapted from Burgin et al. (2021)

The moisture content and G_s data collected in Phase 2 can be combined with estimated void ratio to obtain the degree of saturation. The void ratio was estimated using a compression curve (p' versus e) generated by Stantec from oedometer tests carried out in a previous study (Dawson et al., 2019). Figure 3

(left) plots the resulting saturation profiles relative to depth above the estimated phreatic surface. GP and GMD samples are denoted as circles and exes, respectively. Saturation generally ranges from 10% – 50%. Almost all data points plot < 85% saturation, the minimum threshold value considered by industry upon which static liquefaction could still occur. The saturation data can be further combined with the SWCC to estimate $X^{\cdot}$s, by rearranging Equation 2 and assuming X equal to the normalized volumetric water content (Vanapalli et al., 1996). Figure 3 (right) shows that the calculated $X^{\cdot}$s data points collapse into a narrow-banded range from 7 – 9 kPa with some lower value exceptions.

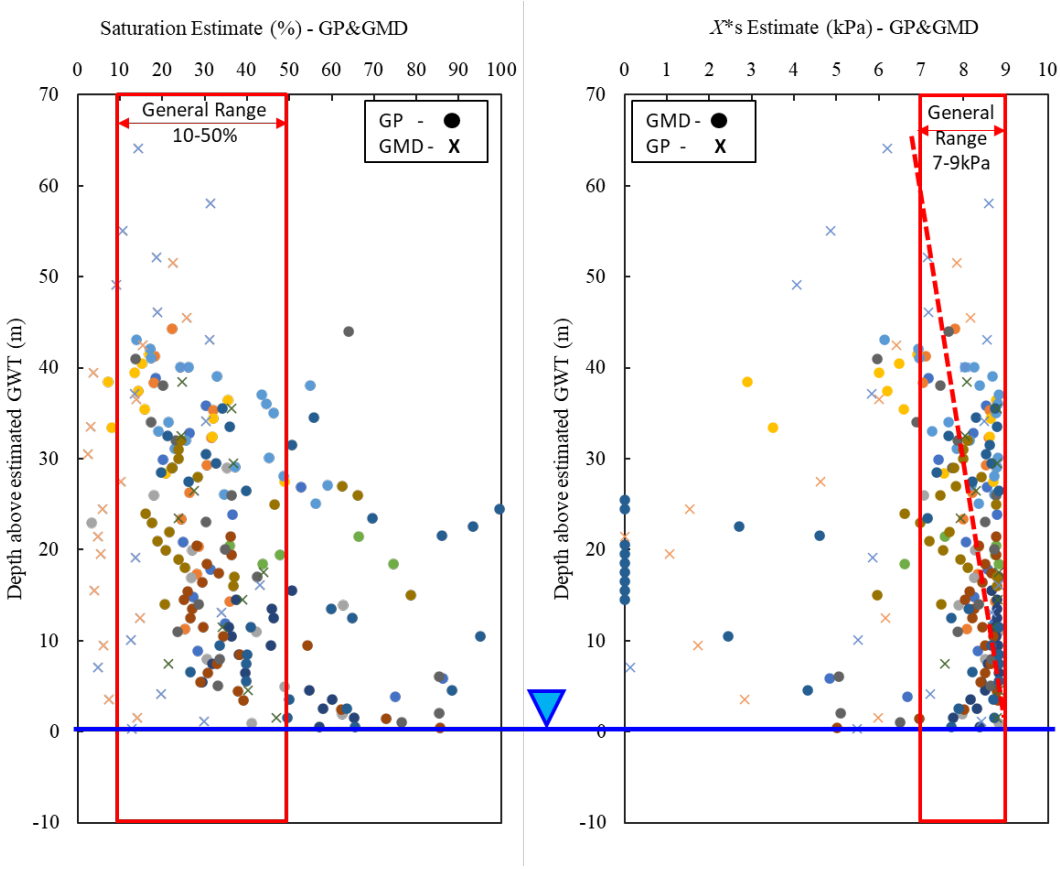

Figure 3: Phase 2 saturation data profiles (left) and $X^{\cdot}$s estimate (right)

The cone bearing ratio ($q_{c,unsat}/q_{c,sat}$), as defined by Pournaghiazar et al. (2013), can be plotted against depth below ground surface using Equation 3 by assuming a representative constant 40% saturation (for calculating normalized volumetric water content and corresponding matric suction, $X^{\cdot}$s) and K_0 of 0.5 (for calculating p_{no}). Figure 4 shows that the calculated cone bearing ratio is greater than 1.05 (dashed line) from 0 – 10 m depth and asymptotically reduces to one (1) as depth increases, demonstrating that the effect of suction hardening for the Germano silty sand tailings is negligible below this 10 m threshold.

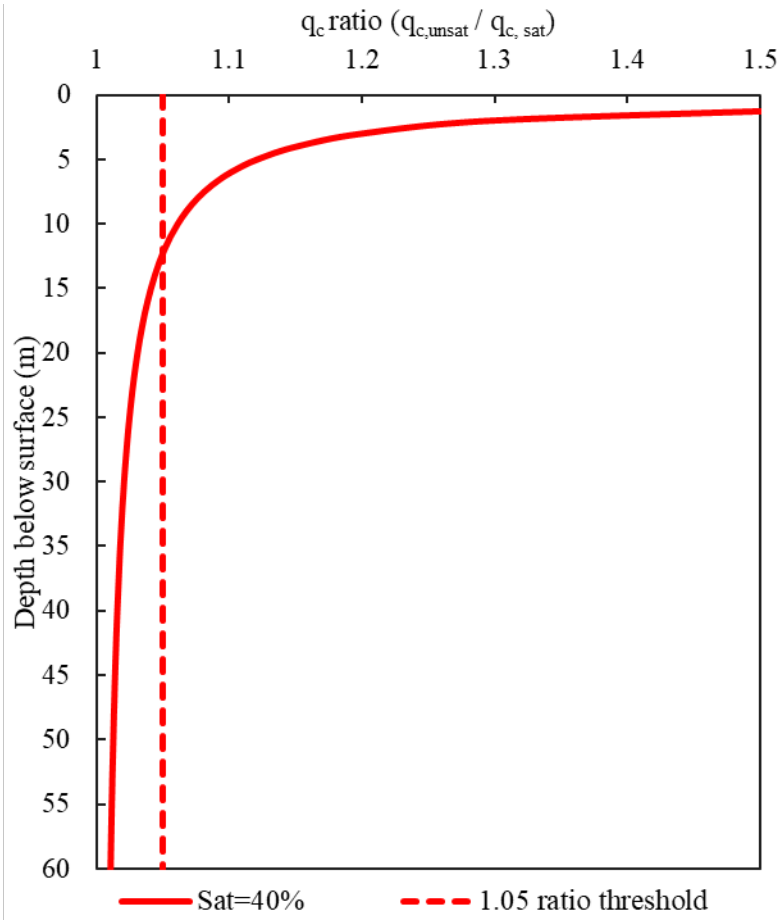

Figure 4: q_c ratio with depth, assuming constant 40% saturation and K_0 = 0.5

Saturation study discussion and findings

The data for Germano Complex indicate that the effect of matric suction on unsaturated strength of the silty sand tailings is limited to shallow overburden stresses where the relative magnitudes of overburden stress to suction hardening are comparable. This effect reduces rapidly below 5 m depth, and becomes negligible below 10 m. These findings are supported by Robertson et al. (2017), who arrived at similar observations for silty sand tailings material, that the effects of suction hardening are only significant at low overburden stresses (typically < 5 m below ground surface, where the magnitudes of effective stress and matric suction are comparable) but reduces significantly with depth as overburden stress increases.

The concept of apparent cohesion, c_{app}', is key to understanding why the twinned CPTu data profiles are similar within the Fringe Zone. Apparent cohesion describes the additional tensile stress due to surface tension of pore water in the unsaturated soil matrix and is included as a term in Bishop's equation for unsaturated shear strength. This cohesion increases the unsaturated shear strength but drops to zero as saturation approaches 100%. The apparent cohesion is calculated using the following equation:

$$c_{app}' = X \cdot (u_a - u_w) * \tan \phi' \quad \text{(Equation 4)}$$

where ϕ' is effective friction angle, which for Germano silty sand tailings is 32° (Dawson et al., 2019); $X \cdot (u_a - u_w)$ can be estimated directly from the saturation profiles with a conservative upper bound of 9 kPa from Figure 3 (right).

For an upper bound $X \cdot (u_a - u_w)$ of 9 kPa, the corresponding c_{app}' is 6 kPa, which is much less than the overburden stresses estimated within the Fringe Zone: 500 – 700 kPa (assuming a unit weight of 20 kN/m^3 for the Germano silty sand tailings). This supports the consistent q_c distributions shown in Figure 2 when comparing saturated (2017, black) vs. saturated (2021, red) data CPTu profiles. These distributions would diverge if the Fringe Zone were located at shallower depth, < 10 m, with unsaturated data inferring an artificially stronger (and possibly dilative) material due to suction hardening.

The q_c ratio profile presented in Figure 4 can be applied to correct the unsaturated CPTu data for the influence of suction hardening. The corrected q_c profile for the 2021 CPTu sounding is presented in Figure 5 in red against elevation, with the uncorrected data profile shown dashed in blue for comparison.

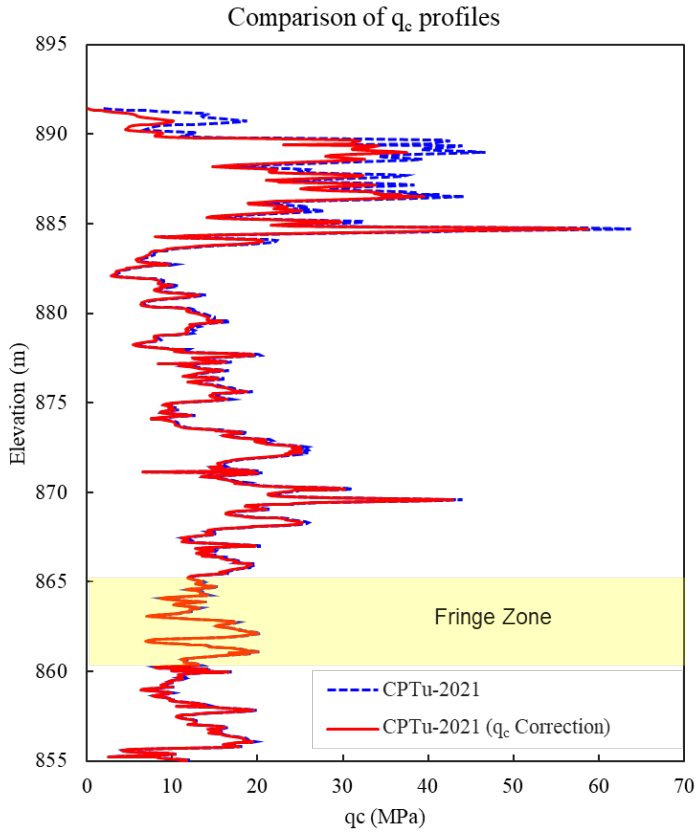

Figure 5: Comparison of raw (blue) vs. correct (red) unsaturated CPTu q_c profiles

Small differences in the two profiles appear to be present for the upper 5 m, where the corrected q_c profile is less than the uncorrected profile, and the two profiles are almost identical below elevation 886 m.

The Fringe Zone is highlighted in yellow for reference and supports the initial Phase 1 findings of similar $Q_{tn,cs}$ values when comparing 2017 to 2021 data (Burgin et al., 2021).

The relationship between decreasing q_c correction and increasing depth is further emphasized in Figure 6, that presents raw (blue) and corrected (red) 2021 CPTu data on the modified Robertson SBT_n plot for three (3) depth ranges. The leftmost plot presents data collected from 0-5 m below ground surface and highlights the pronounced effect of suction hardening at shallow depth, with a large shift in inferred soil behaviors towards increasing normalized cone resistance and reduced normalized friction when comparing the raw with corrected data. The middle plot captures data between 5–10 m depth with increasingly similar but still different soil behavior distributions, and the decreased influence of suction hardening as overburden stress increases. The rightmost plot captures data collected from 27–32 m below ground surface (Fringe Zone) with no discernable shift in raw and corrected data profiles.

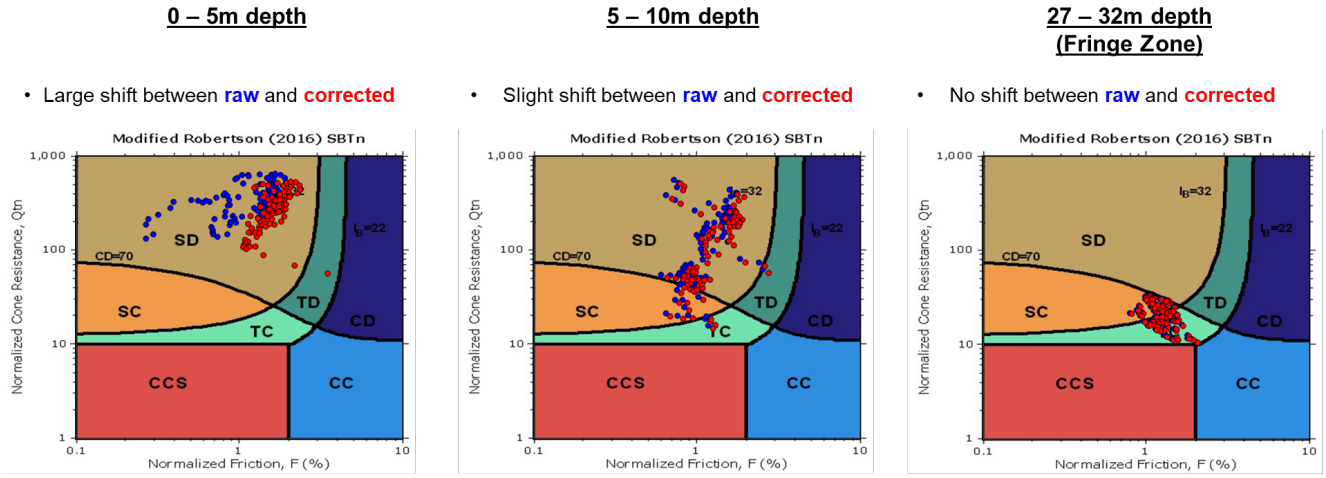

Figure 6: Comparison of raw and corrected 2021 CPTu data at different depth ranges

Conclusion

By combining the findings from both Phase 1 and Phase 2 of this unsaturated tailings study, Stantec has arrived at the following key conclusions for the unsaturated behavior of Germano silty sand tailings:

- Saturation levels at Germano Complex above the water table typically range from 10% to 50%. These values are much less than would be considered susceptible to liquefaction (i.e., S<85%).
- Impacts of suction hardening are significant up to 5 m depth and decrease to negligible beyond 10 m.
- Plots of normalized CPTu data with and without corrections for matric suction show that dilative unsaturated silty sand tailings will not shift to contractive behavior upon saturation beyond 10 m depth.

A New Implicit Kinetics Method to Estimate Shear Strength Mobilized in Liquefaction Flow Failures

Jiarui Chen, University of California, Davis, USA
Scott M. Olson, University of Illinois at Urbana-Champaign, USA
Soham Banerjee, University of Vermont, USA
Mandar M. Dewoolkar, University of Vermont, USA
Yves Dubief, University of Vermont, USA

Abstract

Quantifying the shear strength mobilized during a liquefaction-induced flow failure is of great importance for mitigating related geohazards. In particular, recent high-profile failures of mine tailings and fly ash impoundments, e.g., the Kingston fossil plant (2008), the Fundão tailings dam (2015), the Cadia tailings dam (2018), the Brumadinho tailings dam (2019), etc., have illustrated an urgent need to improve estimates of liquefied shear strength. This study tentatively proposes a new implicit kinetics method to better estimate the mobilized shearing resistance of liquefied soil from liquefaction flow failures. The method was developed using a database of 20 liquefaction-induced flow failures where a sliding-block type kinetics analysis has been performed. Using the results of the kinetics analysis in conjunction with limit equilibrium stability analyses and slope angles of the pre- and post-failure geometries, the authors defined a factor to adjust shearing resistances back-calculated from limit equilibrium stability analysis to account for the kinetics effects during failure, i.e., the momentum of the failed mass, when a sliding-block type analysis cannot be performed. The proposed method is expected to benefit the quantification of liquefied shear strength mobilized during flow failures.

Introduction

Liquefaction triggered by either static or cyclic loading can result in significant deformation of the soil mass involved in the failure. If the failure involves a tailings dam, e.g., Fundão tailings dam, millions of cubic meters of mine tailings can be released (Morgenstern et al., 2016). Those tailings may pollute downstream waters and cause billions of dollars of environmental damage (Ridley and Lewis, 2019). In addition, liquefaction flow failures may lead to loss of life and destruction of infrastructure, particularly if the failure occurs without warning, e.g., Córrego do Feijão Mine Dam I failure in 2019 (Robertson et al., 2019; de

Lima et al., 2020). Evaluation of these flow failures relies heavily on quantifying the mobilized shearing resistance of the liquefied soil mass, termed herein the liquefied shear strength, s_u(liq).

Among all methods for estimating s_u(liq), the case-history based method is valuable because the back-calculated value may reflect the actual strength of the liquefied soil mobilized during the failure if the adopted analysis protocol is scientifically sound. In addition, the back-calculated shearing resistance can be linked to field test indices such as the standard penetration test (SPT) blow count and cone penetration test (CPT) tip resistance, providing relatively easy-to-use correlations for engineering practice.

The kinetics of motion have long been recognized as an essential factor to properly back-calculate s_u(liq) from case histories. Davis et al. (1988) proposed a sliding-block method to account for flow kinetics and back-calculate s_u(liq) from the Lower San Fernando Dam failure. Seed and Harder (1990) also discussed the importance of kinetics (termed momentum/dynamic effects) in estimating s_u(liq) and incorporated the effects of kinetics in an unknown number of cases in their database. However, the procedure and the cases to which it was applied were not described explicitly. Later, Olson (2001) modified the Davis et al. (1988) kinetics method and applied it to 10 out of 33 flow liquefaction cases in an expanded case history database. Shortly thereafter, Wang (2003) developed the Zero Inertial Factor (ZIF) method based on the work of Olson (2001). Most recently, Weber (2015) modified a more refined kinetics method, originally developed by Tan et al. (2000), and re-named this method the Incremental Momentum Method (IMM), which details the evolution of the failed mass movement.

In this paper, the above-mentioned methods for incorporating the effects of kinetics are briefly reviewed, including their benefits and limitations. A tentative modified method then is proposed to overcome the limitations of other methods.

Expanded flow liquefaction failure case history database

First, an expanded database has been utilized in the current study to reduce uncertainties in estimating s_u(liq) from flow liquefaction failure cases. Previously, Olson (2001) and Muhammad (2012) consistently back-analyzed s_u(liq) and s_u(liq)/σ'_{vo}, where σ'_{vo} is the initial effective vertical stress, from a total of 60 case histories. Among those cases, the Kawagishi-Cho building and Fraser River delta case histories reported by Olson (2001) possess rather limited information compared to the other cases and were excluded from the current study. To the remaining 58 case histories, Chen (2022) added 13 new flow liquefaction failure case histories that were not available previously, and which occurred more recently than 2012, or had not been analyzed consistently. These were identified and back-analyzed. Thus, the current database has a total number of 71 case histories. Table 1 summarizes the newly identified flow liquefaction failure case histories. These cases are detailed in Chen (2022).

Table 1: Liquefaction flow failure cases compiled by Chen (2022) to add to database by Olson (2001) and Muhammad (2012)

	Name	Year	Location	Type	Apparent cause of failure

General procedures for the analysis

To maintain consistency, the back-analysis procedures described herein follow those used by Olson (2001) and Muhammad (2012). Specifically, the analysis in the current study focuses on flow liquefaction cases that possess sufficient details, including the geometry, phreatic surface, soil properties, etc., to perform a sliding-block type kinetics analysis, termed an explicit kinetics analysis by the authors. Those cases are classified as Class A by Chen (2022), which incorporate three components: pre-failure geometry limit equilibrium (LE) analysis, post-failure geometry LE analysis, and explicit kinetics analysis.

Limit equilibrium analysis

Limit equilibrium (LE) analysis has served as the primary method to back-analyze pre-failure and post-failure geometries of liquefaction flow failures since the work by Seed (1987). However, it is widely acknowledged that the mobilized shearing resistance back-calculated by LE analysis from the pre-failure geometry approximates the static (driving) shear stress at the time of failure, which almost always exceeds the actual liquefied shear strength. On the other hand, LE analysis of the post-failure geometry typically yields a mobilized shear strength smaller than the actual liquefied shear strength (Olson, 2001). Therefore, in nearly all field case histories, the actual s_u(liq) is bounded by the shear strengths mobilized from LE analysis of the pre- and post-failure geometries. Whether the actual liquefied shear strength is closer to the upper bound derived from the pre-failure geometry or the lower bound derived from the post-failure geometry is generally related to the travel distance of the failed mass (Weber, 2015). As such, all analyses started with the LE back-analysis of the pre- and post-failure geometries (if available).

Explicit kinetics analysis

As mentioned before, to better estimate s_u(liq), Davis et al. (1988) proposed a kinetics method based on a sliding block model (Figure 1). Assuming an initial value for s_u(liq), Newton's second law ($F = ma$) can be used to estimate the acceleration, velocity, and displacement of the sliding block along the assumed travel path of the sliding block center of gravity (CG). When the calculated CG displacement matches the observed CG displacement, the assumed liquefied shear strength becomes the "correct" value. While this method is easy to apply and enables rapid sensitivity analysis of s_u(liq) (Tan et al., 2000), the analogy of a sliding block with mass cannot provide detailed information regarding the shape of the failed mass during flow, unlike some other simplified methods (e.g., Jeyapalan, 1980).

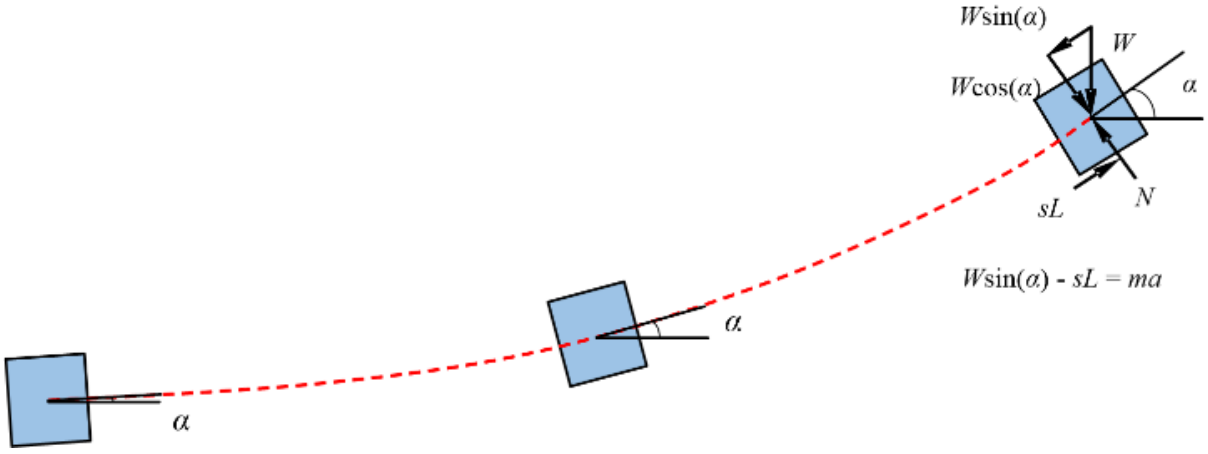

Figure 1: Sliding block analog to incorporate kinetics in the back-analysis of liquefaction flow failures

Olson (2001) proposed several modifications to the Davis et al. (1988) kinetics procedure, including (1) using a high-order polynomial rather than a hyperbola to represent the CG travel path for the failed mass; and (2) using automated functions to incorporate the evolving length of the sliding surface during flow, the shear strength of non-liquefied soil along the slip surface, and the potential effects of the failed mass sliding into a body of water (e.g., mixing and hydroplaning).

Tan et al. (2000) developed the dynamic runout analysis methodology (DRUM), applying Newton's second law to infer incremental geometries of the failed mass rather than representing the CG travel path using an equation. Building on the work of Tan et al. (2000), Weber (2015) proposed the Incremental Momentum Method (IMM). Similar to DRUM, IMM involves developing a series of estimated and feasible cross-sections that incrementally track the progression of displaced geometries from the inception of movements to the final, post-failure geometry. In essence, this details the movement of the sliding mass. As a result, both DRUM and IMM may be particularly useful in retrogressive failures. The only difference between DRUM and IMM is that IMM applies limit equilibrium analysis to each incremental movement stage. Despite the merits of DRUM and IMM, defining the incremental geometries requires significant engineering judgment, particularly if the initial and final slip surfaces are uncertain.

Expanding on the work of Davis et al. (1988) and Olson (2001), Wang (2003) developed the zero-inertial factor (ZIF) method. This method involves estimating the failed mass geometry such that the driving shear stress equals the shearing resistance (see Figure 2 [b] and [d]). At this condition, the total force, and therefore the acceleration, acting on the failed mass in the direction of movement is zero, i.e., zero inertial force. Using this concept, s_u(liq) can be back-analyzed directly from the zero-inertia geometry developed using the ZIF (i.e., the ratio between the failed mass displacement at zero acceleration and the total displacement for various points of reference in the geometry). As noted by Weber (2015), this procedure imposes another layer of uncertainty in addition to the uncertainties involved in the sliding-block analysis. Moreover, if the available case history data are not well suited for kinetics analysis, then the ZIF condition is hard to determine, and the uncertainty increases further.

Despite their differences, Chen (2022) found that s_u(liq) computed using these three methods reasonably agree, suggesting that the complexity of the kinetics analysis has a limited impact on the back-calculated values. Thus, the same kinetics method adopted by Olson (2001) and Muhammad (2012) was applied in this study. Among the four newly identified Class A cases (Table 2), only the Las Palmas tailings dam failure might be classified as a retrogressive failure, but the back-calculated s_u(liq) using the Olson (2001) method was nearly identical to that obtained by Moss et al. (2019) using IMM, suggesting that the Olson (2001) kinetics method was satisfactory for this case history.

Proposed implicit kinetics method

Previous work and its limitations

While the explicit kinetics method, i.e., the sliding-block method, can be applied to well-documented liquefaction flow failures, an implicit method is needed to consider the effects of kinetics for cases with insufficient information to perform an explicit kinetics analysis. Weber (2015) proposed the following implicit method:

$$s_u(liq) = \xi(Weber) \times \frac{1}{2}[s_u(pre-failure\ geometry) + s_u(post-failure\ geometry)] \quad \text{(Eq. 1)}$$

where $\xi(Weber)$ is an empirical parameter that is a function of the travel path ratio (CG travel path distance divided by the initial slope height).

Weber (2015) suggested that the relationship between $\xi(Weber)$ and the travel path ratio could be well-defined. However, the applicability of the method may be poor in cases such as the subaqueous flow slide that occurred along the West Guide Bund of the Jamuna Bridge. In these cases, the initial height of the slope cannot be properly defined because the initial slide involved only a portion of a larger slope. In addition, this method also may be difficult to use for cases where the post-failure geometry is unavailable (e.g., Mochi-Koshi tailings dams or Feijão Dam I). Therefore, an alternative method was proposed in this study to overcome these limitations.

New implicit kinetics method

Wride et al. (1999) reported that the ratio between runout distance and initial slope height, which is similar to the travel path ratio defined in Weber (2015), is strongly related to the ratio between post and pre-failure slope angles ($\theta_{post}/\theta_{pre}$). Two extreme cases analyzed by Olson (2001) are shown in Figure 2. The Calaveras Dam flow failure exhibited the largest $\theta_{post}/\theta_{pre}$ among all 10 cases analyzed by Olson (2001) using an explicit kinetics analysis, while the Uetsu railway embankment exhibited the smallest $\theta_{post}/\theta_{pre}$. As illustrated in Figure 2 (b) and (d), the area of region I should be similar to the area of region II according to the impulse-momentum theorem:

$$\sum F_i \Delta t = m v_t - m v_o \quad \text{(Equation 2)}$$

$$F_i = W_i \sin \alpha_i - s_i L_i \quad \text{(Equation 3)}$$

where F_i is the net force acting on the sliding block in the direction of movement at any time t; v_o is the initial velocity of the sliding block; v_t is the final velocity of the sliding block; Δt is the time step in the numerical integration when calculating velocity and displacement for the sliding block; W_i is the weight of the failed mass at any time t; α_i is the angle between the horizontal and the tangent to the CG travel path at any time t; s_i is the mobilized resistance at the sliding block base at any time t; L_i is the slip surface length of the failed mass at any time t.

In all flow failures, the initial and final velocity, v_o and v_t, respectively, should be zero. The driving shear stresses in Figure 2 (b) and (d) reflect the evolution of the average slope angle of the failed mass, θ, where the pre-failure and post-failure average slope angles are defined in Figure 1. The initial slope angle tangent to the CG travel path (α in Figure 1 at $t = 0$) is similar to θ_{pre}. With the movement of the failed mass, α approaches θ_{post} (Figure 1). When $\theta_{post}/\theta_{pre}$ is small, the relative runout (i.e., runout distance divided by the slope height) usually is significant (Wride et al., 1999). Figure 2 (c) illustrates that, in this case, a majority of the travel time involved movement on a relatively gentle slope. Therefore, in Figure 2 (d), for Area I to match Area II, the mobilized shearing resistance must be closer to the driving shear stress near

the end of the movement, which is the back-calculated shear strength from the post-failure geometry. On the other hand, when $\theta_{post}/\theta_{pre}$ is large, the relative runout is usually small, and the shape of the driving shear stress time history (Figure 1 b) will be more-or-less centrosymmetric. In this case, for Area I to match Area II, the mobilized shearing resistance must be close to the average of the initial and final driving shear stresses, which is the average of the back-calculated shear strengths from the pre- and post-failure geometries.

Based on these observations, $\theta_{post}/\theta_{pre}$ was calculated for all well-documented cases that were analyzed by the sliding-block kinetics method in Olson (2001) and Muhammad (2012). In total, 20 cases were identified to be useful in this analysis. Key parameters are summarized in Table 2.

Table 2: Summary of geometry and kinetics analysis parameters for the Class A cases in the compiled expanded database

ID	Name	ϑ_{pre} (°)	ϑ_{post} (°)	$\vartheta_{post}/\vartheta_{pre}$	ξ

C-7	Las Palmas tailings dam	29	5.2	0.178	0.417
C-8	Abukuma River levee, at the Edano site	25.9	10.3	0.399	1.134
C-10	Naruse River levee at the Shimo-Nakanome site	25.2	9.6	0.381	0.803

Identification (ID) nomenclature is C = Chen (2022); M = Muhammad (2012); and O = Olson (2001). Note that the numbering for M and O case histories is based on the original author's numbering to maintain consistency.

A tentative correlation between ξ and $\theta_{post}/\theta_{pre}$ follows and is illustrated in Figure 3, where:

$$\xi = 2.21\frac{\theta_{post}}{\theta_{pre}} \qquad \text{(Equation 4)}$$

and ξ was defined using shear strength ratios as follows to account for the changes in the representative initial effective vertical stress during the pre- and post-failure conditions.

$$\xi = 2\frac{s_u}{\sigma'_{vo}}\,(kinetics)/[\frac{s_u}{\sigma'_{vo}}\,(pre-failure\ geometry) + \frac{s_u}{\sigma'_{vo}}\,(post-failure\ geometry)] \qquad \text{(Eq. 5)}$$

The only outlier in Figure 3 is the Sullivan tailings dam, which was not used to regress Eq. (4). The large deviation of this case history from the trend may be attributed to its failure mechanism, which involved significant vertical displacement of a non-liquefied fill into liquefied tailings (Jefferies and Been 2006). This type of movement is not consistent with the assumed movement in the sliding-block kinetics method (Figure 1). For cases where the post-failure geometry was not available, θ_{post} was taken as the average slope angle of the ground surface where the failed mass traveled.

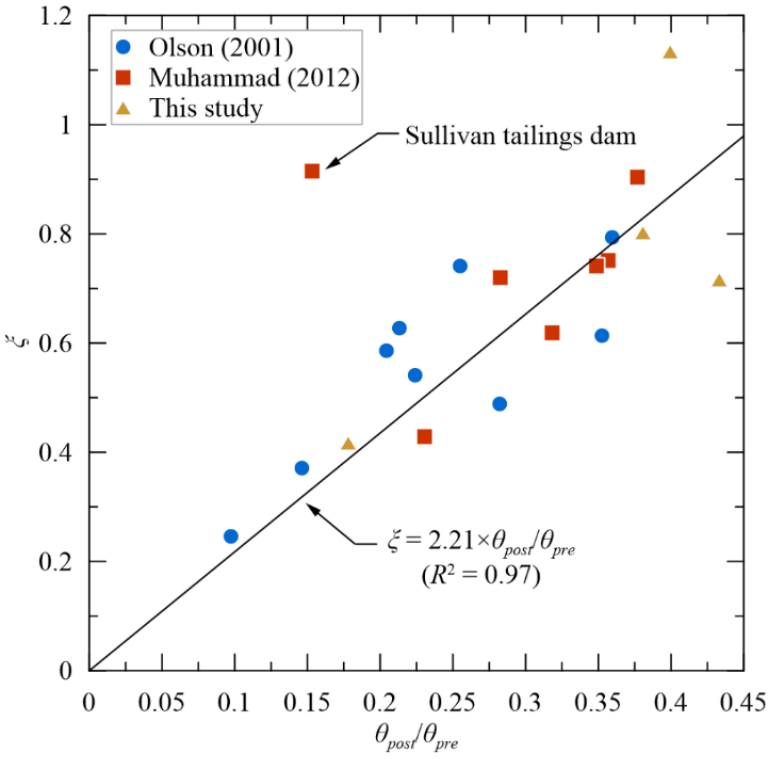

Figure 3: Tentative relationship between ξ and $\vartheta_{post}/\vartheta_{pre}$ using Class A cases in the updated field flow liquefaction failure database

Using this implicit kinetics approximation, the s_u(liq)/σ'_{vo} and s_u(liq) could be estimated tentatively for cases where an explicit kinetics analysis was not possible. It is suggested by the authors to limit ξ to a value of unity to be conservative. Thus, calculations can be done as follows.

$$\frac{s_u}{\sigma'_v}(kinetics) = \min\left(2.21\frac{\theta_{post}}{\theta_{pre}}, 1\right) \times 0.5 \times \left[\frac{s_u}{\sigma'_{vo}}(pre - failure\ geometry) + \frac{s_u}{\sigma'_{vo}}(post - failure\ geometry)\right] \quad \text{(Equation 6)}$$

$$s_u(kinetics) = \frac{s_u}{\sigma'_v}(kinetics) \times \sigma'_{vo}(post - failure\ geometry) \quad \text{(Equation 7)}$$

Additionally, the actual s_u(liq) should also be within the range of the values determined using the pre- and post-failure geometries.

Conclusion

This study focuses on an improved estimation of mobilized shearing resistance of the failed mass in a liquefaction flow failure, considering the kinetics of motion. Despite the existence of well-documented cases, over 70% of the current flow liquefaction failure case histories are not well-suited for a slide-block type kinetics analysis (termed explicit kinetics analysis by the authors), which can provide improved accuracy in estimating mobilized s_u(liq). A physics-based method is needed to enable use of case histories with less information to aid in geotechnical design of structures involving sloping ground (i.e., static shear stresses) and mitigate liquefaction-related geohazards.

As such, stemming from Newton's second law and the impulse-momentum theorem, the authors developed an implicit kinetics method, which utilizes slope geometry parameters and common LE analysis results. The tentatively proposed method should apply to a wider range of situations than other implicit kinetics methods because of the greater ease of obtaining the input parameters. Further research is ongoing to utilize the proposed implicit kinetics method to generate improved liquefied shear strength predictive models.

Seismic Deformation Analyses of Germano Main Dam Part I: Calibration of PM4Sand Model for Sand Tailings Using Field and Advanced Laboratory Test Data

Mauricio Pinheiro, Stantec Consulting Services Inc., USA
Evan Hsiao, Stantec Consulting Services Inc., USA

Abstract

The PM4Sand model is widely used to simulate the behavior of sand deposits subjected to seismic loading. The calibration of input parameters is essential for the model to successfully predict the pore water pressure development and resultant seismic deformations during a seismic event. This study presents a detailed calibration of the PM4Sand model for a potentially liquefiable iron ore tailings from Germano Main Dam, an upstream tailings dam located in the state of Minas Gerais in Brazil.

The calibration used site investigation data and advanced laboratory test results. Due to the thickness of the liquefiable material in the site (up to 60 m), the calibration was done in several steps to obtain stress-dependent relationships for the three primary input parameters of the constitutive model: relative density (Dr), shear modulus coefficient (G_o) and contraction rate parameter (h_{po}). First, the cone penetration testing (CPT) data together with empirical equations were used to determine the relationship between the effective vertical stress, the normalized corrected cone tip resistance (q_{c1N}), and the relative density (D_r). Second, Seismic CPT (SCPT) data were used to obtain the correlation between the confining pressure, the shear wave velocity, and the shear modulus coefficient (G_o). Third, based on the fines content of tailings, an empirical equation was introduced to correct the normalized cone tip resistance as well as the cyclic resistance ratio (CRR) curves that were computed using the CPT-based liquefaction triggering correlation by Idriss and Boulanger (2014).

A single element model was developed to simulate the stress controlled cyclic direct simple shear test to obtain hpo by matching the target cyclic stress ratio (CSR) of the simulation to the desired CRR curve. The process was repeated at multiple q_{c1N} levels to obtain a site-specific correlation between h_{po} and q_{c1N}. Finally, the laboratory cyclic direct simple shear tests were simulated to compare the simulation results against the laboratory data and to obtain the shear modulus reduction curve and the damping curve. The

simulated results were also compared with the empirical modulus reduction and damping curves from the literature for similar materials. Based on these comparisons, the last two steps were repeated until a relatively good match (based on engineering judgement) was achieved.

Introduction

The Germano Main Dam (GMD) is an upstream tailings storage facility located 25 km from Mariana, Minas Gerais, Brazil, which stores approximately 130 Mm^3 of sand tailings derived from iron ore mining and processing operations. The GMD structure spans the Córrego do Germano valley, located south of the Fundão basin and upstream of the New Santarém Dam, as shown in Figure 1.

Figure 1: Situational map of the Germano complex and battery limits for The Germano Main Dam

The facility was designed in the early 1970s, raised from a starter dam (known as Bechtel Dam), followed by multiple upstream raises, and by the decharacterization works after the Fundão failure. The impoundment received sand tailings up until the mid-1990s. Between 1997 and 2006, fine tailings and sand tailings were co-deposited throughout most of the reservoir.

Several studies, including the limit equilibrium analyses, a seismic assessment using QUAD4M, and a preliminary seismic deformation analyses using SLAMMER, have been done previously for the site in its as-is condition. However, it is necessary to introduce a detailed seismic assessment for the decharacterized

GMD in its long-term condition. The 2D finite difference method software FLAC8.0 (Itasca, 2017) was used to analyze the deformation behavior under seismic loading at the selected critical cross-section. As part of the study, this paper presents a detailed description of the calibration of advanced constitutive model PM4Sand, which is used to simulate the behavior of liquefiable material during seismic loading.

Site conditions and basic material properties

The GMD structure is composed of a variety of materials, ranging from engineered fills (Bechtel Dam, starter berm, decharacterization buttress, and rockfill drains) to contractive/dilative tailings. The structure is underlain by residual soils, which are dilative soil units that originated from weathered bedrock, and are underlain by saprolites, phyllites, and schists (simply referred to as "bedrock"). Figure 2 shows the most critical cross-section selected for the seismic deformation analysis.

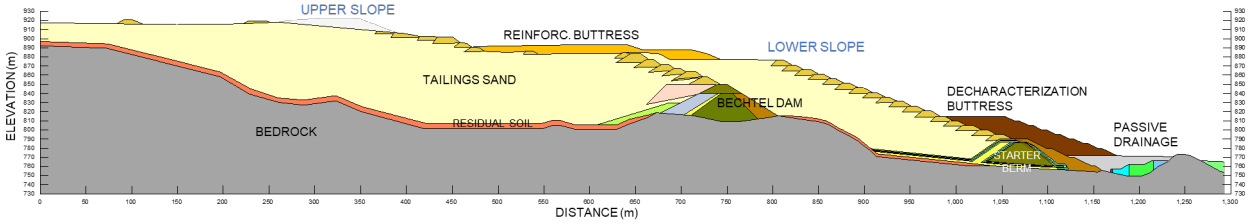

Figure 2: Selected cross-section of GMD for seismic deformation analysis

Table 1 summarizes the basic engineering properties of the materials encountered in the deformation analysis that were determined in previous analyses, together with the selected constitutive models.

Table 1: Conventional properties of materials encountered in the deformation analysis

Material	Unit weight (kN/m³)	Cohesion (kN)	Friction angle	Poisson's ratio	Density (kg/m³)	Gmax[1] (Pa)	Constitutive model
Bedrock	24	–	35°	0.30	2,250	440 MPa (Vs = 470 m/s)	Elastic
Residual Soil	18	5	25°	0.36	1,779	50% bedrock (Vs=235 m/s)	Elastic
Jet Grout	20	77	–	0.30	2,141	350 MPa	Mohr-Coulomb
Fill/Core	19	–	30°	0.35	2,040	$14000(\sigma'_m)^{0.50}$	UBCHYST
Drain/Rockfill/Buttress	20	–	35°	0.37	2,140	$43763(\sigma'_m)^{0.50}$	UBCHYST
Tailings – Compacted	20	–	33°	0.30	2,040	$23000(\sigma'_m)^{0.35}$	UBCHYST
Tailings	20	–	32°	0.30	1,781	$5400(\sigma'_m)^{0.52}$	PM4Sand/ UBCHYST

Note: [1] The equations for Gmax for different material are based on Vs data from SCPT tests performed at site

The PM4Sand is used to simulate the behavior of saturated tailings, which has the potential to liquefy during seismic events. The following section will discuss the calibration of the PM4Sand model with available field and laboratory test results. A brief description of the UBCHYST model calibration is also presented.

Calibration of the PM4Sand model

The PM4SAND model is a state-of-the-art constitutive model developed specifically for earthquake engineering purposes at the University of California at Davis (Boulanger and Ziotopoulou, 2017). Version 3.1, released on October 2017, was used in this study. The PM4SAND model follows the basic framework of the stress-ratio controlled, critical state compatible, bounding surface plasticity model for "sand-like" soil materials. The three primary parameters of PM4SAND are the apparent relative density (D_r), shear modulus coefficient (G_o), and contraction rate (h_{po}).

In this study, PM4SAND was used to represent the behavior of the saturated sand tailings material, which is potentially liquefiable during an earthquake. The field and laboratory test results were used to calibrate the model, as described in the following sections. Only the primary parameters were calibrated. The secondary parameters were set as the default values, as proposed by Boulanger and Ziotopoulou (2017).

Determination of the relative density (D_r)

As suggested by Boulanger and Ziotopoulou (2017), the relative density can be determined from the CPT results, based on the following equation:

$$D_R = 0.465\left(\frac{q_{c1N}}{C_{dq}}\right)^{0.264} - 1.063$$

where $C_{dq} = 0.9$; q_{c1N} is the normalized corrected CPT tip resistance.

The 30th percentile line from 24 CPTs from multiple site investigation campaigns was chosen to represent the penetration resistance profile (q_{c1N}) as a function of the effective vertical stress (σ_v'), as follows:

$$q_{c1N} = -\frac{1}{0.065}\ln\frac{\sigma_v'}{4283.7}$$

The selection of the 30th percentile is based on engineering judgement and on the results of the previous liquefaction analysis using QUAD4M software.

Determination of the shear modulus coefficient (G_o)

The shear modulus coefficient (G_o) can be determined from the following equations:

$$G = G_o p_A \left(\frac{p}{p_A}\right)^{1/2}$$

$$G = \rho \cdot (V_s)^2$$

where p_A is the atmosphere pressure, p is the confining stress, ρ is the density and V_s is the shear wave velocity.

The 30th percentile line from seven SCPT tests data was chosen to represent the shear wave velocity profile of the material, This was calculated as a function of the confining stress:

$$V_s = \frac{1}{0.0189} \ln \frac{\sigma'_m}{3.465}$$

Calibrating the contraction rate parameter (h_{po})

The contraction rate parameter (h_{po}) is used to obtain the target cyclic resistance ratio, which is commonly estimated based on CPT or SPT penetration resistances and liquefaction correlations. In this study, hpo was calibrated by matching the Cyclic Resistance Ratio values (CRR) from the FLAC single-element cyclic direct simple shear (CyDSS) simulations with the CRRM = 7.5 values from CPT-based liquefaction triggering correlation by Boulanger and Idriss (2014). For this purpose, a CPT-based estimate of CRR for an M = 7.5 earthquake and an effective overburden stress of 1 atm was assumed to be approximately equal to the CRR, corresponding to 15 uniform loading cycles causing a peak shear strain of 3% in CyDSS simulations.

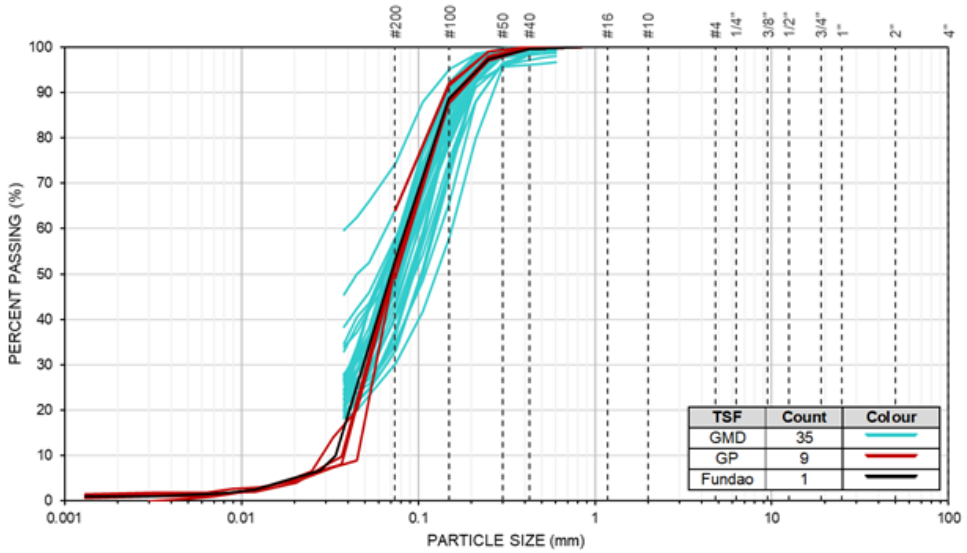

Figure 3: Particle size distribution of the tailings

Figure 3 shows the particle size distribution of the sand tailings material at Germano Mine. The tailings have a fines content of about 50%. This value was selected to correct the clean sand equivalent normalized cone tip resistance (q_{c1Ncs}) as follows:

$$\Delta q_{c1N} = \left(11.9 + \frac{q_{c1N}}{14.6}\right) \exp\left(1.63 - \frac{9.7}{FC+2} - \left(\frac{15.7}{FC+2}\right)^2\right)$$

The corrected q_{c1Ncs} was then used to calculate the CPT-based triggering correlation as follows:

$$CRR_{M=7.5,\sigma'_V=1\text{atm}} = \exp\left(\frac{q_{c1Ncs}}{113} + \left(\frac{q_{c1Ncs}}{1000}\right)^2 - \left(\frac{q_{c1Ncs}}{140}\right)^3 + \left(\frac{q_{c1Ncs}}{137}\right)^4 - 2.80\right)$$

The final selected correlation is presented in Figure 4.

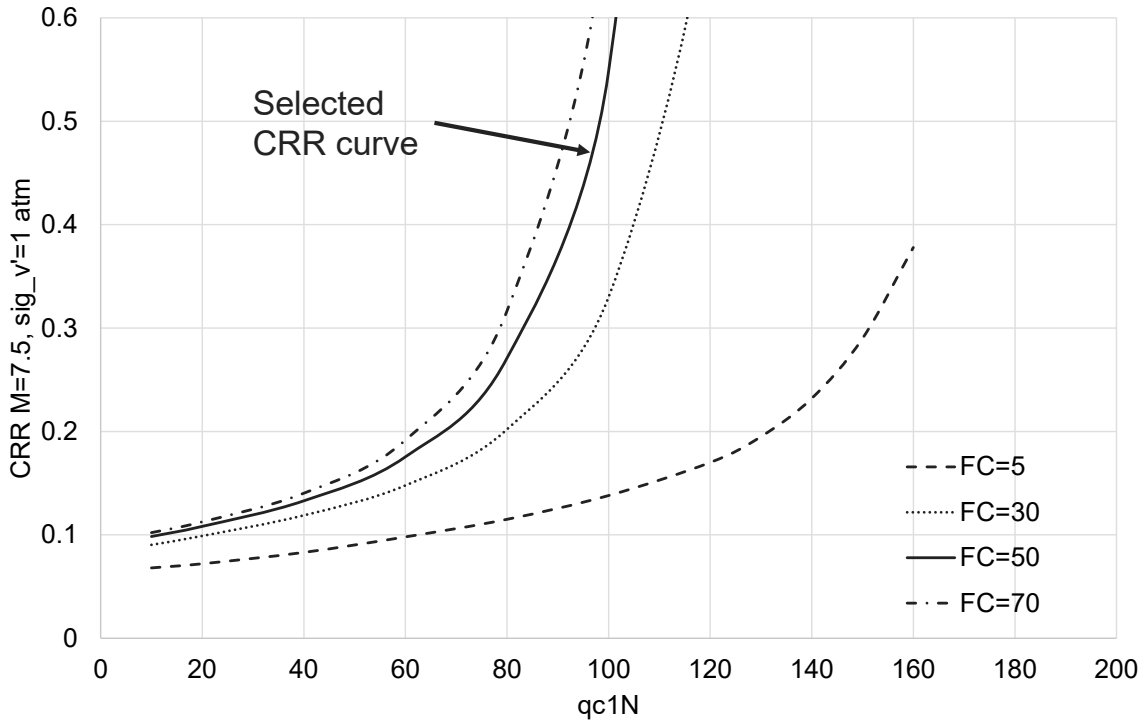

Figure 4: Deterministic CPT-based triggering correlation based on Boulanger and Idriss (2014)

Multiple single-element CyDSS simulations were then performed at various q_{c1N} levels within the modeling interest. A value of h_{po} was obtained at each q_{c1N} level by matching the CRR from simulation (reaches 3% shear strain at 15 uniform loading cycles with a confining stress of 1 atm) to the $CRR_{M=7.5}$ curve from Figure 4. Figure 5 shows the calibrated h_{po} at multiple q_{c1N} levels. A fitting function was used to correlate h_{po} with q_{c1N}, which is further related to the vertical effective stress, as previously described.

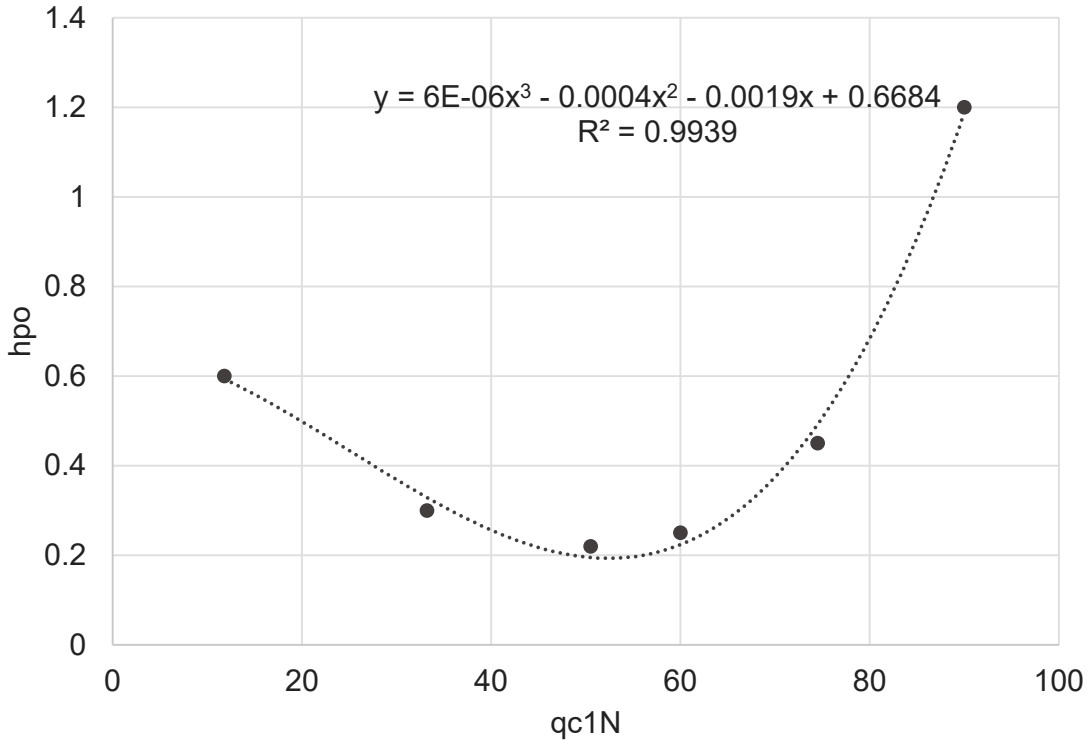

Figure 5: Calibrated h_{po} versus q_{c1N}

Verification with laboratory cyclic DSS tests

No cyclic DSS tests were carried out on the sand tailings material at GMD. However, multiple cyclic DSS tests were carried out on the sand tailings at Fundão TSF. The results are reported in Appendix D of the Fundão dam failure review panel report (Morgenstern et. al., 2016). Since the sand tailings at these two sites have similar granulometry and mineralogy, two of the cyclic DSS tests (DSS1 and DSS4) were selected to verify the calibration of the PM4Sand model in this study. A single element model was used to simulate the cyclic DSS test with the input parameters summarized in Table 2.

Table 2: Parameters used for simulating laboratory CyDSS tests

Test ID	q_{c1N}	q_{c1Ncs}	D_r	σ'_v (kPa)	σ'_m (kPa)	V_s (m/s)	G_o	h_{po}
DSS1	11.8	60.9	0.35	1,989	1,326	300	437.0	0.6
DSS4	0	46	0.2	4,284	2,856	325	349.5	0.6

The stress path, the stress strain curves, and the pore pressure ratio development were examined by comparing the simulated tests results against the laboratory data for both the DSS1 and DSS4 tests, as shown in Figure 6. A reasonable match between the simulated results and laboratory data were noticed for both the cases, which verifies the calibration of the PM4SAND model.

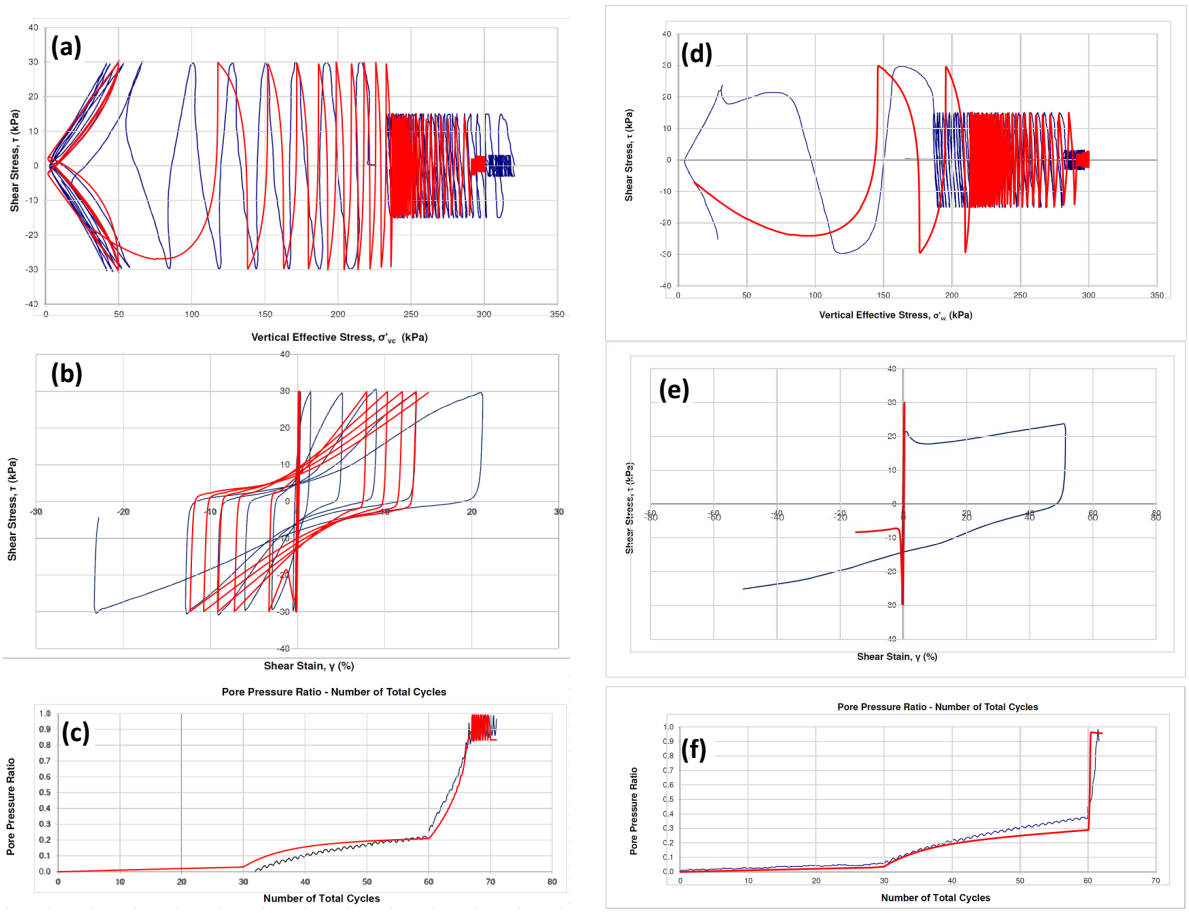

Figure 6: Simulated CyDSS test against laboratory test result of: DSS1 for (a) stress path, (b) stress-strain development, and (c) pore pressure ratio; DDS4 for (d) stress path, (e) stress-strain development, and (f) pore pressure ratio. The red line represents the simulation result and blue line represents laboratory data

Modulus reduction curves

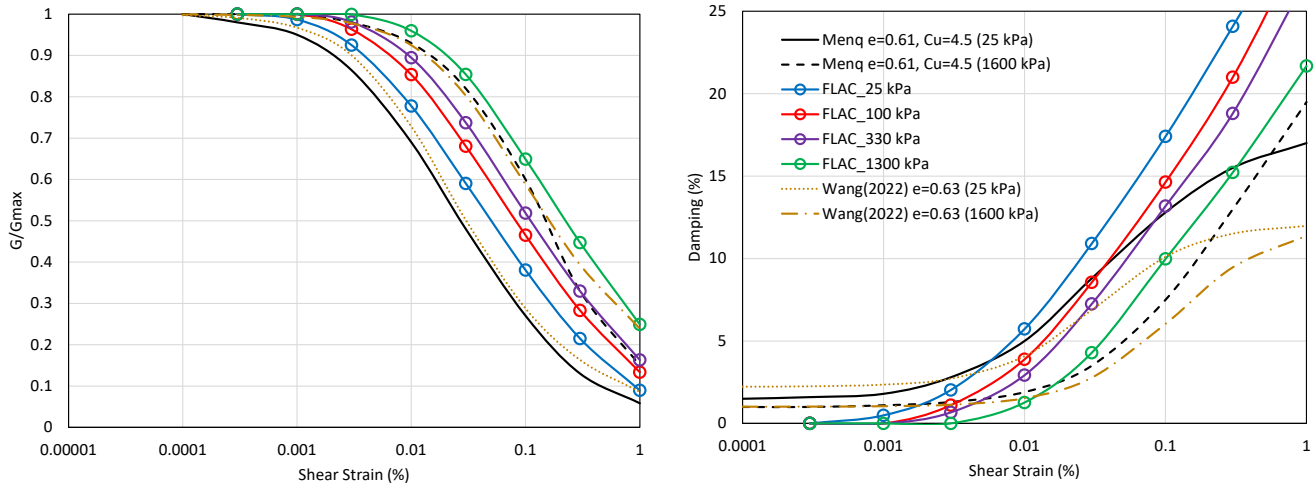

Figure 7: Modulus reduction curve for saturated tailings

Figure 7 shows the simulated shear modulus reduction curves and the damping curve for the saturated tailings, against the selected literature curves at the interested confining stress range. References used for these calibrations include (Wang and Stokoe, 2022) and (Menq, 2003). It is noted that the simulated reduction curves are generally in range with the literature reported curves, which further validates the calibration of the PM4SAND model.

Calibration of UBCHYST model

The UBCHYST model is a variation of the FLAC Mohr-Coulomb model in which the soil is considered non-linear below the failure envelope. Possible loss in stiffness and strength due to generation of excess pore pressure are not considered. The model is a user-defined model and operates within the FLAC Mohr-Coulomb model (Naesgaard, 2011).

In this study, the UBCHYST model was used to simulate the mechanical behavior of the non-liquefied materials, which include the unsaturated tailings, compacted tailings, fill/core and drain/rockfill/buttress. The selection of UBCHYST parameters is based mainly on the calibration against the previously determined modulus reduction curves, and engineering judgement. Table 3 summarizes the calibrated properties for all the materials. Figure 8 presents the calibrated modulus reduction curves against selected literature curves. References used for these calibrations include (Wang and Stokoe, 2022; Darendeli, 2001; Menq, 2003; Rollins et al., 1998).

Table 3: UBCHYST parameters calibrated for deformation analysis

Material	Density (kg/m³)	Friction Angle	Cohesion (kPa)		Rf	Hn	Modf1	Dfac	rm
Fill/Core	2,040	30°	0	$14000(\sigma'_m)^{0.50}$	0.98	0.9	1	0.1	0.8

Conclusion

This paper presents a detailed calibration of the PM4Sand model. The three primary input parameters of the constitutive model: relative density (D_r), shear modulus coefficient (G_o) and contraction rate parameter (h_{po}) were calibrated against penetration resistance based on site investigation data and verified using advanced laboratory test results. Stress-dependent relationships were obtained during the calibration process for these parameters, considering the thickness of the liquefiable material in the site (up to 60 m). The relative density (D_r) was related to the normalized corrected cone tip resistance (q_{c1N}) and effective vertical stress (σ_V') from cone penetration testing (CPT) data through empirical equations. The shear modulus coefficient (Go) was estimated based on the shear wave velocity (V_s) from seismic CPT (SCPT) data and expressed as a function of confining stress (σ_m'). An empirical equation was introduced to correct the normalized cone tip resistance (q_{c1N_CS}) and the cyclic resistance ratio (CRR) curves based on the fines content of tailings. The contraction rate parameter (h_{po}) was determined by matching the target cyclic stress ratio (CSR) of single element simulation of stress controlled cyclic direct simple shear test to the corrected CRR curve.

The process was repeated at multiple q_{c1N} levels to obtain a site-specific correlation between h_{po} and q_{c1N}. The laboratory cyclic direct simple shear tests were simulated to compare the simulation results against the laboratory data. The shear modulus reduction curve and damping curve were obtained through single element simulation of strain controlled cyclic direct simple shear test. The simulated results were also examined against the literature reported modulus reduction and damping curves for similar materials. A brief description of the UBCHYST calibration is also presented in this paper, as part of the complete calibration process that prepares all the constitutive models for the seismic deformation analysis that is to be discussed in part II of the authors' work.

Abstract

The Germano Main Dam (GMD) is an upstream tailings storage facility (TSF) situated north of Mariana, in the State of Minas Gerais, Brazil. The TSF received iron ore tailings from the late 1970s until 2013. The dam is currently going through the decharacterization process that is required by the latest local regulations. This paper presents a study of estimating the impacts of seismic events on the structure, as part of the decharacterization process.

A two-dimensional FLAC dynamic model was developed to estimate the range of excess pore water generation in the contractive tailings and the resulting seismic displacements of the structure. Existing field investigation data and laboratory tests results were used to calibrate advanced constitutive models: (a) PM4SAND for the saturated tailings, and (b) UBCHyst for unsaturated tailings and other non-liquefiable soil units. Staged construction of the structure was introduced in this study to mimic the stress conditions prior to the seismic event.

A base case analysis was first carried out to evaluate the model performance during designed earthquake time histories. Designed earthquake time histories were developed from the recorded earthquake time histories spectrally matched to the site-specific response spectra for a 10,000-year return period. Sensitivity analyses were then performed to evaluate the effect of some key factors to the model response including (a) the behavior of the model subjected to various earthquake time histories, and (b) the existence of pockets of weaker material in the tailings deposits. The development of excess pore pressures, shear strains and displacement at selected critical locations was evaluated. This study provided a systematic insight into the seismic performance of the Germano Main Dam.

Introduction

The Germano Main Dam (GMD) is an upstream tailings storage facility (TSF) located 25 km from Mariana, Minas Gerais, Brazil. GMD is the main dam of the Germano TSF, which stores approximately 130 Mm^3 of sand tailings and slimes derived from iron ore mining and processing operations. The GMD structure spans the Córrego do Germano valley, located south of the Fundão basin and upstream of the New Santarém Dam.

Several studies have been done previously to assess the seismic-induced failure potential regarding the as-is condition of the site, including simplified liquefaction assessments using QUAD4M, which concluded there was a low chance of development of liquefaction at this site. However, it is necessary to perform a detailed seismic assessment for the decharacterized GMD regarding the long-term condition to estimate the range of displacements and excess pore water pressures that would result from a seismic event. Thus, the finite difference method based 2D numerical model was developed with FLAC 8.0 to analyze the potential deformation behavior of the site under seismic loadings. As part II of the entire study, this paper describes a detailed development of a 2D FLAC model to capture the seismic deformation behavior of the selected GMD cross-section, together with two sensitivity studies that used to address the uncertainties of this study. The dam cross-section, site characterization and model calibrations are presented in Part I of this paper.

Design earthquakes and input ground motions

Table 1 summarizes the parameters of the design earthquake developed during the probabilistic site hazard analyses previously completed. The candidate seed time histories were selected from the PEER NGA-West2 database based on the following search criteria: magnitude (M) – 7.0 to 8.25; Rupture Distance (RRUP) – 35 to 195 km, 5–95%; Significant Duration – 27 seconds to 72 seconds. Figure 1 presents the final acceleration time histories used in the analyses, which are spectrally matched to design response spectra developed for this site.

Table 1: Input parameters for the design response spectra

Input parameters	Design event
M_w	7.75
R_{RUP} (km)	130
V_{S30} (m/sec)	470
Fault mechanism	Strike slip
Dip (deg)	90

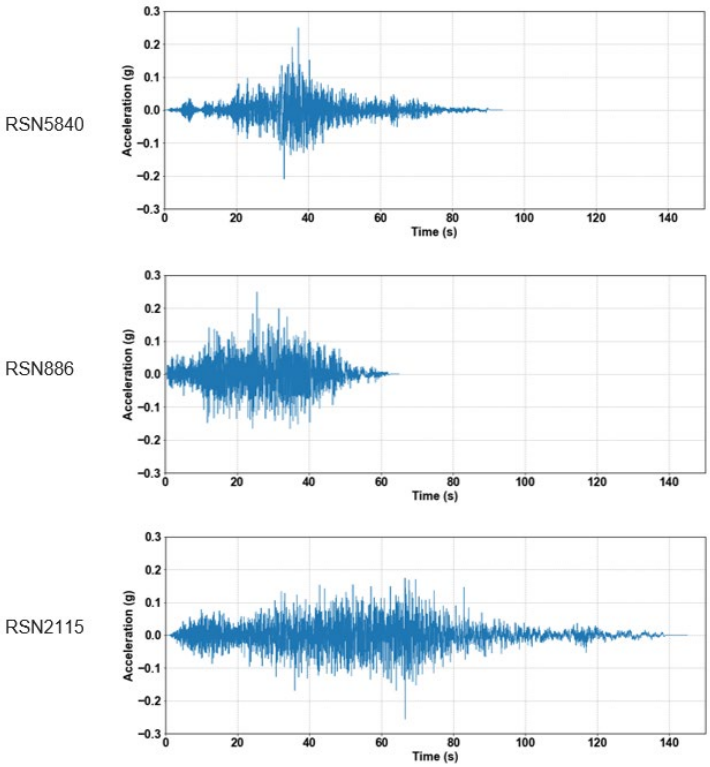

Figure 1: Acceleration time histories used in this study

Development of the base model

Material properties and constitutive models

In this study, the PM4SAND model (Boulanger and Ziotopoulou, 2017) was used for liquefiable material (saturated tailings), the UBCHYST model (Naesgaard, 2011) for all non-liquefiable materials, and the elastic model was used for bedrock. The basic engineering properties of all the materials and the detailed calibration of the PM4SAND model and the UBCHYST model were discussed in Part I of the authors' work (previous paper in this *Proceedings*).

Development of the base model in static conditions

Figure 2 shows the model geometry and the material zonation used in the FLAC analysis. A mesh size of approximately 2 m × 2 m was used in the FLAC model. A single element layer of bedrock was used at the base of the model where the ground motions will be applied during dynamic analyses. The model geometry was built in layers to approximately mimic the construction sequence of the structure, and to establish an initial stress distribution that closely represent the in-situ condition prior to the dynamic loading. For each layer of material, the density was gradually increased until the target value was reached, so as to avoid any potential stress concentration due to the sudden load from the new layer of material. The elastic model was

used for foundation material and the Mohr-Coulomb's model was used for other materials at the static stage.

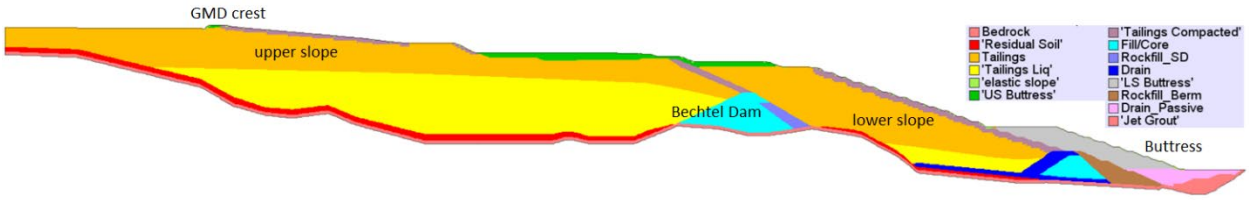

Figure 2: Geometry and material zonation of the FLAC model

The phreatic surface was introduced after all the layers had been built to initialize the pore pressure in the model domain. Figure 3 presents the initial distribution of pore water pressure, together with a solid line that represents the phreatic surface, which indicates that the pore water pressure was properly initialized.

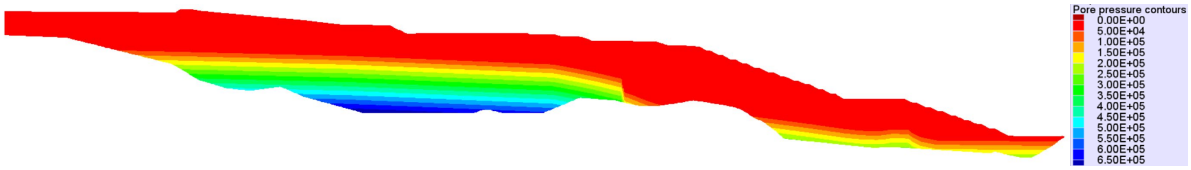

Figure 3: Initial distribution of pore pressure before dynamic analysis

Figure 4 shows the distribution of K_0 at the end of the static stage. Most of the model domain has a K_0 value close to 0.5, which is based on the results of pressure meter tests at the site. Figure 5 shows the K_α distribution at the end of the static stage (the ratio of static shear stress to vertical effective stress). The range of K_α for the majority part of the saturated tailings is less than 0.05, except for a limited area beneath the lower slope. No correction for the bias shear was considered in the modeling. Figure 6 shows the distribution of both horizontal and vertical stress at the end of static stage; no stress concentration was noticed from the figure. Such observations from these figures validate the stress initialization during the static stage.

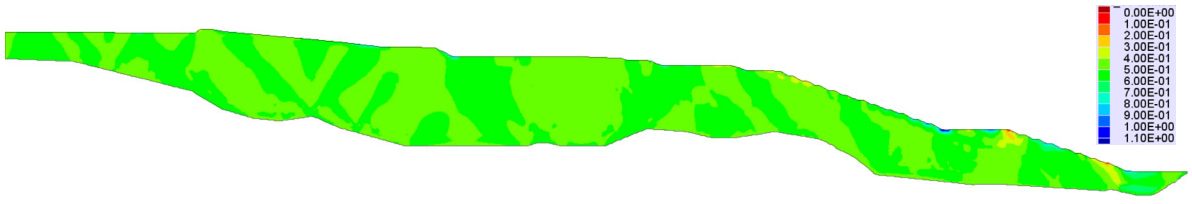

Figure 4: K_0 distribution at the end of static stage

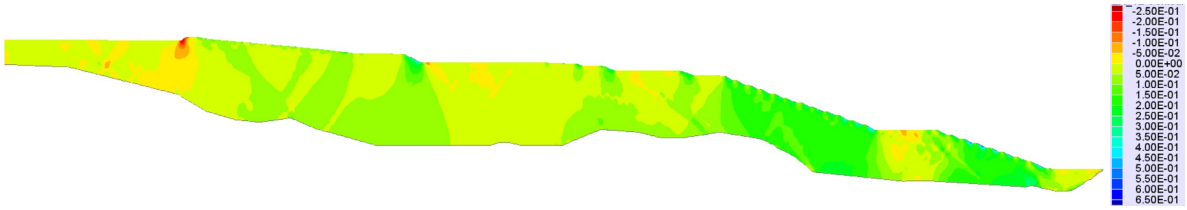

Figure 5: K_α distribution at the end of static stage

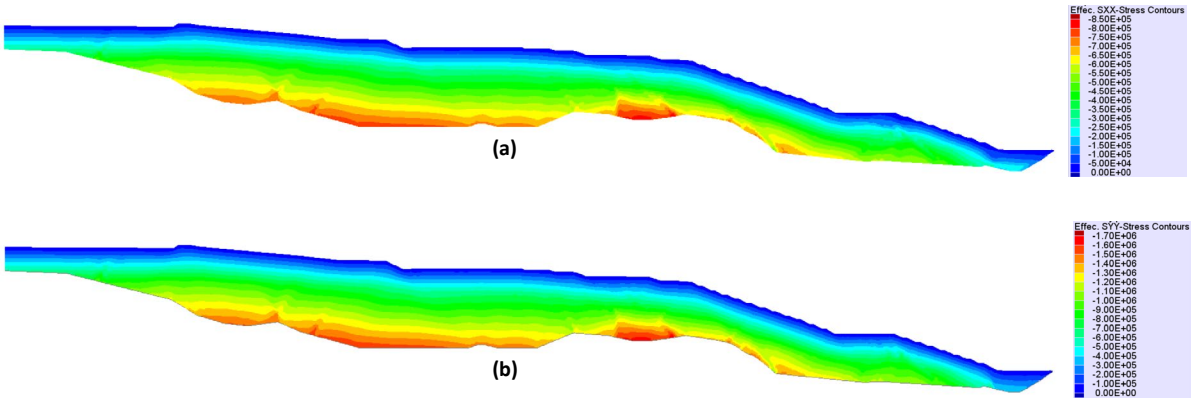

Figure 6: Distribution of (a) horizontal effective stress and (b) vertical effective stress at the end of the static stage

Model preparation for dynamic analysis

At the end of the static stage, the advanced constitutive models (UBCHYST and PM4SAND models) were initiated in the model to prepare it for the dynamic analysis. Figure 7 shows the distribution of the parameters used by PM4SAND during the initiation. The q_{c1N} ranges from 15 to 30, G_o ranges from 475 to 550 and h_{po} ranges from 0.3 to 0.6. The ranges of these parameters were in line with the PM4SAND calibration discussed in the first part of this paper, model calibrations. A Rayleigh damping of 0.5% was assigned to the base model, based on the recommendations for the PM4SAND model to prevent over damping of the saturated tailings. The dominant frequency of input motions designed for the site is 4 Hz (0.25 s). The time history RSN5840 was applied at the bottom of the bedrock layer as velocity histories.

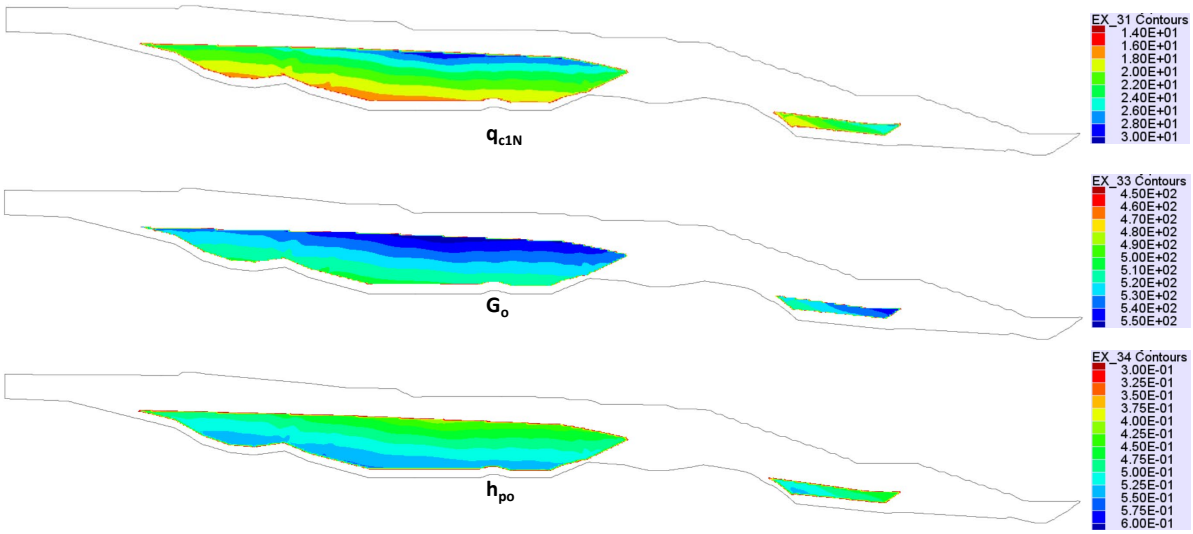

Figure 7: Distribution of PM4SAND parameters within the saturated tailings

Dynamic analysis results of the base model

The results of the seismic deformation analysis of the base model are shown in Figure 8 to Figure 13.

Figure 8 presents the deformed mesh at the end of the earthquake motion. Upwards deformation was noticed for both the upper slope toe area and the buttress toe area, which is likely due to the downwards sliding of the main body of the upper slope and the lower slope mass. On the other hand, downwards movement was observed at the crest of the lower slope, which is likely due to the sliding of the lower slope during the earthquake.

Figure 9 shows the maximum excess pore pressure ratio (Ru) distribution within the saturated tailings at the end of the dynamic analysis, with a maximum value of 40%. The presented Ru contour indicates that no liquefaction is triggered during the seismic loading for the base model.

Figure 10 presents the contour of the maximum shear strain increment at the end of the earthquake. Three potential shear planes were identified from the figure. The first shear plane starts at the upper slope crest, and passes through the bottom of the tailings deposits in the upper area and ends at the tailings – the Bechtel Dam interface, with a shear strain ranging from 0.5% to 1%. The second shear plane starts at the lower slope crest (the top of the Bechtel Dam), deeply seated into the bottom of the tailings, and reaches the base of the decharacterization buttress, with shear strain ranges from 1% to 3%. The identification of these two shear planes is consistent with the critical failure surfaces considered in the limit equilibrium analyses previously performed for the site. Additionally, a surficial shear plane was observed at the lower slope surface, with shear strain ranges from 5% to 7.5% and a depth of around 8 m.

Figures 11(a) and (b) show the horizontal and vertical displacement contours at the end of shaking. The horizontal and vertical displacements at the crest of GMD are 0.13 m and –0.21 m, respectively. The maximum horizontal and vertical displacements on the crest of Lower Slope (i.e., on the ground surface on top of Bechtel Dam) are 0.38 m and 0.17 m.

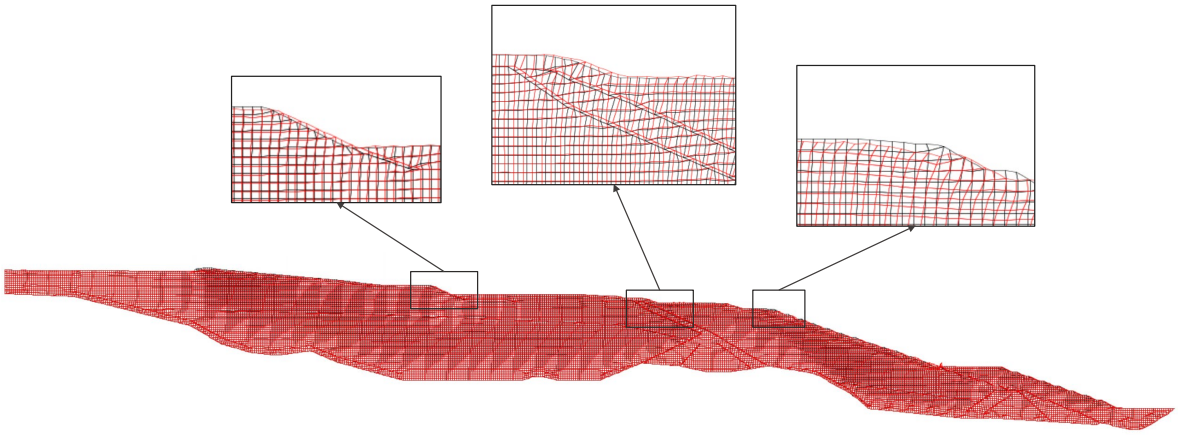

Figure 8: Deformed FLAC mesh at the end of motion, with a zoomed view at selected locations

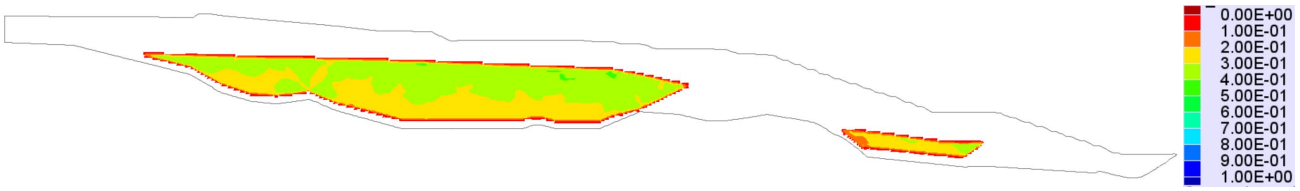

Figure 9: Maximum excess pore pressure ratio (Ru) contours at the end of motion

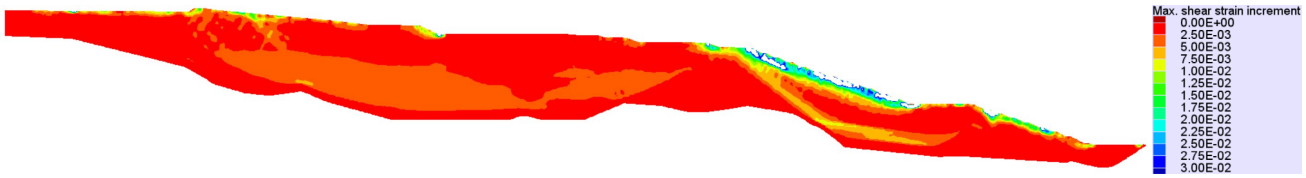

Figure 10: Maximum shear strain increment contours at the end of motion

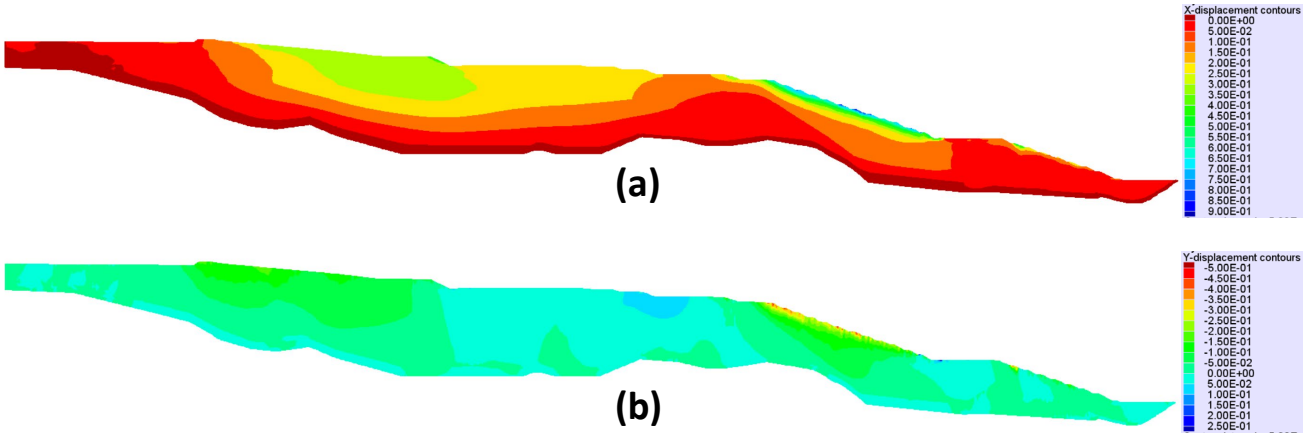

Figure 11: (a) Horizontal and (b) vertical displacement contours at the end of motion

Post-shake analyses

To perform post-earthquake analysis, the "Post-Shake" flag of the PM4SAND model was activated after 95% of the earthquake energy was transferred to the model (based on Arias Intensity). The simulation was continued for 40 more seconds past the end of shaking time in dynamic mode. Figure 12 shows the history of horizontal displacement, shear strain increment, and the Ru at selected locations. It showed negligible additional displacements during the post-earthquake phase. Minimal development of the shear strain increment was noticed initially, and it quickly reached a plateau during the post-earthquake analysis. No development of the Ru was noticed for the post-earthquake analysis. The rates of displacements are stabilized at the end of earthquake, and the movements are expected to cease at the end of shaking.

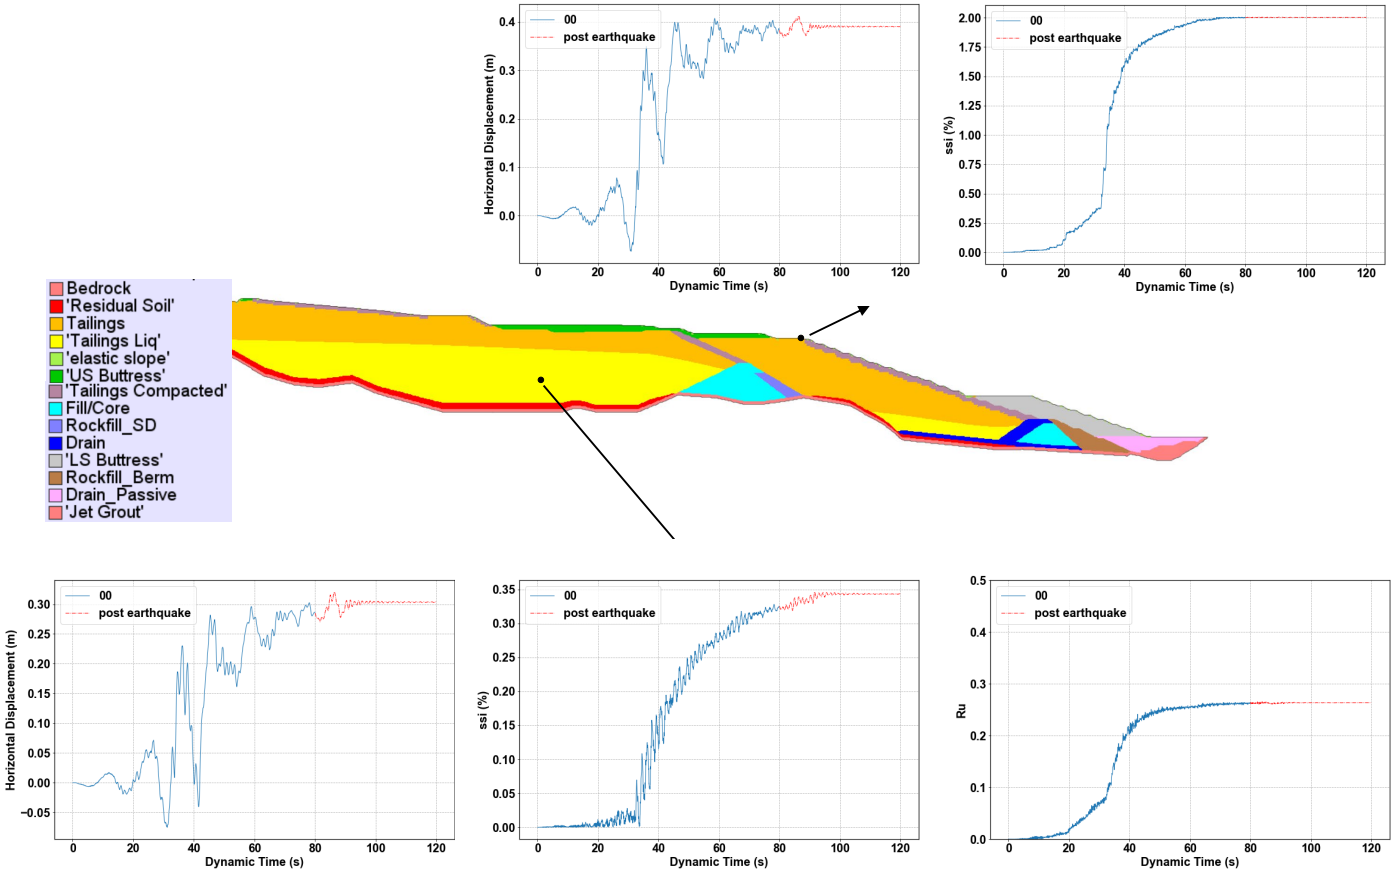

Figure 12: Element behavior at selected locations at the end of a post-earthquake analysis

Sensitivity studies

Two sensitivity studies are presented in this section to investigate the main uncertainties from the base model previously presented, which includes the uncertainty of the input ground motion, and uncertainty regarding the penetration resistance profile adopted from the CPT campaigns (30th percentile).

Earthquake motions

The two other time histories described earlier were applied to the base model to study the response of the structure; Case 41 used the ground motion RSN886 and Case 42 used the ground motion RSN2115. Figure 13 shows the contour of Ru at the end of shaking for all three ground motions and the Ru development history at selected locations. The ground motion RSN2115 leads to the largest development of Ru during shaking. A maximum Ru of 0.5 was observed at the lower slope saturated tailings, which is 67% higher than that of the base model.

Figure 14 shows the contour of shear strains at the end of shaking for all the three ground motions and the development of the shear strains at selected locations. While the results from the ground motion RSN5840 and RSN886 are in the same range, the ground motion RSN2115 leads to higher shear strains at the end of shaking. At the bottom of the lower slope saturated tailings, a maximum shear strain increment of 2.4% was observed, which was still in a reasonably low range of strains.

Table 2 summarizes the displacements at the end of shaking for all the three ground motions at selected locations. It is clearly noticed that ground motion RSN2115 (green color in Figures 13 and 14) has increased deformation compared with the other two motions. It should be noted that all three motions were spectrally matched to the same response spectra developed during the PSHA studies; however, RSN2115 has a significant duration of almost double that of the other two time histories, which contributes to the greater seismic response of the structure to this earthquake.

Table 2: Comparison of displacements at selected locations for different ground motions

Case ID	00 (RSN5840)		41 (RSN886)		42 (RSN2115)	
Location	Xdisp (m)	Ydisp (m)	Xdisp (m)	Ydisp (m)	Xdisp (m)	Ydisp (m)
GMD Crest	0.13	-0.210	0.22	-0.330	0.44	-0.580
Crest of Lower Slope	0.38	-0.170	0.53	-0.220	1.35	-0.540
Crest of Lower Buttress	0.12	-0.010	0.18	-0.015	0.35	-0.018

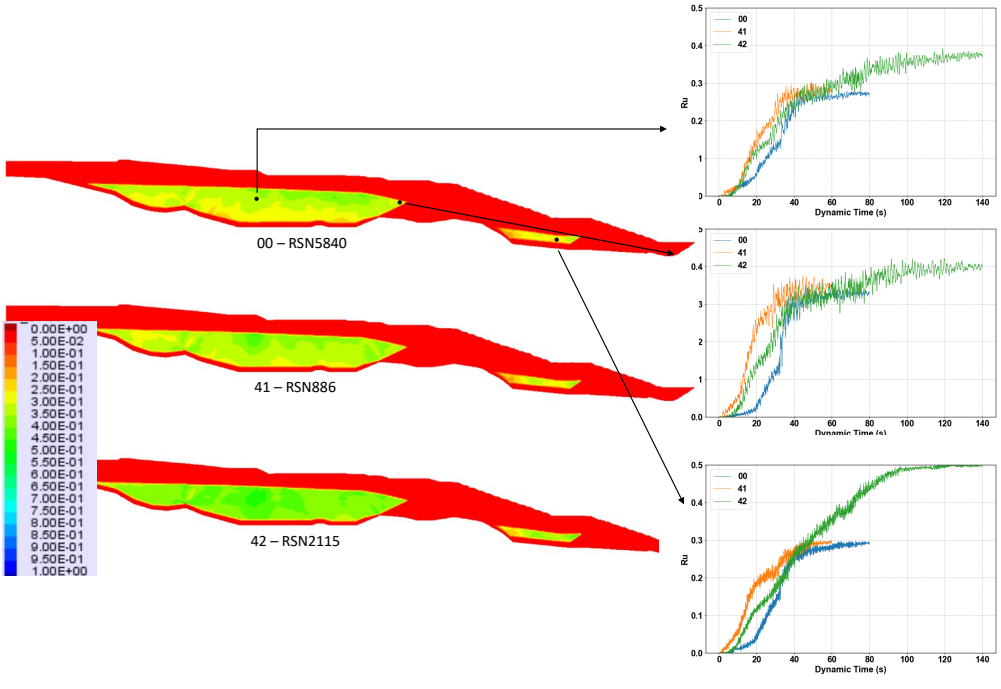

Figure 13: Ru distribution at the end of an earthquake for selected ground motions

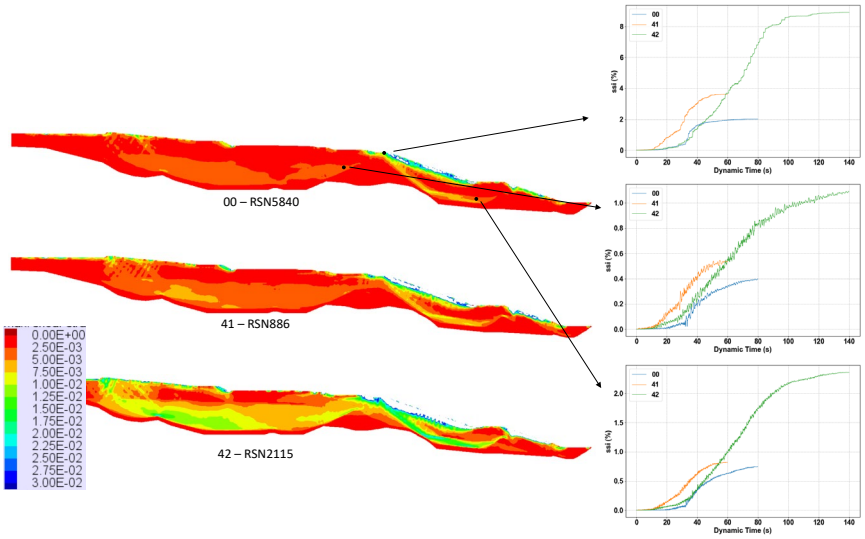

Figure 14: Maximum shear strain increment (shear strains) distribution at the end of an earthquake for selected ground motions

Tailings weak zones

Based on the existing site investigation report, weak tailings clusters may exist due to segregation of the historical depositions of tailings. These weak pockets may not use the base calibration of PM4SAND as developed for this site because their average penetration resistance may be less than the limits of the calibrated model, and they have a large deviance from the adopted 30th percentile curve. Thus, a sensitivity study was introduced to account for the effect of these weak zones on the seismic response of the structure. Figure 15 shows the three identified weak zones in saturated tailing, based on the review of available CPT data and with a conservative approach to delineate these pockets. For each of the weak zones, an iterative process has been then used to re-calibrate the parameters of PM4SAND, as listed in Table 3.

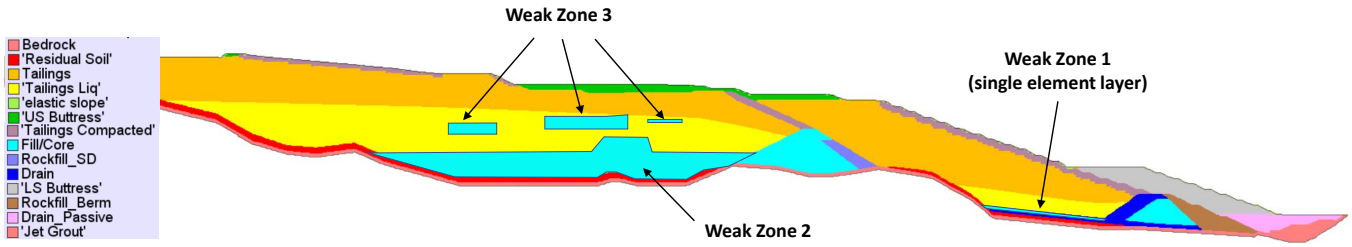

Figure 15: Location of the identified weak zones in saturated tailings

Table 3: Summary of the calibrated PM4SAND parameters for weak zones

Weak Zones	Confining Stress (kPa)	q_{c1N}	Dr	Vs (m/s)	Go	hpo
1	1,070	4.7	0.29	220	320	0.45
2	1,250	6.2	0.31	230	324	0.45
3	690	8.6	0.33	220	399	0.45

Figure 16 shows the comparison between the base model and the weak zone model for the distribution of Ru at the end of shaking. The development of Ru during shaking at selected locations is also shown in the figure. Larger excess pore pressure development was observed in all three of the weak zones, with a maximum Ru increased from 30% to 40% for weak zone 1.

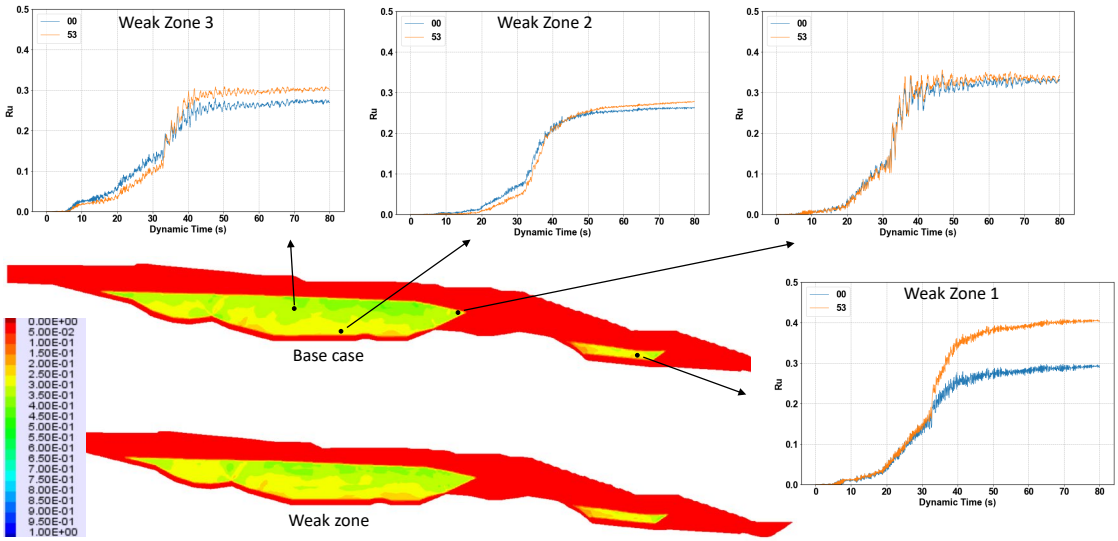

Figure 16: Comparison between the base case and the weak zone case for Ru at the end of shaking

Figure 17 shows the comparison for the maximum shear strain increment during the shaking. The range of shear strains increases considerably in the lower slope area (~100% increase) but less in other areas (~10% increase), which indicates that a potential weak layer at the bottom of the lower slope tailings deposit can significantly increase the shearing movement along the lower slope shear planes.

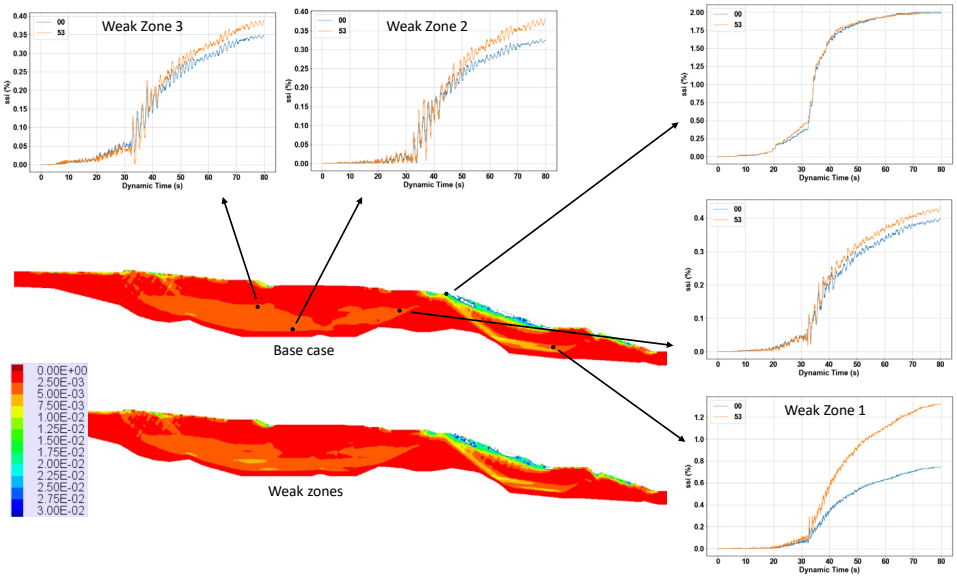

Figure 17: Comparison between the base case and the weak zone case for shear strains at the end of shaking

However, no change was observed between the two cases for the displacement at the GMD crest. At the middle of lower slope surface (where the maximum displacement of the entire model was observed), the horizontal displacement increased from 0.81 m to 0.89 m, while the vertical displacement increased from -0.19 m to -0.25 m. Overall, based on the FLAC analyses results, the existence of weak tailings can increase the deformation of the structure, especially at the toe of lower slope, while no fully developed liquefaction zones are predicted in the entire cross-section.

Conclusion

The Germano Main Dam (GMD) contains contractive tailings material. This paper presents finite difference method based 2D seismic deformation analyses to estimate the range of excess pore water pressures within tailings deposits, shear strains, and deformations resulted from seismic loading at the critical locations of GMD structure (upper slope and lower slope).

A base model was first developed to predict the seismic response of the structure with a reasonable amount of conservatism. Sensitivity analyses were then performed to address uncertainties from the base model including the input ground motion, and the existence of pockets of weak tailings. It was concluded that the most significant aspect affecting the response of the GMD structure was the input ground motions and specifically the duration of the shaking. The ground motion with the longest duration resulted in the highest seismic excess pore pressures of Ru < 50 % and maximum shear strains, $\varepsilon < 5\%$ in the entire model, which remained in the reasonably low range. It was also concluded that the existence of soft pockets of weak tailings does not significantly alter the seismic response of the dam, except at locations where the largest shear stains was observed.

Particle Size, Hydraulic Transportation, and In-line Mixing, from a Tailings In-Line Flocculation Perspective

Raymond Guang, Paterson & Cooke Canada Inc., Canada
Trong Dang-Vu, SNF, Canada

Abstract

The method of in-line flocculation or in-line polymer addition is a niche dewatering method that is commonly used in the oil sands industry in Northern Alberta, Canada. This method promotes tailings slurry to release clear water, increase the yield stress, and create a steepened beach slope, without the need for additional capital-intensive dewatering equipment compared to a conventional tailings slurry disposal method. With coarser particles in the tailings slurry (i.e., an increased sand-to-fine ratio, SFR), the in-line flocculation process will be impacted as well as the tailings transportation. This paper will utilize typical oil sands tailings as an example of where in-line polymer injection was used as the tailings treatment method.

Adding coarse particles to treat mature fine tailings (MFT) samples has been studied in order to improve tailings dewatering characteristics (Thakurta et al., 2013; Dang-Vu et al., 2014). One of the oil sands operators – Canadian Natural Resources Limited – uses a non-segregating tailings process, in which coarse sand and fines are mixed to produce a tailings stream with improved fines capture and accelerated dewatering (CNRL, 2022). However, coarse particles will increase the deposition velocity during hydraulic transportation and also impact the rheology characteristics of the slurry. On the other hand, the higher pipeline velocity poses the challenge of potentially higher shear in the pipeline, which will impact the flocculation process that was previously designed for a specific process condition.

It is demonstrated in this paper how the variation of coarse particles in the oil sands tailings slurry (change in SFR) created an interesting yet complex issue. An improved understanding of tailings transportation, the in-line flocculation process, and of how they are interdependent, would lead to a better expectation of the tailings' Key Performance Indicators.

Introduction

In-line flocculation or in-line polymer addition typically comprises the injection of a polymer solution directly into the tailings stream (via a specially designed injector or a simple tee) at or close to the point of

discharge. The injection location may vary from several hundred meters upstream of the discharge point to the plunge pool immediately downstream. From Hogg's (2013) paper, high turbulence created by in-line mixing (i.e., injecting polymers into a pipe) has several benefits over a stirred tank. Sufficiently high turbulence could ensure high polymer-particle and particle-particle collision frequencies are achieved without the severe flocculant degradation that can be seen in a stirred tank (Hogg, 2013).

The use of static mixers for in-line flocculation has been explored by Demoz (2012, 2014) with some promising results. A different method, the application of a dynamic mixer for polymer and tailings mixing, has been commercially trialed by COSIA on fluid fine tailings (FFT) (COSIA, 2015).

Polymer and tailings mixing is always a challenging area that, when optimized, can result in maximizing the initial water release and reducing the polymer dosage. Questions are still asked about the polymer injection location in relation to the discharge point, and whether the in-pipeline mixing is sufficient for flocculation.

This paper will discuss the link between hydraulic transportation, tailings rheology, and inline mixing. Oil sands tailings are used in this study due to the authors' industry experiences.

Oil sands tailings

Oil sands tailings are the byproducts of the Clark hot water process, which separates bitumen from sand, water, and clay. The composition of oil sands tailings varies substantially, with differences in solids content, sand-to-fine ratio (SFR), clay content, and other mineral compositions.

Mining operators classify the size fractions of solid particles in the tailings as "sand," "silt," and "clay" based on several standards. In the Canadian oil sands industry, sand (coarse) particles are classified as those with a size larger than 44 microns, silt (fines) particles are classified as those with a size between 2–44 microns, and clay particles are classified as those with a size less than 2 microns (Wang et al., 2014). A finer stream PSD and a slightly coarser stream PSD can be found in Figure 1.

The three main tailings streams are coarse tailings, fine tailings, and froth treatment tailings. Coarse tailings contain approximately 55 wt% solids, mostly sand (>44 microns), with high SFR. Fine tailings consist mainly of fine mineral solids (<44 microns) with an SFR lower than 1. The last stream is froth treatment tailings, also referred to as Naphtha or Solvent Recovery Unit tailings, which contain mostly diluent.

When the resulting tailings discharge into a tailings pond, the sand particles settle quickly on the beach and at the bottom of the pond, while the fine fraction accumulates in the center of the pond and eventually settles, forming what is referred to as mature fine tailings (MFT). MFT is one of the biggest challenges for oil sands operations due to its extremely slow settling rate and poor consolidation.

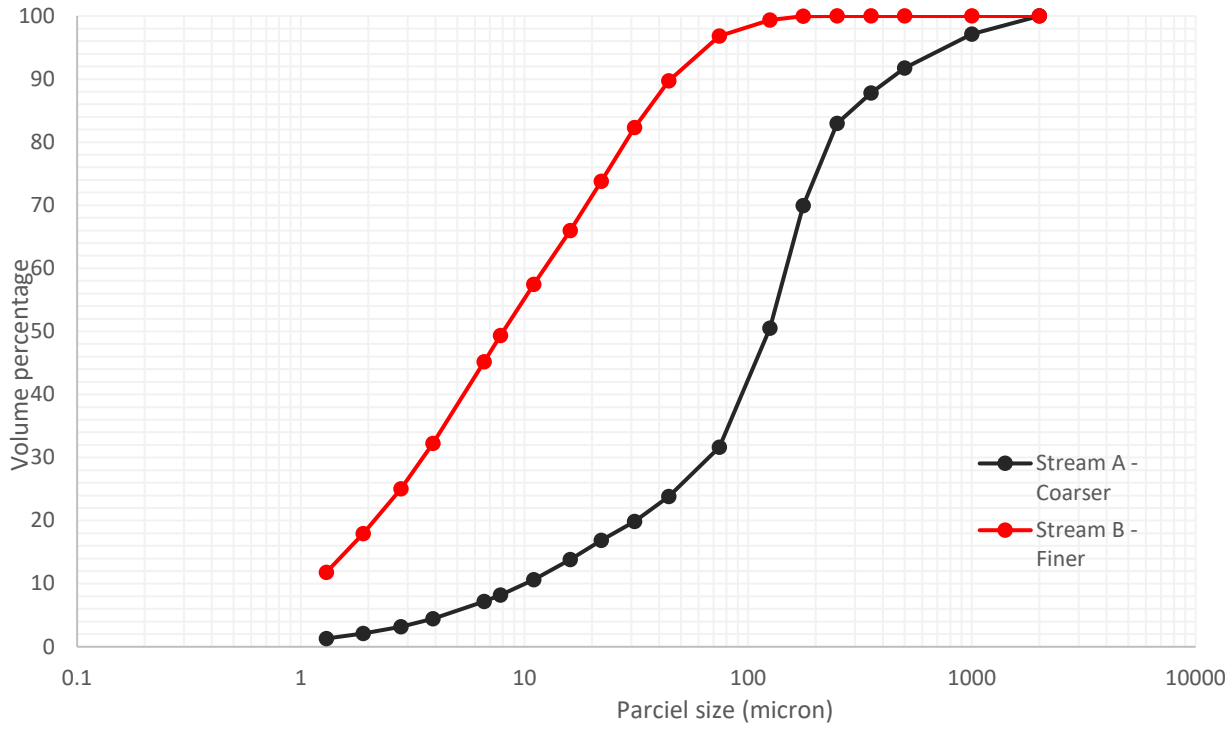

Figure 1: Typical oil sands tailings PSD

Polymer treatment and flocculation

The selection of polymer, dosages, and the flocculation process (mixing the polymer with tailings slurry) can vary greatly due to the significant variations in oil sands tailings types, their composition, and intended application. MFT is typically treated with either a single anionic flocculant or dual anionic and cationic flocculants (Najafi et al., 2014; Dang-Vu et al., 2016). Laboratory-scale procedures depend heavily on the specific applications due to the required mixing intensity and mixing duration. For example, during laboratory-scale flocculation of oil sands tailings, the sample is poured into a one-liter beaker. A given amount of polymer solution is added, followed by mixing. Mixing is conducted at 300 rpm using a portable mixer equipped with a paddle-mixing blade. After mixing, the treated tailings are allowed to settle for one minute, and the solids content of a supernatant is determined to calculate fines capture (Dang-Vu et al., 2014). Yield stress can be measured on the treated tailings using a rheometer.

To determine the dewatering rate after flocculation, gravity settling and drainage are often used. Sometimes, the capillary suction test (CST) is also applied (Wells et al., 2011).

The effect of polymers on the flocculation of tailings has been well-studied and understood since the 1950s (Henderson and Wheatley, 1987). It is reinforced in Stock (2006) that particle size, shape, and surface texture impact the effectiveness of a polymer in flocculating a tailings sample.

When coarser sandy particles are present in the tailings stream, the SFR of the tailings stream will be higher. In terms of optimum polymer dosage for flocculation, a summarized plot from Anstey and Guang (2017) is shown below:

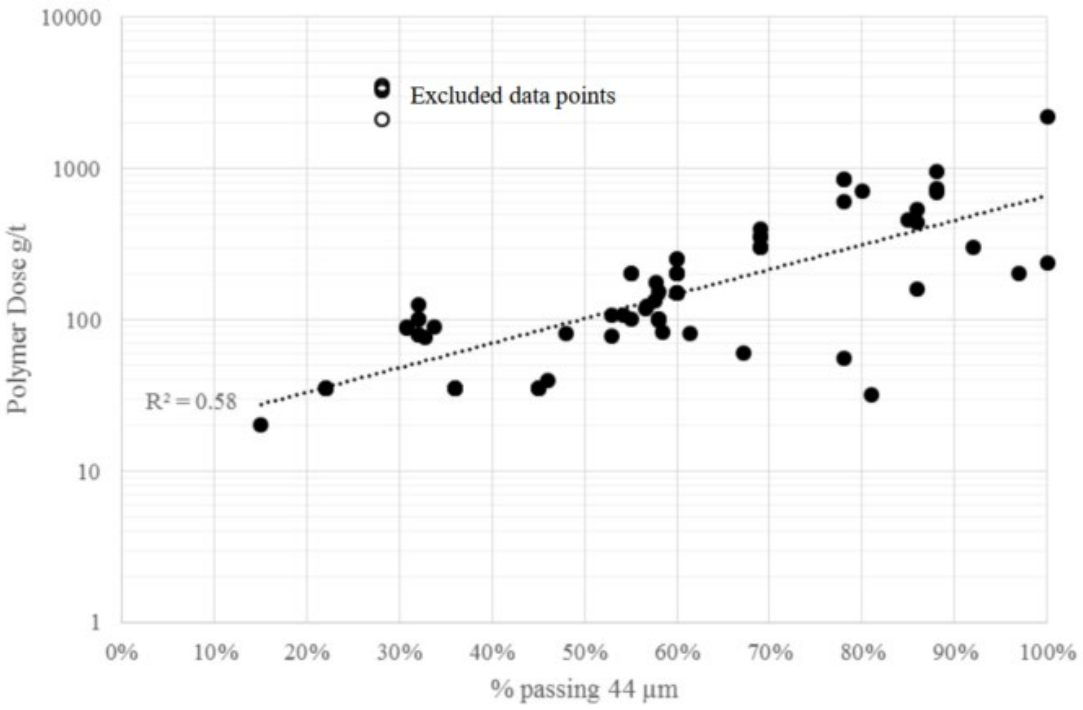

Figure 2: Optimum polymer dose versus percentage passing 44 microns (Anstey and Guang, 2017)

In the plot shown above, the optimum polymer dose was presented as a function of the proportion passing 44 microns. Despite not all the data points from the plot being oil sands tailings based, the plots nonetheless showed a strong relationship between the dosage required and the percentage passing 44 microns. A higher percentage passing 44 microns yielded a higher polymer optimum dosage. When a lower percentage passing 44 micron was recorded, a lower polymer optimum dosage was also observed. This is in line with what has previously been reported by Wells et al. (2011).

The impact of SFR on the dewatering rate was assessed by adding sand into MFT. Based on a study completed by the lead author, from Figure 3 below, it is seen that as the SFR increased from 0 (MFT) to 1 (with coarse sand addition), the net water released from the polymer-treated slurry after one hour improved from 8% to 19%. This shows that with some sand addition (i.e., elevating sample SFR), KPI in terms of net water release was trending in a favorable direction.

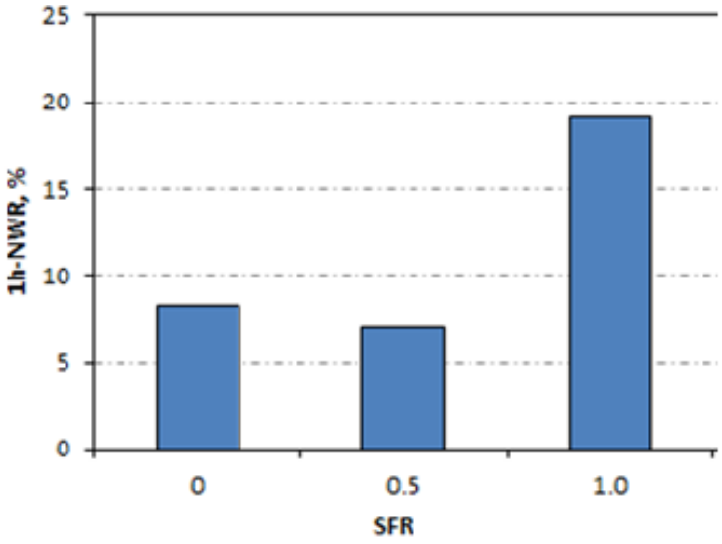

Figure 3: SFR versus one hour net water release post flocculation

Polymer and tailings mixing

As described in an earlier section, usually a mixer is used to provide mixing energy for mixing the polymer with tailings in a laboratory setting. In actual operations, the mixing mechanism differs significantly between mechanical agitation with an agitator and "in-pipeline" mixing with turbulent flow.

It is acknowledged by Costine et al. (2014) that turbulent dispersion is disadvantaged by the highly viscous nature of the underflows and large processing volumes. This statement was focused on a thickener underflow issue. However, it is also relevant to the polymer and tailings mixing in a turbulent pipeline. Nevertheless, Costine et al. (2014) proposed a chaotic topological mixer for mixing polymer and tailings in order to improve the efficacy of flocculation. Their work demonstrated that the chaotic advection improved dewatering performance and enhanced consolidation. Based on the authors' understanding, this type of device is not used in any of the current operating oil sands mines or in base metal tailings operations.

Currently, a basic in-line polymer addition method (a typical tee) is used at some oil sands tailings operations. In other words, a polymer transportation line is connected into a tailings transportation line and the polymer solution is "injected" into the tailings pipeline. The turbulence from the tailings flow is used to mix the polymer and tailings. To replicate this in a laboratory setting, a simple setup with a beaker and agitator is usually used. The agitator's mixing speed and mixing time can be controlled and monitored. In the on-site tailings operation, as pipeline sizes are fixed, velocity is controlled by the flow rate (typically varies within operational range) and the mixing efficacy is dictated by the amount of turbulence generated. It is critical that the long chain, high molecular weight anionic polymer needs to be well dispersed into the tailings stream for effective flocculation. This sounds simple enough, but is it?

Settling slurry pipeline flow

Before getting into in-pipeline mixing scenarios, the first thing to do is to understand what material is flowing in the pipeline. Generally speaking, tailings slurries can be divided into two broad categories – settling slurries and non-settling suspensions. A settling slurry consists of a diverse range of particle sizes, and is one where the turbulence present in the slurry flow is relied upon to lift and suspend the solids in order for them to be conveyed by the fluid flow. Non-settling slurries consist of finer particles that form stable homogenous mixtures exhibiting an increase in apparent viscosity, and turbulence damping (Bartosik, 2011).

A paper by Messa et al. (2021) describes three basic types of settling slurry flow. For a typical oil sands tailings stream, it is seen that the flow can be categorized as a pseudo-homogeneous regime. In this type of flow, the stream contains fine particles (typically fine sand of particle sizes between 60 and 200 microns) that flow at high velocity. The submerged weight of the solids is carried by fluid support mechanisms associated with flow turbulence (Messa et al., 2021).

The second intermediate case, where both inter-granular contact and fluid support mechanisms are significant, is called heterogeneous flow. And the other extreme case is the fully stratified flow; typically, the flow conveys large and rapidly-settling particles at a low velocity (Messa et al., 2021).

Li et al. (2016) and Fessler and Eaton (1999) wrote about the influence of solids particles on the modulation of turbulence. It is clear from a wealth of existing academic research that the behavior of solid particles in a liquid can enhance or suppress turbulence.

Turbulent behavior

When the tailings particles are mainly suspended by turbulence in the pipeline, it is prudent to understand what turbulence is and how it can be quantified.

Turbulence intensity in pipeline flow can be expressed by the Reynolds number. This dimensionless number is the ratio of inertial forces to viscous forces. The transition from laminar to turbulent flow, or the critical Reynolds number, is approximately at 2300.

With a Herschel-Bulkley fluid, which is a generalized model of a non-Newtonian fluid, the equation for a non-Newtonian Reynolds number becomes:

$$Re = \frac{8\rho V^2}{\tau_y + K\left(\frac{8V}{D}\right)^n}$$

Other than the well-known and broadly used Reynolds number, turbulent flow is also characterized by velocity fluctuations and random fluctuations of swirling regions of fluid such as eddies. Mean velocities in the X, Y, and Z directions are usually denoted by $\bar{u}$, $\bar{v}$ and $\bar{w}$, and u', v', and w' denote the velocity

fluctuations. Bulk velocity is fairly easy to calculate, whereas these velocity fluctuations require measurements obtained by specific instruments or validated simulations.

One of the methods that can be used for turbulence characteristics analysis is the quadrant analysis. This particular method is used to investigate the Reynolds stress structures and features of the large eddy.

Reynolds shear stress is caused by the x-direction velocity fluctuation u and y-direction fluctuations v having a non-zero correlation. These two quantities are the focus of the quadrant analysis. This technique is introduced by Willmarth and Lu (1972) for a turbulent boundary layer. This technique sorts contributions to the Reynolds shear stress $u'v'$ into quadrants of the u-v plane. The largest positive contributions to the turbulent energy were provided by the ejection ($u'<0$, $v'>0$) and sweep quadrants ($u'>0$, $v'<0$), while small and negative contributions were made by the interaction quadrants ($u'<0$, $v'<0$ and $u'>0$, $v'>0$). This is usually referred to as the sweep-ejection event (Kim et al., 1987).

Robinson (1991) mentioned that the near-wall turbulence production process is considered to be an intermittent, quasi-cyclic sequence. It is usually referred to as "bursting." It was described as a "violent breakup of a low-speed streak after lifting," and a "shear-layer interface sandwiched between an upstream, high-speed sweep and a downstream, low-speed ejection" (Robinson, 1991). This is a useful concept for the production of turbulent motion.

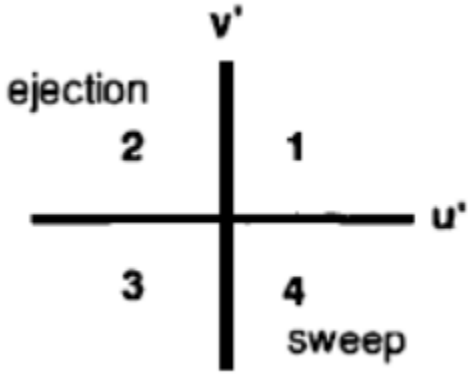

Figure 4: Quadrants of the Instantaneous u'v' plane

If the velocity fluctuation of the flow can be measured or simulated, a more quantitative quadrant analysis can be performed. An example of this can be found in both Guang (2011) and Fiorini (2017). In Guang (2011), a turbulent non-Newtonian channel flow was simulated through direct numerical simulation (DNS). Quadrant analysis was performed by obtaining the velocity fluctuation in the axial and radial direction (u' and v'). From the results, it was concluded that the largest percentage of the ejection and sweep events occurred away from the centerline and close to the side wall at approximately y/R = 0.4. It was hypothesized that the particles could be easily suspended and re-suspended in those areas.

Fiorini (2017) conducted an experimental campaign in a pipe flow facility. The Reynolds shear stress was analyzed in conjunction with the near-wall events such as ejections and sweeps. It was also concluded that with an increasing Reynolds number, the contribution of these ejection and sweep events on the total shear stress increases. Fiorini also pointed out that the ratio of contribution to the shear stress from the ejection and sweeps event is found to increase logarithmically with the distance from the wall at y/R = 0.3.

To the authors' current knowledge, the majority of the current in-line injectors used in oil sands tailings operations inject from the top of the pipe to the bottom. From the abovementioned studies, the ejection and sweep events were recorded towards the bottom of the pipe/channel. This could be an opportunity for a potential injection nozzle orientation with polymer injecting into the turbulent production regions.

In summary, ejection and sweep events can be linked to the mechanism of particle suspension. By using this quadrant analysis technique to capture the locations of Q2 and Q4 activities, better decisions could be made in terms of the best polymer injection velocity and injection location by obtaining Reynolds shear stress at specific pipeline quadrants and polymer injection pipe orientation.

Rheology impact on turbulent behavior

As described earlier, tailings particles can be categorized into fine particles and coarse particles. The particle behaviors and the turbulence in the pipeline are interdependent on each other. The finer particles (< 44 microns) became part of the carrier fluid. With higher concentrations of finer particles, especially in oil sands tailings, the rheological characteristics of the carrier fluid will change – i.e., there will be an increase in viscosity and yield stress.

If the Reynolds number was used to assess how the carrier fluid impacts turbulent behavior, as the rheology parameters of the fluid are the denominator of the Reynolds number equation, the higher the values for rheology parameters the lower the Reynolds number.

From a slightly different point of view, how does a higher yield stress or higher viscosity impact the turbulence characteristics (turbulent structures)? In a prior study by Guang et al. (2011), fluid samples with different rheological characteristics (change in yield stress) were used for DNS. It was found that in the simulation with lower yield stress values, higher turbulent production values were observed. With an increasing yield stress, the turbulent structures were weaker than in the Newtonian fluid simulation with the same viscosity.

For visualization, contours of axial velocity at a certain distance from the wall are shown in Figure 5. As the yield stress increased, the turbulent structures in simulation C were longer than the structures in the control simulation. The black structures represent low-velocity streaks. It can be seen that the streaks in simulation C were longer and wider. This further suggested that the flow was not fully developed for this

non-Newtonian fluid. The structure in the Newtonian case was smaller in scale and more random; this indicated the flow was more developed.

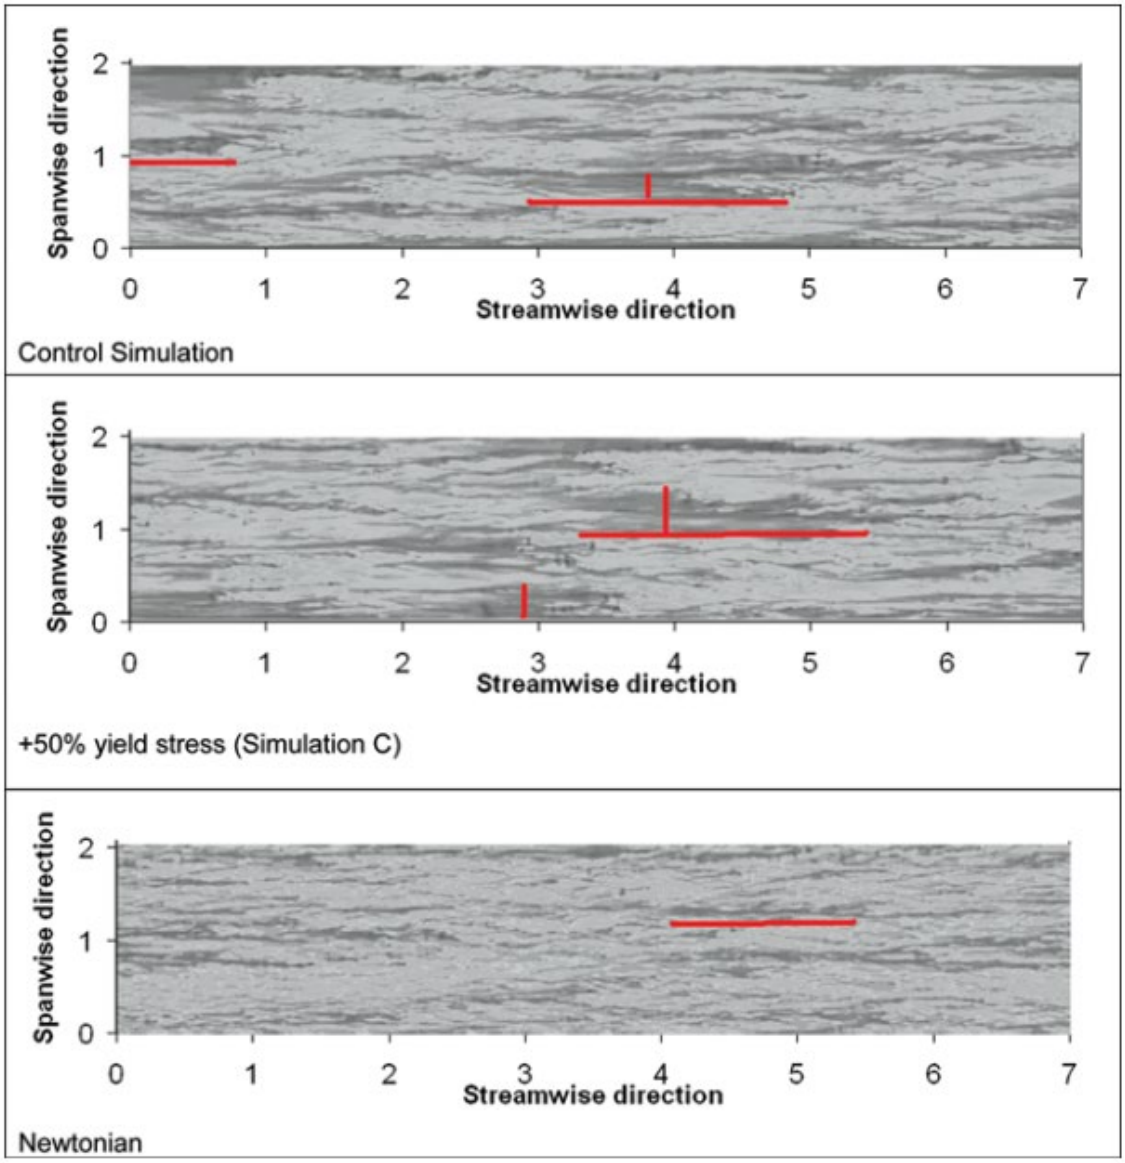

Figure 5: From top to bottom: control simulation (Re=8294), simulation C (Re=6481). White represents high velocity and black represents low velocity (Guang et al., 2011)

Discussion

To illustrate the relevance of pipeline hydraulics to flocculation, consider two different oil sands tailings streams at the same solids content, one with a higher SFR of 5.0 and one with a lower SFR of 0.1. Based on the previous section, it is expected that the stream with a higher SFR will need a lower polymer dosage, whereas the stream with a lower SFR will require a higher polymer dosage. However, assuming there is no

"injector" for the in-line injection, instead, a typical tee is used for polymer injection. The turbulence generated by the flow will be used as the mixing mechanism for polymer-tailings interaction.

Considering the above, the following is noted:

- Increased fines content (low SFR) means an increase in carrier fluid rheology.
- Fine particles become part of the carrier fluid. As the solids content of the carrier fluids increases, the apparent viscosity of the carrier fluid will increase.
- Increasing carrier fluid apparent viscosity means:
    - The deposition velocity requirement for coarse particles in this stream decreases – potentially, lower bulk velocity will be required to keep particles in suspension.
    - Turbulence is suppressed – i.e. lower turbulent energy production, weaker turbulent structure.
- Increased coarse particle content (high SFR) means a decrease in carrier fluid rheology.
- Decreased carrier fluid rheology means:
    - The required deposition velocity for coarse particles in the stream will be higher than the required deposition velocity for the low SFR stream.
    - Turbulence is enhanced.
    - Due to the higher deposition velocity requirement, the pipeline bulk velocity needs to be higher than the pipeline bulk velocity for the lower SFR scenario.

It is interesting to note that, due to the difference in rheology between the high SFR and low SFR tailings stream, even if the bulk velocity is the same, the turbulent characteristics will be different. As alluded to in previous sections, the two streams will have different carrier fluid rheology due to the SFR differences. The particle size and particle population will dictate the deposition velocity requirement. The population of the finer particles will impact the turbulent characteristics, which in turn impact the Reynolds shear stress. The Reynolds shear stress will lead to variation in the wall events, hence affecting the suspension of the coarse particles.

It may be naïve to assume that the turbulence can mix the tailings and polymer sufficiently in this complex scenario without even considering the shear sensitivity nature of the flocculated stream. At the same bulk velocity, it needs to be acknowledged that the turbulent characteristics of two different SFR materials will be different. This will ultimately impact the polymer tailings flocculation efficacy. Without fully grasping the complex nature of the physical and chemical behavior of such a large-scale of in-line mixing application, it would be easy to set an unrealistic KPI for the tailings operation.

Conclusion

This paper used the oil sands tailings treatment process as an example to illustrate the importance of tailings flow behaviors and the fluid dynamics of tailings for the design of in-line flocculation. Ideally, if all the turbulent characteristics of the flow can be measured in real-time, then it will help the engineers to understand the challenge better. Unfortunately, some of the measuring devices and/or methods are not applicable to large-scale operations.

The use of computational fluid dynamics (CFD) may offer opportunities for system optimization. The advantage of such simulations relative to physical experiments is that all the quantities of interest can be obtained for the whole flow field (McIver et al., 2000).

With the advancement of computer power, CFD is becoming an increasingly powerful tool for gaining a fundamental understanding of in-line mixing fluid mechanics. By illustrating the internal flow patterns and quantifying the turbulent characteristics, optimization could be completed by changing operating parameters without altering the configuration of the injection setup. Implementing targeted solutions will help the operation to avoid straining limited resources on numerous trial solutions.

Preliminary Design of the Tailings Cover System Using Numerical Modeling to Perform Sensitivity Analysis

Bibhuti Panda, AECOM, USA
Rouzbeh Rasouli, AECOM, Canada
Jason Chen, AECOM, Canada
Anne-Marie Dagenais, AMD Solutions, Canada

Abstract

The purpose of a cover system for tailings is to protect the downstream receiving environment following the closure of the tailings facility. In general, a cover system provides physical stability for dust and erosion control, chemical stability to reduce containment release, and meets the land use expectation for vegetation. Five components of the cover system are normally designed: (1) a top vegetation layer, (2) a protection layer, (3) a drainage layer, (4) an impermeable layer, and (5) a capillary break layer. A pre-feasibility level study was performed to design a cover system for a tailings storage facility in Eastern Canada. A two-dimensional (2D) numerical model was developed to estimate the net percolation into tailings under the planned thickness of the cover system. The percolation from the base of the cover was estimated and this value is used as an input to the hydrogeological model for the site. The model estimated infiltration due to rainfall, snowmelt, root transpiration, surface evaporation, and runoff. The model simulated liquid and vapor phase water transport in a two-dimensional model section. The model also included a feature to simulate thin layers of geomembrane liners and considered potential defects.

Sensitivity analyses were performed to investigate the critical input parameters and a long-term (60-year) simulation was performed to find the variability of net percolation estimate in future climate change conditions. The sensitivity analyses were performed for a selected year representative of normal climate conditions to evaluate critical parameters and their effect on the net percolation and to study the effect of climatic conditions, hydraulic conductivity of the geomembrane, defects on the geomembrane, slope of the cover, vegetation parameter, protective layer thickness, et cetera. The numerical model showed that the selected cover option is suitable based on the estimated infiltration and meets closure objectives for the study site.

Introduction

The management of mine waste such as mine tailings that is either a reactive or non-reactive waste product during mining operations and closure is an important function that requires the application of numerous technologies. The design and construction of a cover system for mine tailings is the most critical aspect of mine closure. The main objective of installing a cover system over the tailings is to protect the downstream receiving environment following closure of the tailings facility. In many cases, this is achieved by reducing the net percolation of water into the tailings, thereby reducing the effluent seepage quantity. The cover system for any site is designed based on the following important design objectives (INAP, 2017):

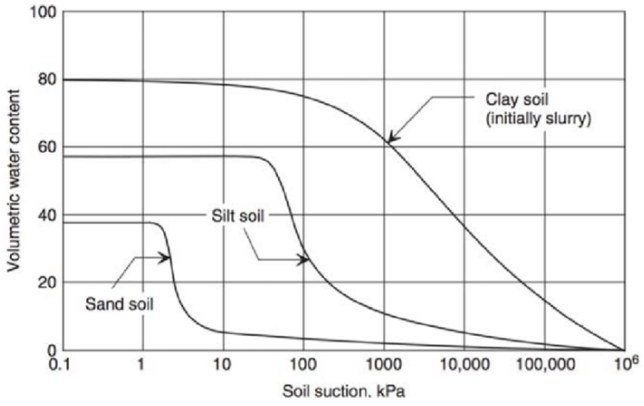
- physical stability – dust and erosion control;
- chemical stability – reduce contaminant release; and
- meeting the land use expectation – vegetation.

In a cover system design approach, the selected methodology goals are to develop a cover system that is technically the best option, is cost-effective with the appropriate balance of capital and operating expenditure, is implementable, and meets stakeholders' expectations. Various cover systems may be employed to meet the above design criteria as discussed in the "Cold Regions Cover System Guidance Document" (MEND, 2012). The following categories of cover systems have been identified as appropriate cover systems.

1. Simple protection cover system – vegetation and erosion protection cover system that is needed in areas where vegetation can help promote evapotranspiration and reduce soil erosion.
2. Store and release cover system – these covers require climate conditions where there is greater evapotranspiration than precipitation, both seasonally and annually.
3. Enhanced store and release cover system, with a lower permeability layer, and capillary break. The objective is to further reduce net percolation during short duration seasonal events when the storage capacity of a store and release cover system might be exceeded. The capillary break layer cover system is another form of enhanced store and release cover system.
4. Barrier type cover system – a compacted clay layer. This controls the ingress of atmospheric water and in some cases atmospheric oxygen. It should include a layer with an as-built (field) saturated hydraulic conductivity of less than or equal to 1×10^{-9} m/s.
5. Cover systems with engineered layers – geosynthetic/fabric layers. These can be used either as a drainage layer or as a barrier layer that can reduce net percolation and oxygen ingress.

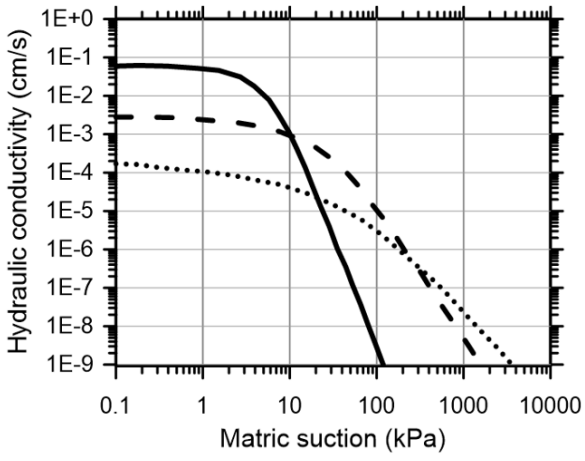
The selection of a cover system depends on site conditions and the design objective. Cost will depend on material sourcing and overall cover configuration, which will also depend on closure objectives and site conditions. In some cases, a combination of more than one category of cover system may be used for cover design at a specific site. The integration of landform and cover system is also an essential part of the cover system design. The important factors that control landform are geology, soil type, hydrogeology, topography, constructability, and final land use.

The selection of a cover thickness to support the chosen revegetation plan is also an important consideration in cover design. The vegetative growth medium (i.e., topsoil and fill layers) above the drainage layer is designed to adapt to future land use planning, which could include shallow rooted grasses and shrubs or deeper-rooted trees. A growth medium thickness of 76 cm (30 inches) will support the root zone depth of grasses, shrubs, and/or large trees, depending on which revegetation plan is chosen for the cover.



A cover system was evaluated for a tailings facility. A preliminary semi-quantitative analysis and a capital cost assessment were performed to compare different cover options. In the comparative analysis, the required thickness and characteristics of the growth medium were considered common to all cover design options. A Multi-Criteria Analysis (MCA) also called a “Multiple Accounts Analysis” (MAA) was performed to evaluate the options and facilitate a final decision. The selected cover option was evaluated using numerical modeling to perform a range of sensitivity analyses for the effect of critical parameters on a suitable cover system for the study site, located in Canada. The average climate condition at the site can be described as a humid continental climate with a significant variation in temperature between summer and winter. The 30-year average annual precipitation is about 927 mm (36.5 inches) at the study site, which typically consists of 8 months of rainfall and 4 months of snowfall.

Past studies



The Canadian Mine Environment Neutral Drainage (MEND) initiative developed a manual for cover systems (MEND, 2012) for waste rock and mine tailings. MEND is a co-operative research program that is directed by a partnership of the Canadian mining industry, federal and provincial governments, and non-governmental organizations (NGOs). The capillary barrier concept is commonly used in the design of mine waste cover systems and more specifically, the design of multi-layered cover systems (MEND, 2004). This system is used to maintain a tension saturated layer within the cover system and thus mitigate oxygen ingress and reduce net percolation flow. A fine-textured material placed between an underlying and overlying coarse-textured materials can result in a capillary barrier for downward as well as upward moisture migration from the sandwiched layer. The cover system may contain some, or all, of these components depending on local site conditions.

The capillary barrier layers generally consist of fine-grained soil over coarse-grained soil layers, though the fine-grained soil over a geotextile in lieu of coarse-grained soil also produces a capillary barrier effect (Zornberg et al., 2009). Water is held in the fine soil until evapotranspiration, horizontal drainage, or percolation removes the water. Differences in pore size distribution between the two layers cause infiltrated water to be retained in the upper soil layer under unsaturated flow conditions, as long as the contrast in unsaturated hydraulic conductivity of the soils in the two layers is sufficiently large (Dwyer, 2003). The upper soil layer exhibits greater moisture content than the lower soil layer at the same matric suction. Thus, a capillary barrier effect occurs when a relatively fine-grained soil overlies a relatively coarse-grained soil or a geotextile. The matric suction in the fine-grained soil layer typically must become negligible (i.e., saturated conditions) before any appreciable flow occurs into the lower coarse-grained layer (or geotextile).

The performance of a cover can be explained by the following: beginning at relatively dry conditions, that is, at high suctions, the fine-grained soil has a significantly larger hydraulic conductivity than that of the coarse-grained soil layer. With increasing water content and decreasing matric suction, the hydraulic conductivity of the fine layer will increase gradually. The hydraulic conductivity of the coarse-grained soil layer will remain comparatively low until suction corresponding to the air entry value (AEV) is overcome. Before reaching these conditions, water will not move from the fine-grained layer into the coarse layer even though the water content of the fine layer will increase during infiltration. Breakthrough into the coarse-grained soil layer occurs when the matric suction at the interface equals that of the air entry value of the coarse-grained soil layer (AEV for sand soil is low), as shown in Figure 1.

b) Coarse-solid, Medium-dashed, Fine-dotted

Figure 1a: Soil-water characteristic curve for different soils (Fredlund and Rahardjo, 1993)
Figure 1b: Hydraulic conductivity vs. suction (van Genuchten and Pachepsky, 2011)

Geosynthetic layers can be used as alternatives to earthen soil material layers. Some advantages of geosynthetic layers include:

- Net percolation rate can be significantly reduced.
- A geosynthetic layer can be installed quickly and easily.
- Overall cover thickness and requisite imported materials and settlement issues can be reduced significantly. However, if a final profile surface is being driven by drainage elevations at the perimeter of the tailing's footprint, a thinner cover thickness could mean that more profile fill would be required underneath the cover to maintain the same finished drainage levels at the perimeter.
- Geosynthetic clay liner (GCL) can replace compacted clay soil when it may not be available at every site.
- GCLs are more resistant to freeze/thaw events than natural clay liners.

In any cover system, the geosynthetic layers that can be used in place of soil layers include:

- a non-woven geotextile filter layer can be used as a filter to protect a drainage layer;
- a geonet can be used as a drainage layer; and,
- geomembrane and GCL layers can be used as barrier layers.

The five components of a cover system, as discussed in MEND (2004) are:

1. A top vegetation/soil layer – an evapotranspiration layer with vegetation supported by topsoil.
2. A protection layer – protects the lower layers from physical damage and freeze/thaw impacts.
3. A drainage layer – a drainage soil or an equivalent layer of geosynthetic material.
4. A low hydraulic conductivity geomembrane/soil layer – a layer of compacted low-hydraulic conductivity soil/amended soil or an equivalent geomembrane liner.
5. A capillary break layer – a coarse-grained soil/composite geonet layer, which acts as a break in unsaturated soil conditions.

A cover system was selected from different options, similar to the one discussed above, which comprises five components system, as shown in Figure 2. A numerical model was developed to evaluate the system, as discussed in the following section.

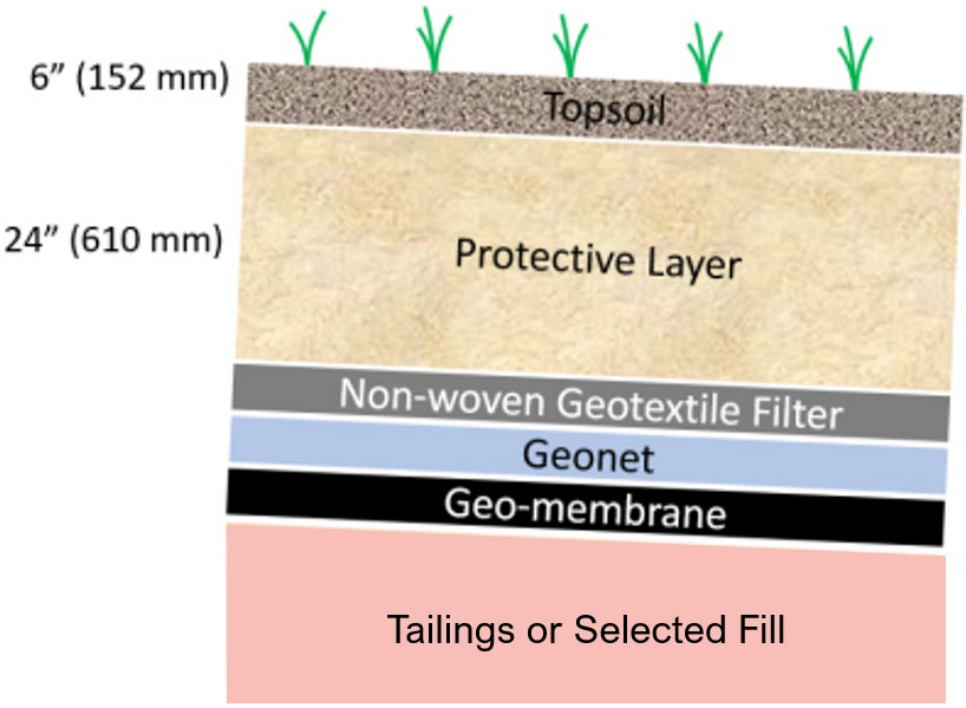

Figure 2: Different layers for cover model

Methodology

SEEP/W Version 2021 R2 finite element software was used to develop the numerical model to design the cover. SEEP/W is a commercial computer program developed by Geo-Slope International Ltd. SEEP/W can analyze the water flow from the environment across the soil surface, through the cover, and into the groundwater regime. The analysis includes infiltration due to rainfall, snowmelt, root transpiration, surface evaporation, and runoff. The model simulates liquid and vapor phase water transport in a two-dimensional cross-section. The code includes a feature to simulate geomembranes using line elements. The percolation from the base of the cover is estimated and is used as an input to the hydrogeological model for the site.

Near-surface processes of evaporation and infiltration are represented as boundary conditions applied to the surficial nodes in the finite element mesh. Infiltration during a timestep with precipitation is computed by subtracting the actual evaporation from the precipitation. The resulting value, which can be either positive (net infiltration) or negative (net evaporation), is applied as a specified flux to the surface node. However, if a positive flux value would result in the surface node becoming saturated, the boundary condition changes to a specified pressure equal to the saturated pressure head, and the net infiltration is calculated from the solution to the flow equation. In this case, runoff occurs equal to precipitation, minus actual evaporation, minus calculated infiltration. SEEP/W also has procedures for accounting for snow accumulation and snow melt.

Key features of the cover modeling in SEEP/W include:

- Material properties can be estimated relatively easily using data such as grain-size, saturated hydraulic conductivity, and saturated water content, or alternatively they can be imported from the built-in material database if this information is not known.
- Large site-specific climate datasets can be applied to the model over extended time periods using transient analyses. Climate input parameters include temperature (minimum and maximum), relative humidity (minimum and maximum), wind speed, evaporation, and rainfall. These can be specified daily or at any other time interval.

The current study was focused on the cover profile, which may include up to about 1 m (3 feet) to 2 m (6 feet) of fill material for profiling below the cover. The model consisted of a 150 mm (6 inches) layer of topsoil, 610 mm (24 inches) of protective layer, a geonet, and a geo-membrane. The fill above the water table and tailings below water level were modeled with their respective hydraulic properties. The bottom of the model and the toe end of the cover were modeled with drain boundary condition. The initial groundwater level was considered constant at 2 m (6 feet) below the cover surface at the toe of the slope. as presented in Figure 3.

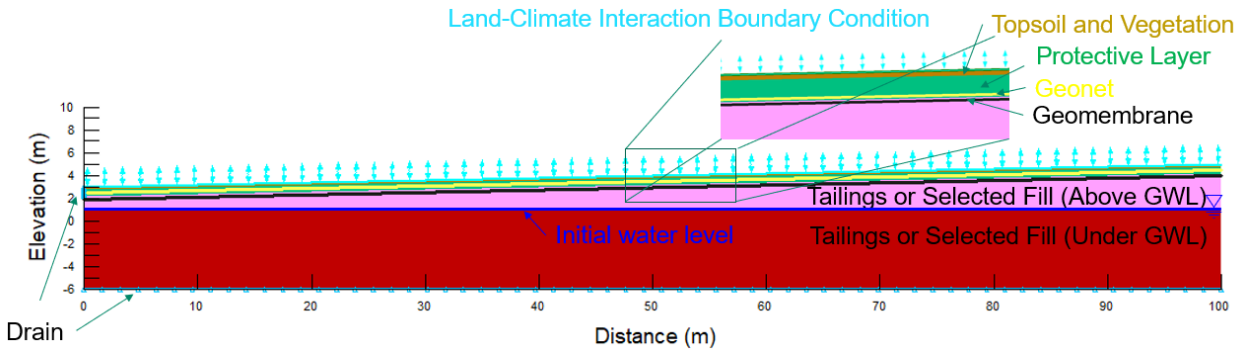

Figure 3: Two-dimensional cover model

Input parameters

The major input parameters for the model include climatic data, vegetation data, physical and hydrological properties of the cover material, fill and tailings. The climatic data for the cover design is mainly based on the available data from Environment Canada for the study site station for the past 30 years, including: air temperature (hourly); precipitation (daily); relative humidity (hourly); wind speed (hourly) and snow depth (daily).

Precipitation is the most important parameter for any cover system. The variation of total precipitation (monthly) for the last 30 years is presented in Figure 4. The average annual precipitation is presented in Figure 5.

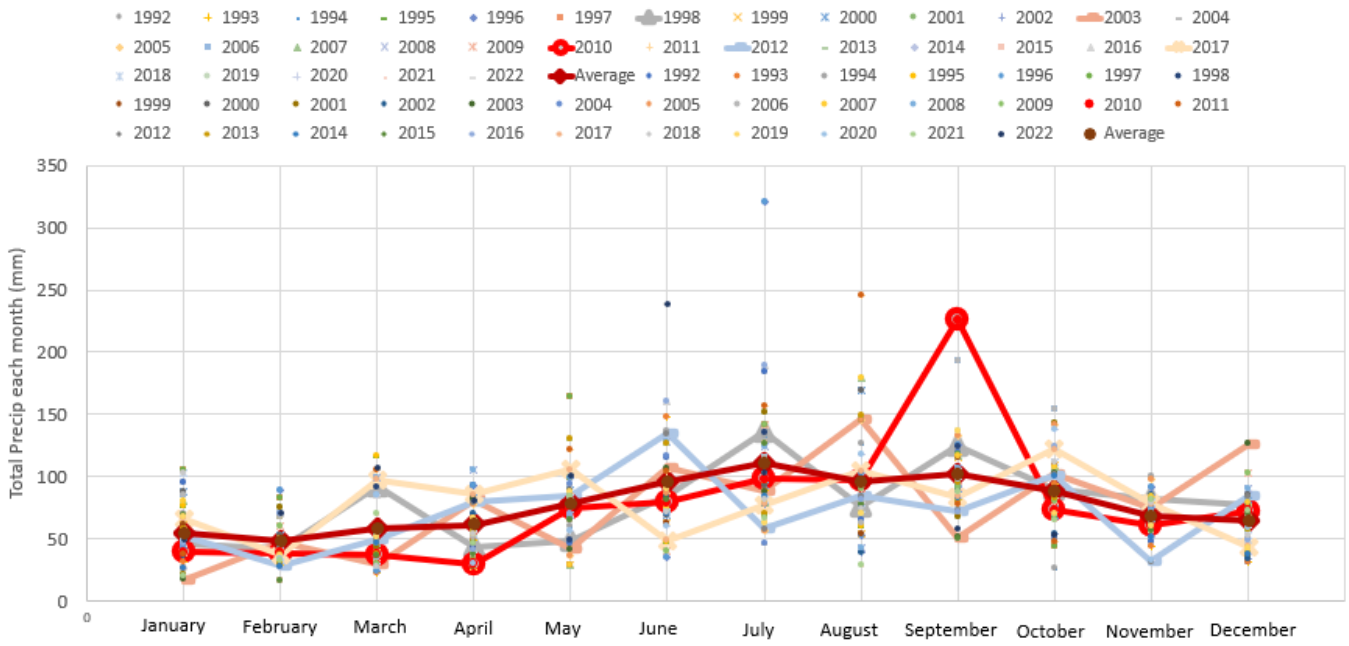

Figure 4: Monthly variation of total precipitation for the last 30 years

The vegetation data are shown in Table 1 and data are selected using a standard vegetation function stored in the SEEP/W database. The vegetation data was approximated from past studies based on expected vegetation type. The figures for leaf area index, root dimensions, and plant height are based on the assumption that the cover will evolve from grasses to shrubs. The plant moisture limit and normalized root density are derived from typical functions. The 75% soil cover fraction is a conservative assumption representing the minimum expected cover.

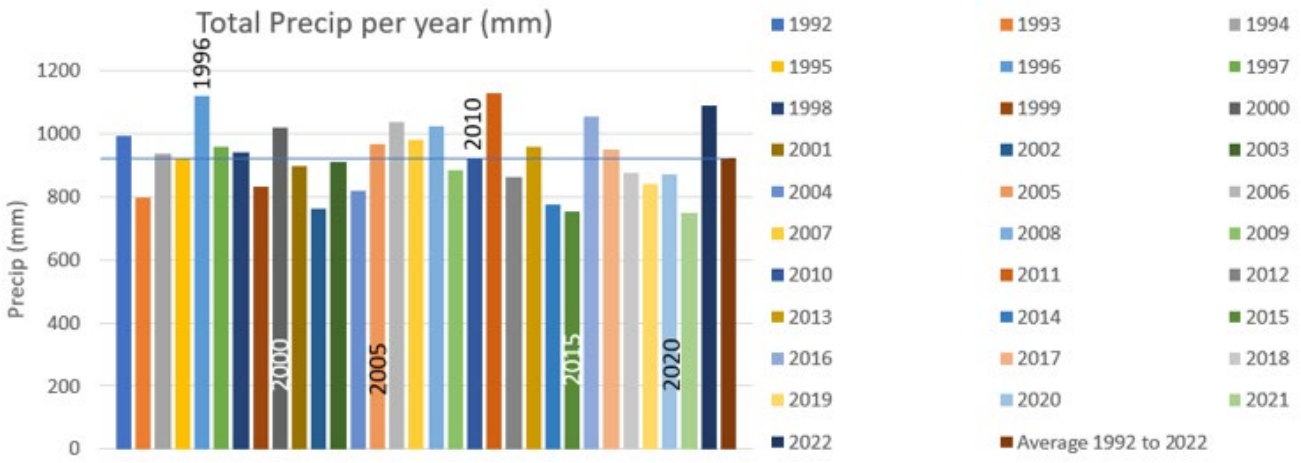

Figure 5: Variation of total annual precipitation from 1992 to 2022

Table 1: Boundary condition – vegetation data

Parameter	Input data
Leaf Area Index	Between 0 and 0.5
Root Depth	0.6 meter
Plant Moisture Limit	Limiting when water table is less than 10 m
Normalized Root Density	Linear decrease from 1 to 0
Soil Cover Fraction	0 for leaf index area less than 0.5 0.75 for leaf index area equal or more than 0.5
Vegetation Height	1.5 m

The main model parameters include hydraulic conductivity function, soil water characteristic curve, material density, hydraulic anisotropic condition, and material compressibility. The constitutive relations between water content, soil-water potential, and unsaturated hydraulic conductivity can be described using three different methods: Fredlund and Xing (1994), Green and Corey (1971), or van Genuchten (1980). Model input parameters were selected from previous modeling studies by others for the soil, fill, and tailings parameters and for geosynthetic layers from the literature.

The material parameters for the key layers are presented in Figure 6. The material parameters for the non-woven geotextile filter were not considered as this layer has no effect on the flow and is aimed at separating the protective layer from geonet only. The geonet was modeled with a saturated only material model with saturated lateral conductivity equal to 1 m/sec and a ratio of vertical to lateral conductivity (Ky/Kx) equal to 20. The geomembrane was modeled with a saturated only material model with saturated lateral conductivity equal to 1×10^{-12} m/sec and a ratio of vertical to lateral conductivity (Ky/Kx) equal to 1.

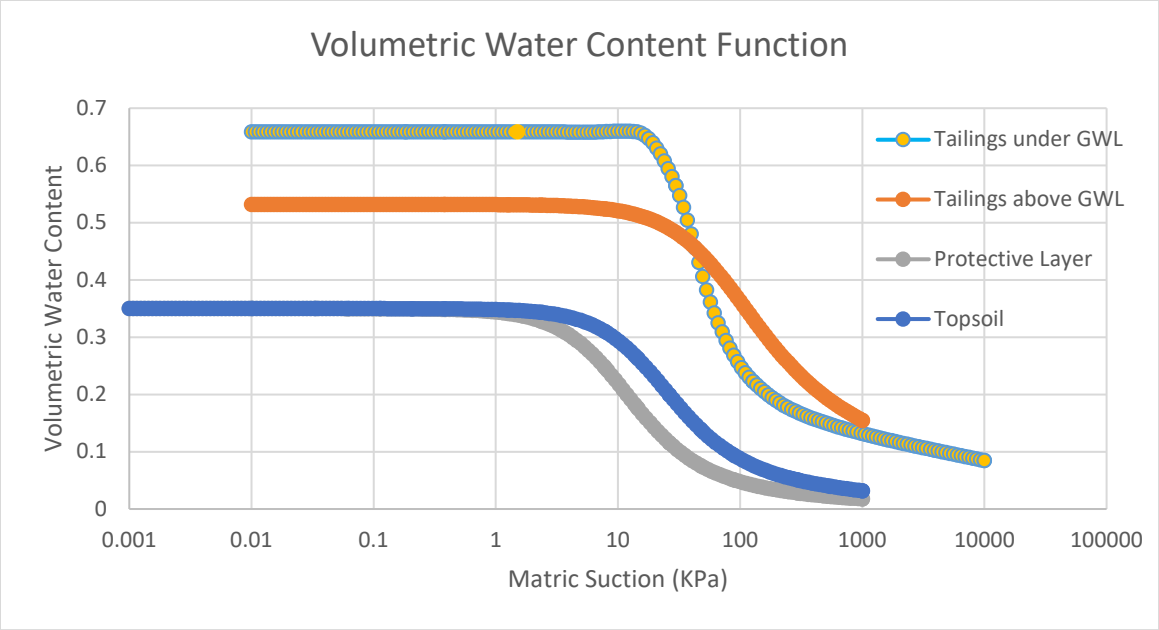

Figure 6a: Soil water characteristic curve

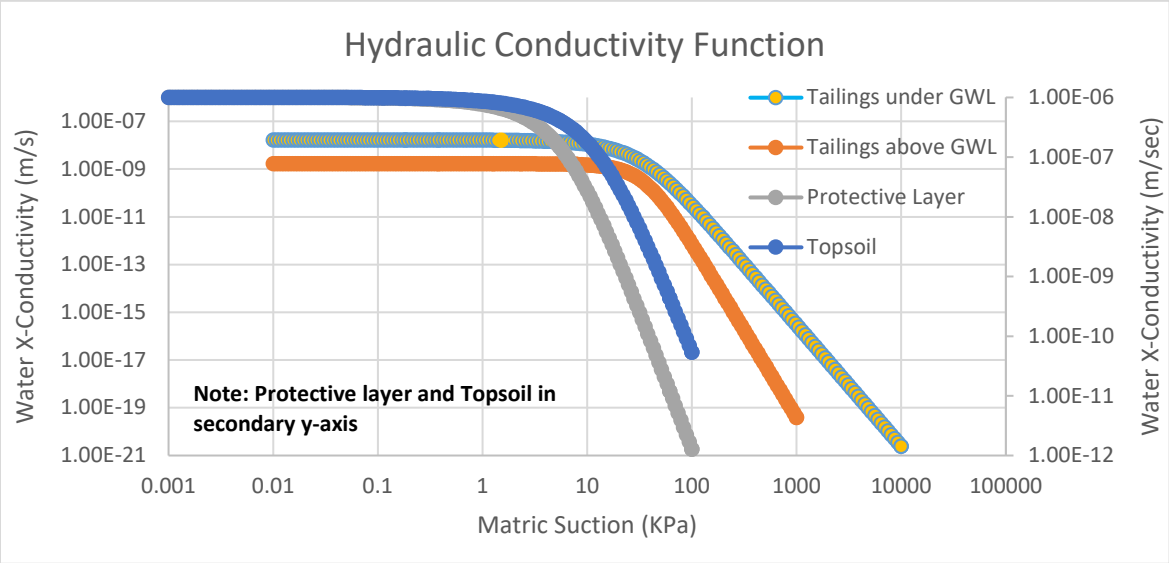

Figure 6b: Hydraulic conductivity function

The geomembrane and geonet were modeled using the interface element in SEEP/W. The thickness of each of them is 3 mm. The sensitivity analyses performed for key parameters are described in Table 2.

Table 2: Input data for sensitivity analyses

Analysis Case	Climatic Conditions	Protective Layer Thickness (inches)	Cover Slope (%)	Material Parameters (Geomembrane) Hydraulic conductivity – Thickness	Vegetation -Soil Cover Fraction (SCF)
1 (base case)	2010	24	2	1×10^{-12} m/sec-3 mm	0.75
2	2012	24	2	1×10^{-12} m/sec-3 mm	0.75
3	2017	24	2	1×10^{-12} m/sec-3 mm	0.75
4	2010	18	2	1×10^{-12} m/sec-3 mm	0.75
5	2010	30	2	1×10^{-12} m/sec-3 mm	0.75
6	2010	24	1	1×10^{-12} m/sec-3 mm	0.75
7	2010	24	3	1×10^{-12} m/sec-3 mm	0.75
8	2010	24	2	1×10^{-12} m/sec-3 mm	0.75
Y9	2010	24	2	1×10^{-12} m/sec-3 mm	0.9
10	2010	24	2	1×10^{-12} m/sec-3 mm	0.6
11	2010	24	2	1×10^{-12} m/sec-3 mm	0.4
12	2010	24	2	1×10^{-12} m/sec-one 1 cm hole/100 m	0.75
13	2010	24	2	1×10^{-11} m/sec-one 1 cm hole/100 m	0.75

19	2010	24	2	1×10^{-11} m/sec-3 mm	0.75
20	2010	24	2	1×10^{-13} m/sec-3 mm	0.75
21	2010	24	2	1×10^{-12} m/sec-3 mm-No Geonet	0.75
22	2010	24	2	24-inch clay layer; 1×10^{-9} m/sec	0.75
23	2010	24	2	1×10^{-12} m/sec-3 mm-Geonet 0.1 m/sec	0.75

Modeling results

The sensitivity analyses were performed for a one-year period to evaluate critical parameters and their effects on the net percolation. The sensitivity analyses were performed to study the effect of such parameters as climatic condition; hydraulic conductivity of geomembrane; defects on geomembrane; slope of the cover; vegetation parameter; protective layer thickness; and use of geonet. Three years of climate data from 2010, 2013 and 2017 were selected for the model to determine the baseline scenario. These three years have a total annual precipitation close to the average annual precipitation of the past 30 years. The water balance was also checked at the ground surface to verify the SEEP/W model. All three climate conditions showed similar net infiltration into the fill material below the cover. Based on this, the 2010 climate condition was selected as a baseline scenario for the sensitivity analyses as it showed slightly higher infiltration.

The infiltration results were evaluated for the different scenarios analyzed in the sensitivity analyses, and the percentage of annual infiltration with respect to annual precipitation was estimated for the different scenarios. Based on O'Kane and Ayres (2012), an infiltration percentage of lower than 5% is considered to

be very low for a cover design and between 5% to 15% is considered to be low. Results from the baseline scenario and the sensitivity analyses indicate that for most cases the infiltration is less than 5%. This cover option is considered adequate for this site.

Discussion and conclusion

The numerical model results showed that the selected cover option is suitable and effective for the study site. The sensitivity analyses showed that the infiltration is sensitive to climatic conditions, slope of the cover, hydraulic conductivity of the geomembrane, and defect in the geomembrane. Among the different parameters studied, the geomembrane permeability appeared to have the most effects.

The statistical analysis of the climatic data for the past 30 years was performed, and 3 representative years were selected for the sensitivity analyses. There was a relatively small variation in the annual precipitation of the past 30 years. As there was a relatively small variation in precipitation in each year, the sensitivity analysis with three different years' precipitation data showed minimal effects on the infiltration through the cover layer. Regarding the slope of the cover, it was found that less infiltration will occur on a steeper surface. Geomembrane degradation, modeled with an increase in permeability of an order of magnitude and/or defects with sizes ranging from 10 cm to 1 meter, which is deemed conservative, will also increase the infiltration. Vegetation parameters showed minimal to no effects on infiltration.

Based on the sensitivity analysis results, the model was developed to study the performance of the cover for a period of 60 years with an increase in average annual precipitation to consider potential climatic changes. For this scenario, it is assumed that the average annual precipitation will increase by 18% over the next 50 years.

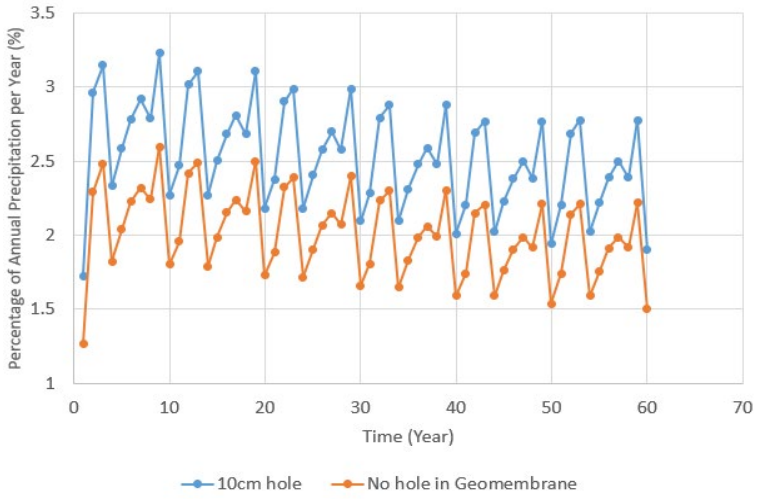

Figure 7: Percentage of infiltration with respect to precipitation

The long-term analysis results (Figure 7) showed that 1.5% to 2.5% of the annual precipitation may infiltrate through a cover with no liner defect and 2% to 3% infiltration may be expected in cover with a hypothetical liner defect (0.1% of the length), which is modeled with one 10 cm hole in every 100 m length of cover in a 2D condition. The infiltration was found to be decreasing over time over a period of 60 years, as presented in Figure 7.

The Evaluation of Nonlinear Dynamic Numerical Simulations of TSFs

Michael James, Agnico Eagle Mines, Canada

Abstract

The use of nonlinear dynamic (numerical) analysis (NDA) for the evaluation of the seismic stability of tailings storage facilities (TSF) is becoming more common due to rigorous standards that mandate the use of the maximum credible earthquake (MCE) or a 10,000-year recurrence interval in the presence of extreme consequences during operations or for closure. The increasing usage of NDA is also due to an increase in the capacity and expertise of consultants. However, there is considerable uncertainty in the review of NDA. There are few guidelines and no industry standards for the execution and review of NDA for TSF. As a result of this, as well as the very complex nature of NDA, the reports for such analyses may lack sufficient information to be verified and the reviewers must rely on the expertise and judgement of the consultant. Furthermore, experienced numerical modelers are relatively rare, and many modelers are specialized and lack experience and judgement in other relevant aspects of geotechnical engineering. This paper presents, in terms accessible to technical professionals who are not modelers, information and guidelines to assist in the understanding and review of NDA for TSF. This is accomplished with an explicative NDA of an example TSF. Basic guidelines for the evaluation of NDA studies for TSF are provided.

Introduction

Historically, seismic activity has not been a primary cause of the failure of tailings storage facilities (TSF). However, when it has been a cause, the consequences have been devastating. Of particular note is the El Cobre Tailings Dam failures (Chile, 1965), when three upstream raised tailings dams failed as a result of the Valparaíso earthquake (moment magnitude, M_w 7.5). The flow of 2.25 M m^3 of liquefied tailings destroyed the town of El Cobre and more than 200 lives were lost (Dobry and Alvarez, 1967). Due to the indefinite lifespans of TSF and the consequences of failure, it is imperative that all TSFs be designed or upgraded to withstand reasonably anticipated seismic loadings, even in areas of low seismicity.

This paper presents the nonlinear dynamic (numerical) analysis of an example TSF in an explicative manner to inform technical professionals not familiar with such analyses and to provide basic guidelines for the review of technical studies on this subject.

The effects of earthquakes on TSFs

Locally, earthquakes induce transient, alternating three-dimensional accelerations in the bedrock underlying a TSF. These accelerations (ground motions) are transmitted upwards from bedrock, through any overburden, and through the TSF. In practice, the ground motions are separated into three orthogonal components: 1) vertical, 2) horizontal and parallel to the alignment of a perimeter dike, and 3) horizontal and perpendicular to that alignment. The ground motion perpendicular to the alignment is of concern because it acts to reduce physical stability ($F=M \cdot A$). Generally, the most important effects are in the downstream direction. However, for dikes with upstream raises, the stability in the upstream direction may be of concern.

Within saturated, contractive materials, such as loose tailings, silts or sands, the ground motion may induce the generation of excess pore water pressures (epwp) and, ultimately, liquefaction. The loss of stiffness and strength associated with epwp generation and liquefaction can result in the deformation or failure of a perimeter dike.

Following shaking, the dissipation of epwp in an unfavorable direction can induce destabilizing seepage pressures. This is a postulated cause of failure of Dike No. 2 of the Mochikoshi TSF in Japan following the 1978 Izu-Ohshima-Kinkai earthquake (M_w of 7) (Ishihara, 1984).

Methods of evaluation

Typically, the seismic performance and stability of a TSF are evaluated using analytical methods consisting of, for each perimeter dike, a) a site response analysis, b) a simplified liquefaction analysis, c) a pseudo-static or post-liquefaction analysis, d) an estimation of permanent displacements, if applicable, and e) an evaluation of the results. However, in most instances these methods do not well represent the effects of earthquakes on TSFs. Some important phenomena are ignored, while others are treated in an overly simplistic or unrealistic manner (James et al., 2022). For example, the results of simplified liquefaction analysis in level ground conditions where there are no initial static shear stresses (e.g., within a TSF away from the influence of the perimeter dikes) agree reasonably well with numerical analysis (James and Aubertin, 2016), but tend to significantly differ near dikes, particularly below upstream raises (James 2024a, 2024b). Unrealistically, the pseudostatic method of stability analysis replaces the transient, random horizontal accelerations of an earthquake with a "static" horizontal acceleration that tends to be much more detrimental to stability; hence, there is significant conservatism that can lead to overdesign.

Generally, the results of the analytical methods are conservative. However, when a phenomenon that is critical to the seismic performance and stability of a particular dike is not represented, the results of these methods may be misleading.

The Mile High TSF

The Mile High TSF is in a board alluvial valley northeast of Denver, Colorado and was in operation from 1996 to 2014. It retains nonreactive, slurry-deposited tailings from hard rock gold mining.

Locally, the topography is relatively flat. Subsurface conditions consist of 1 to 2 m of dense alluvium (clayey sand with gravel) over bedrock of hard, relatively intact siltstone and sandstone. The groundwater table is near the surface.

The TSF is oval in plan with dimensions of 600 m north-south by 300 m east-west. The perimeter dikes are Dike 1 on the west side and Dike 2 on the east. An east-west cross-section of the TSF is shown in Figure 1.

Dike 1 is composed of a 5-m-high starter dike of compacted fill (clayey sand with gravel). The dike is founded on the native alluvium and is served by 1-m-thick granular subdrains at regular intervals. The upstream (u/s) and downstream (d/s) slopes are at 1.5:1 (H:V) and 2:1, respectively. Two 4-m-high upstream raises of compacted tailings were constructed from the starter dike. Working pads of tailings mixed with waste rock were placed on the tailings beach, prior to the construction of the raises. The inclinations of the slopes of the raises are like those of the starter dike.

Dike 2 is a rockfill structure with slopes of 1.5:1 u/s and 2:1 d/s. The u/s slope has a 1-m-thick transition filter zone. This dike is founded directly on bedrock.

The tailings in the TSF were deposited by end-of-pipe from around the perimeter to a height of 17 m, leaving a freeboard of 1 m. The surface of the tailings slopes downwards at about 1% from the perimeter towards the center.

As noted, tailings deposition ended in 2014. In 2016, a 1-m-thick multi-layer cover was placed on the tailings for closure.

The phreatic level within the TSF is relatively high, and in the long term is expected to vary seasonally from 3 to 6 m below the surface, including considerations for climate change.

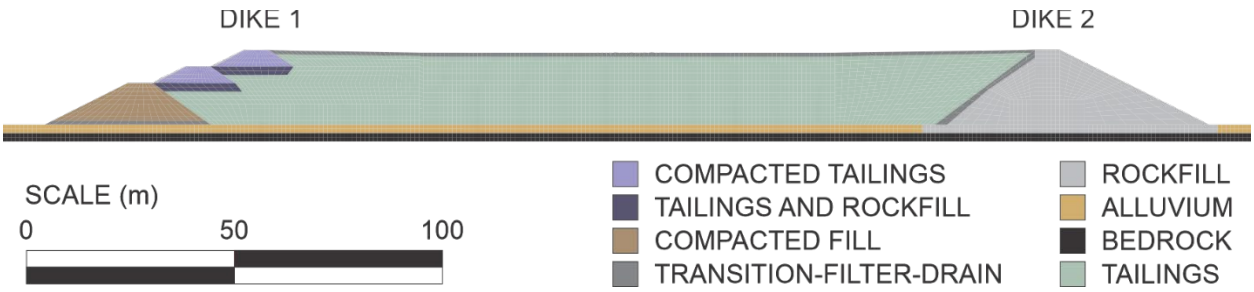

Figure 1: Cross-section of the Mile High TSF

Design Earthquake Ground Motion

For closure, the Design Earthquake Ground Motion (DEGM) corresponds to a recurrence interval of 10,000 years. The parameters for the DEGM were obtained using the ASEC Hazard Tool/ Standard ASCE/SEI 7-22 (ASCE, 2024) for Soil Class A (Hard Rock). The peak (horizontal) ground acceleration (PGA) of 0.226 g and spectral acceleration (Sa) envelope are shown in Figure 2. The PGA is not actually associated with a period, but is shown at a period of 0.001 s for convenience. The results of deaggregation analysis (Figure 3) indicate a modal magnitude-distance pairing of 5 (M_w) and 5 km (ASCE, 2024). The Arias intensity of the pairing varies from 0.01 m/s to 0.5 m/s for one horizontal direction (Bahrampouri et al., 2020).

The S_a envelope represents the probable maximum values of spectral acceleration from many different magnitude-distance pairings from different regional sources. It does not represent a single earthquake. The modal magnitude-distance pairing is the most probable pairing of those considered.

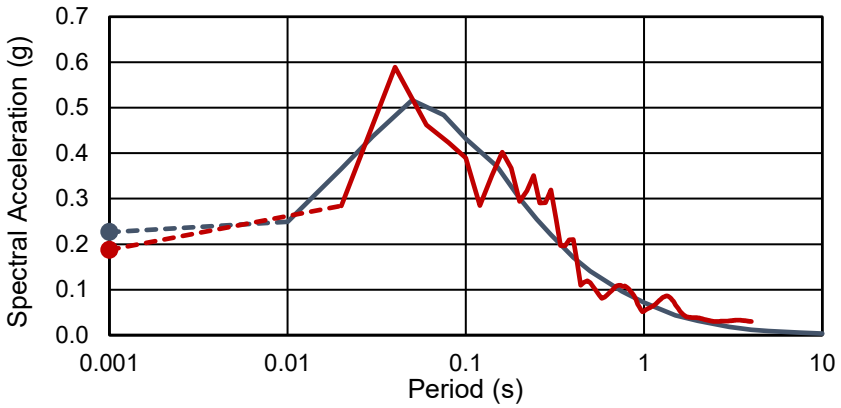

Figure 2: Spectral acceleration envelope of DEGM 5 % damping (blue) and spectral acceleration graph of ground motion H4-04 (red)

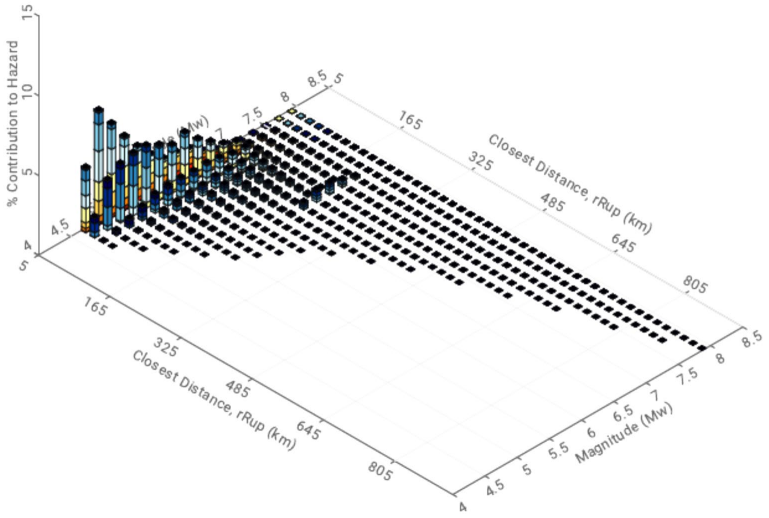

Figure 3: Graphic of deaggregation analysis (from ASCE, 2024)

Nonlinear dynamic analysis of the TSF

This section presents the NDA of the TSF. It should be noted that the methodology employed in NDA varies depending on the particularities of each case as well as the objectives of the analysis. There is no one-size-fits-all method.

Methodology

This study employed version 8 of the FLAC finite differences program (Itasca, 2016) with the dynamic and user-defined model options. The analyses were conducted in plane strain mode.

The methodology was as follows:

1. Development of grid (geometric model), establishment of mechanical boundary conditions, and assignment of constitutive models with associated material properties.
2. Analysis for mechanical equilibrium.
3. Assignment of flow boundary conditions and initial pore water pressures (to facilitate computation).
4. Analysis for flow equilibrium.
5. Analysis for coupled (mechanical and flow) equilibrium (static condition).
6. Verification of static stresses and pore water pressures within the model.
7. Dynamic analysis by the application of dynamic boundary conditions and of a ground motion record to the bottom of the model.

Geometric model, constitutive models and material properties

A geometric model of quadrilateral elements, nominally 1-m-square, was created. The 1-m-height of the elements was sufficient for the faithful transmission of the seismic waves through the model per Itasca (2016) and provided sufficient granularity for evaluation of the results. In some less critical areas, such as the shoulders of Dike 2, larger elements were used for convenience. The use of larger elements in these areas did not affect the results. The geometric model is shown in Figure 4.

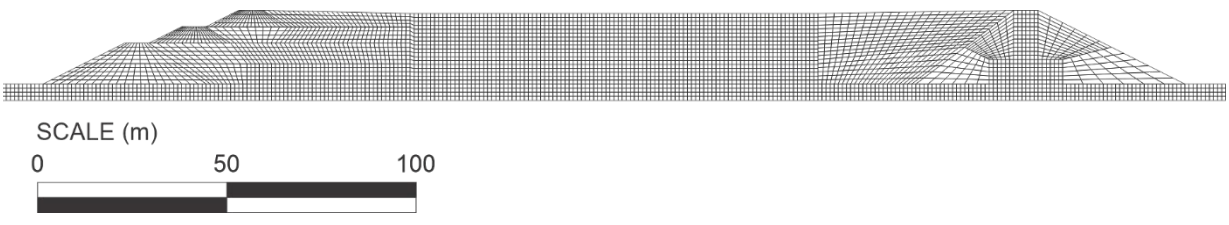

Figure 4: Geometric model of the TSF

For bedrock, a shear wave velocity, Vs, of 1,500 m/s and a total unit weight, γ, of 26.5 kg/m^3 were assumed. As the bedrock is unyielding relative to the expected loads, the elastic model was used to simulate its behavior. The bedrock was given a hydraulic conductivity of 1×10^{-8} cm/s.

As tailings deposition ended in 2014 and a granular cover was placed in 2015, it is assumed that the tailings are, or will soon be, normally consolidated. Accordingly, the properties of the tailings were derived from in-situ testing as well as laboratory testing of consolidated specimens (James, 2009). Even when normally consolidated, the tailings will be contractive and subject to excess pore water pressure (epwp) generation and liquefaction where saturated. Due to the potential for epwp generation and liquefaction, the UBCSAND constitutive model (Beaty and Byrne, 2011) was used for the tailings. The model parameters were obtained by numerically simulating the dynamic laboratory testing (James, 2009; James and Aubertin, 2016). These parameters are an average standard penetration test blow count, $(N_1)_{60\text{-}CS}$, of 10 blows/30 cm, a dry unit weight γ_{DRY} of 23.1 kN/m^3, an effective angle of internal friction, ϕ', of 35° and a porosity, n, of 0.62. The high values of γ_{DRY} and ϕ' of the tailings are a result of their mineralogy (specific gravity of 3.8). To simulate the heterogenicity typical of tailings, even after consolidation, a normal distribution factor of 2 blows/30 cm was used. As this is the primary variable with respect to epwp generation and liquefaction, it creates some randomness in the response of the individual elements of tailings. The tailings were assigned a hydraulic conductivity of 1×10^{-10} cm/s.

The raises of Dike 1 are composed of compacted tailings; this material was modeled similarly to the retained tailings but with an $(N_1)_{60\text{-}CS}$ value of 20 blows/30 cm and no randomization.

The properties of other materials are given in Table 1. The properties are from published sources and the author's experience. The Mohr-Coulomb (elastic-plastic) model was used for these materials.

Table 1: Material properties

Property	Rockfill	Alluvium	Compacted Fill	Filter-Transition	Rockfill-Tailings
γ_{DRY} (kN/m^3)	23.5	22.6	22.6	22.6	23.5
ϕ'	48°	35°	35°	34°	35°
c' (kPa)	-	50	50	-	-
n	0.15	0.15	0.15	0.15	0.1
Vs (m/s)	600	400	400	325	300
μ	0.2	0.25	0.25	0.25	0.3
K (cm/s)	100	1×10^{-5}	1×10^{-5}	1	1×10^{-4}

Where γ_{DRY} is dry unit weight, ϕ' is effective friction angle, c' is effective cohesion, n is porosity, V_s is shear wave velocity, μ is Poisson's ratio, and K is hydraulic conductivity.

A general shear modulus reduction (versus shear strain) curve (Seed and Idriss, 1970) was applied to all materials except for bedrock and the retained and compacted tailings. In FLAC, damping is estimated from the shear modulus reduction curve. This was not applied to bedrock as it is considered rigid (no appreciable shear strains) with respect to the applied loading. Nor was it applied to the tailings because shear modulus reduction and damping are implicit in the UBCSAND model. Shear modulus reduction curves are typically horizontal at very low strains, so it is necessary to include a small amount of Rayleigh damping. Through trial and error, it was found that 0.0125 of Rayleigh stiffness suited this purpose, while allowing faithful transmission of the ground motion through the model, particularly the bedrock.

Selection of ground motions

Due to the considerable variation and uncertainty in ground motions, numerical analysis should consider at least five ground motions that correspond to different magnitude-distance pairings and sources, if applicable, that satisfy the DEGM in terms of the spectral acceleration envelope and the intensity of earthquake loading as measured by the Arias intensity, I_x, and the anticipated predominant period and durations of shaking.

The Denver region has moderately low seismicity and produces earthquakes of relatively high frequency; as a result, there are very few, if any, recorded ground motions that could be reasonably scaled to simulate the DEGM. For this paper, several ground motions were created and processed using software by SeismoSoft (2022). Ground motion H4-04 (Figure 5) was then selected for use in this example. This ground motion (GM) has a PGA of 0.188 g, an Arias intensity, I_x. of 0.251 m/s, predominant and mean periods of 0.04 s and 0.22 s, respectively, a duration of 12 s, and a significant duration (between 5 and 95% of I_x) of 6.81 s. The spectral acceleration graph of the GM is shown in Figure 5.

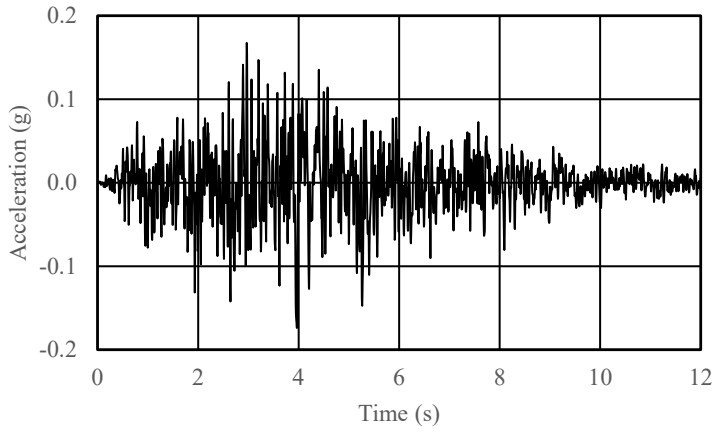

Figure 5: Ground Motion H4-04

Site response

How well a model transmits acceleration is fundamental. Given that bedrock is assumed to be rigid and unyielding, the accelerations should not be amplified or damped within the bedrock. The accelerations measured at the top of the bedrock should be nearly identical to those input at the bottom of bedrock. Figure 6a presents the input and measured accelerations. They are nearly identical, confirming faithful transmission. Had they been different, then the TSF would not have experienced the DEGM.

Figure 6b shows the accelerations in the center of the TSF near the surface. Note the appreciable amplification, which is expected in soft soil, at least until the generation of significant epwp.

The accelerations on the crests of Dikes 1 and 2 are shown respectively in Figures 6c and 6d. The ground motion within the dikes was substantially amplified. Ground motions are always amplified by embankments, typically by a factor of 1.5 to 2.5, increasing with stiffness and steepness. The accelerations on the crest of Dike 1 are a bit more chaotic due to its reliance on the tailings for support, which produces significant interaction between the dike and the tailings.

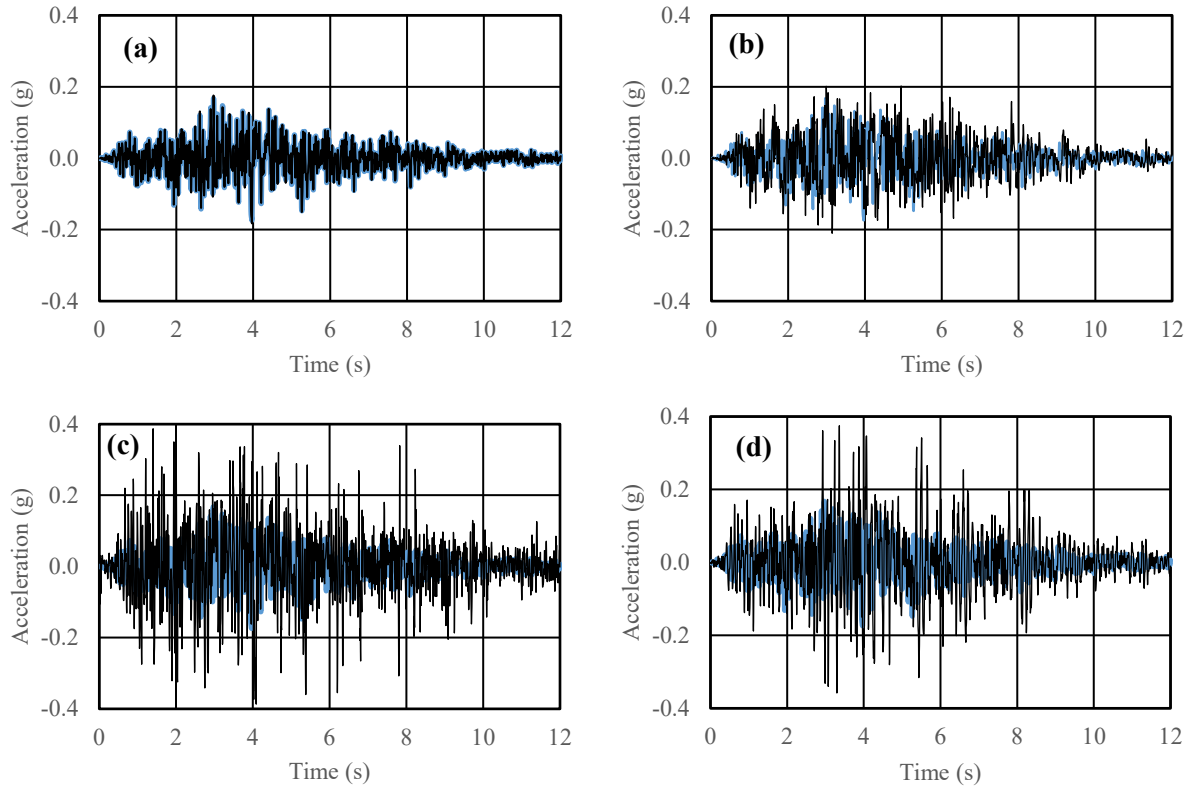

Figure 6: Accelerations – (a) GM H4-04 (blue) and measured on top of bedrock (black), (b) GM H4-04 (blue) and measured near top of tailings (black), (c) GM H4-04 (blue) and on crest of Dike 1 (black), and (d) GM H4-04 (blue) and measured on crest of Dike 2 (black)

The response of the tailings

Figures 7a, 7b, and 7c respectively present the accelerations, cyclic stress ratio, CSR, and epwp ratio, r_u, in the center of the TSF. The accelerations and CSR are at mid-height and the r_u is at 0.25, 0.5, and 0.75 of the height, H, of tailings. The CSR is the ratio of the applied shear stress on an element of soil and is mostly due to the applied accelerations (which induce shear stress) but may also be affected by stress redistribution during shaking. The parameter r_u is the ratio of the developed epwp to the initial effective vertical stress. It is zero at the start of shaking and increases as the application of CSR triggers a contractive response causing epwp generation.

The accelerations indicate appreciable amplification during shaking, as expected. The amplitudes of CSR are considerable, generally varying from about 0.05, where epwp generation typically commences, to over 0.1, where several cycles will induce liquefaction, which is defined here as an r_u of 0.7 or more. The graphics of r_u indicate that liquefaction occurred in the upper half of the tailings by the 5th second of shaking but did not occur in the lower half.

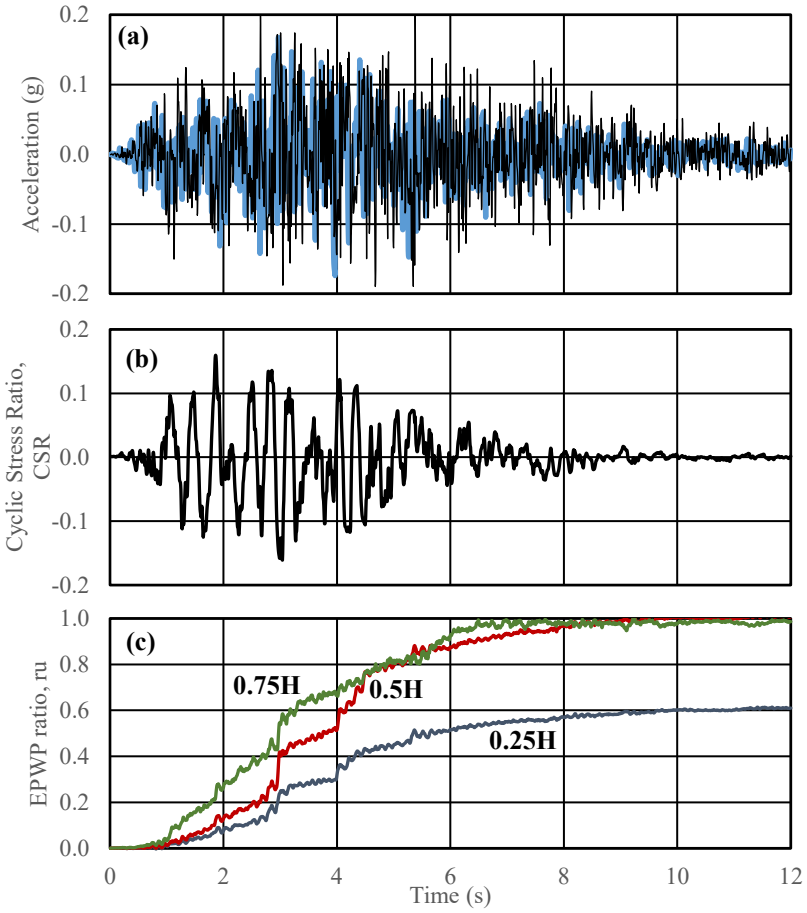

Figure 7: (a) GM H4-04 and accelerations in center of tailings at mid-height (h=0.5H), (b) CSR in center of tailings at h=0.5H, and (c) development of r_u at 0.25H, 0.5H and 0.75H

Displacements of the crests of the dikes during shaking

The horizontal (x) and vertical (y) displacements of the crests of the dikes during shaking are shown in Figure 8, where x and y are positive to the right and up, respectively. The crest of Dike 1 displaced about 10 cm d/s by the 5th second, then reversed by 5 cm before moving d/s for a displacement of about 12 cm by the end of shaking (EoS). The crest of Dike 2 followed a similar path, except that the displacement was initially u/s and then changed to d/s, with about 2 cm of d/s displacement by EoS. The vertical displacements of the crests were relatively uniform and were about 5 cm downwards for Dike 1 and 0 for Dike 2 at EoS.

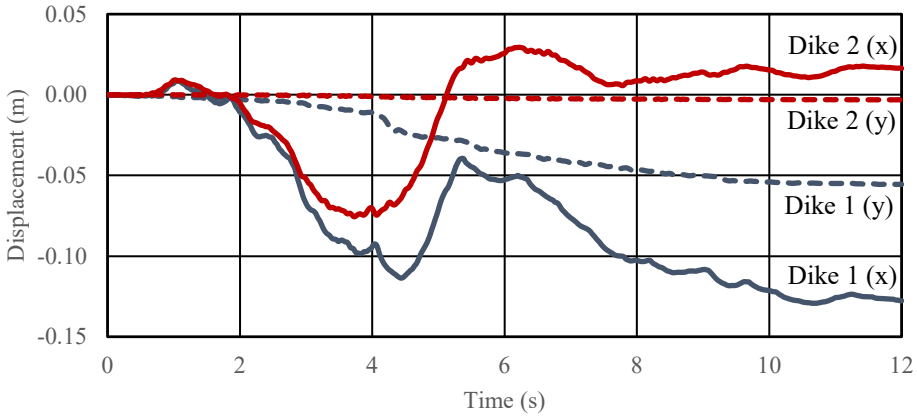

Figure 8: Displacements of the crests of Dikes 1 and 2

Conditions at the end of shaking

As shown in Figure 9 (top), there was extensive liquefaction in the upper half of the tailings. The generation of epwp and liquefaction was favorably affected by the presence of the upstream raises of Dike 1, due to the presence of initial static shear stresses. Near Dike 1, interaction between the dike and the tailings, due to their different periods, resulted in additional liquefaction at depth.

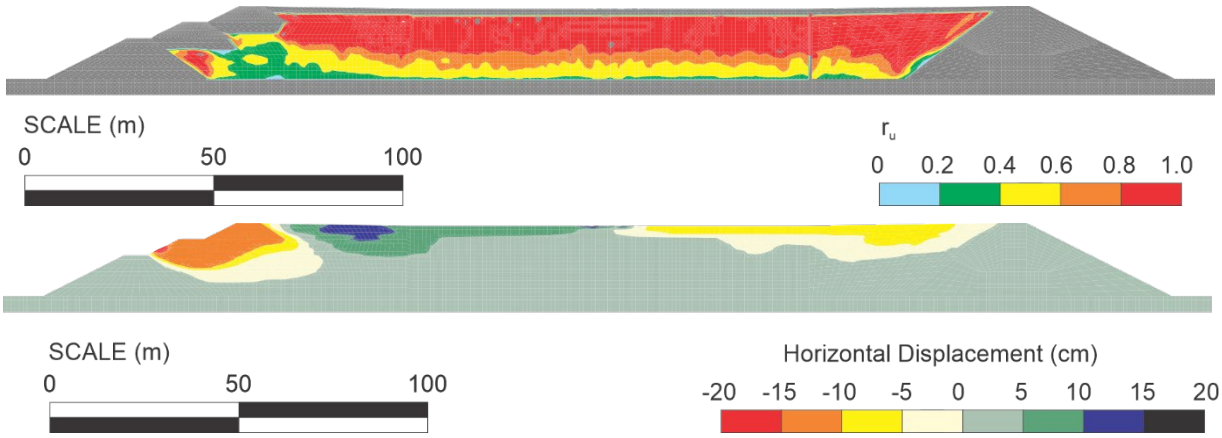

Figure 9: Conditions at the end of shaking: (top) excess porewater pressure ratio, and (bottom) horizontal displacements

Evaluation of performance and stability

Using NDA, the performance and stability of a TSF is evaluated based on the magnitudes and patterns of displacements at EoS, the magnitude and pattern of nodal velocities at EoS, or the occurrence of failure (excessive deformation) during shaking. When excessive deformation occurs during shaking, execution is stopped due to numerical instability. However, the magnitude and pattern of velocities when execution stops are usually sufficient to determine failure.

In many cases, the velocities at EoS may be indicative of continued displacement and possible failure. In such cases, a post-shaking analysis should be conducted by continuing the NDA with appropriate changes to the constitutive models or parameters in elements with liquefaction.

Depending on the configuration of the perimeter dike, epwp development at EoS may indicate a potential for epwp dissipation to cause failure. In these cases, an appropriate post-shaking analysis is needed.

Basic guidelines for review

Basic guidelines for the review of the NDA of a TSF are:

1. Life cycle considerations: The analysis should be focused on operational (current) or closure (long-term conditions).
2. The material properties should correspond to the phase in the life cycle under consideration.
3. Plots of vertical stresses and pore water pressure in the static phase, before shaking, should be provided for verification.
4. Ground motions records should be selected based on agreement with different ranges of periods of the spectral acceleration envelop of the DEGM (e.g., 0.1 to 1 s), and the anticipated Arias intensity corresponding to a given moment-distance pairing. The PGA is not a significant factor in NDA. Also, spectral matching is not recommended because the resulting ground motions are generally overly intense.
5. The constitutive models used should be capable of reasonably well simulating the behaviors of concern, for example excess pore water pressure generation and liquefaction, and this should be demonstrated by appropriate examples or the simulation of laboratory testing.
6. The ability of the model to reasonably well transmit accelerations through bedrock and through the model should be demonstrated graphically.
7. Plots of acceleration, cyclic stress ratio, and excess pore water pressure ratio at key locations should be provided for verification.

8. Plots of the condition of the model at the end of shaking, including excess pore water pressure ratio, horizontal and vertical displacement and horizontal velocity should be provided as a basis for evaluation and used to determine if post-shaking analysis is required.
9. When post-shaking analysis is conducted, it is important to establish the objective, i.e., verify that velocities will decrease with time, determine effects of post-shaking dissipation of epwp, or estimate post-shaking consolidation settlements, and modify the constitutive models and parameters as necessary.

Conclusion

Numerical modeling, particularly dynamic numerical modeling, is not an exact science. At best it is a simplified mathematical expression of very complex and interrelated phenomena, and thus cannot provide precise predictions of behaviors, strains, or displacements. What it provides is a better understanding of the various phenomena and information for comparison, to which engineering judgement must be applied.

Modeling of Embankment Scour Caused by a Tailings Pipeline Break and Potential Risk of Dam Breach

Angus Rose, WSP, Australia
Mateus Nogueira, WSP, Australia
David Accadia, WSP, Australia

Abstract

Slurry pipelines for tailings facilities can deliver tailings slurry at high pressures and flowrates. For arrangements that require discharge from an embankment, a pipe break could result in a significant scour risk to the embankment. If the break goes unnoticed and tailings delivery is not stopped, the subsequent erosion could lead to a breach of the embankment and loss of containment.

Computational Fluid Dynamics (CFD) software was used to model scour erosion of a hypothetical compacted rockfill embankment due to pipeline break at the upstream crest edge, and consequent flow of a high mass concentration tailings slurry onto the upstream face. Rheological data for the tailings slurry was used to characterize it as a non-Newtonian fluid. Geotechnical properties assigned to the embankment fill were key inputs for the erosion modeling. The modeling, undertaken for an operating facility, showed that scour erosion can progress through an embankment in a matter of hours, leading to a substantial loss of freeboard and therefore a potential embankment breach. Outcomes of the modeling prompted the installation of monitoring instruments on the embankment for early detection of a pipe break.

Introduction

This paper presents an analysis of pipe-break induced erosion of a hypothetical compacted rockfill embankment due to a failure of a tailings delivery pipeline. Many tailings storage facilities (TSFs) operate under an arrangement that requires tailings slurry deposition from an embankment, into the tailings impoundment area. For these facilities, a rupture/break of the tailings delivery pipeline could represent a large risk of erosion of the embankment, if the break were to go unnoticed, potentially resulting in loss of freeboard and loss of containment.

The scenario summarized in this paper was for a pipeline break at the crest of an embankment, with uncontrolled tailings slurry flow, causing scour of the crest and upstream face.

Assessment characterization

Embankment and pipeline layout

The tailings delivery pipeline was modeled along the upstream crest edge of the embankment, positioned about 1.2 m from the edge, with the center of the pipe assumed to be about 0.4 m above the embankment crest, allowing for pipe supports. See summary of the pipeline parameters adopted for the assessment in Table 1.

Table 1: Adopted tailings delivery pipeline parameters

Parameter	Value
Pipe internal diameter (mm)	292
Tailings slurry flow rate (m^3/hr)	600
Tailings slurry flow rate (m^3/s)	0.17

Embankment geometry and materials

The embankment was formed with compacted rockfill, with a 0.5-m-thick layer of compacted screened rockfill on the upstream face to form a bedding layer for a geosynthetic liner. The embankment geometry is summarized in Table 2 and is shown in cross-section in Figure 1. A tailings surface 6.5 m below the embankment crest was adopted for analysis and instantaneous failure of the geosynthetic liner was assumed.

Table 2: Embankment geometry

Parameter	Value
Upstream slope gradient of embankment	2.7H:1V
Embankment crest width (m)	8

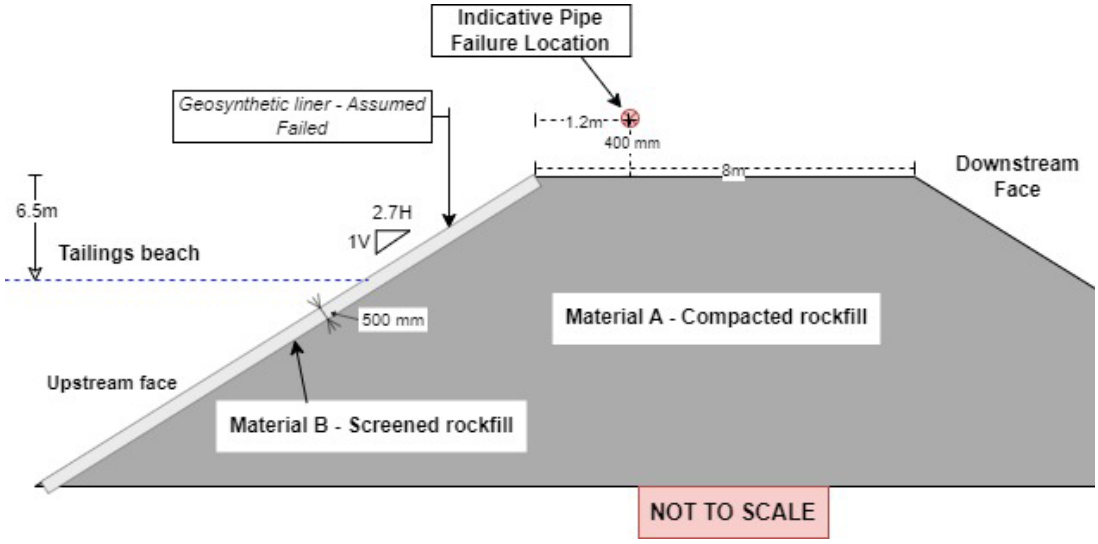

Figure 1: Cross-section of embankment arrangement for pipe break modeling

The fill materials in the embankment are as follows:

1. Material A – Compacted Rockfill: Well-graded, particles typically sand to cobble size. Soil (sand and gravel) content up to 70% by volume.
2. Material B – Screened Rockfill**:** Well-graded mine waste rock, with particles smaller than 50 mm. Characterized as sand and gravel.

Fill material parameters for analysis

The materials were assigned erodibility classifications according to the method of the U.S. Bureau of Reclamation (USBR), for comparison to modeled erosion rates (U.S. Department of the Interior – Bureau of Reclamation, 2019). These erodibility classifications, along with key material parameters that were used to characterize the embankment materials in the hydraulic modeling software, are summarized in Table 3.

Table 3: Embankment material parameters for assessment

Material	Maximum particle size (mm)	Particle density (t/m³)	Representative D_{50} (mm)	Angle of repose (°)	Layer thickness (mm)	USBR erodibility classification[1]
Material A	130	2.8	20, 40 (Note)	33	n/a	Medium to Low (IV)
Material B	50	3	10	33	500	Medium erodibility (II)

Note 1: Material A split into soil and rock component for this assessment (soil component, D_{50} = 20 mm, rock component D_{50} = 40 mm)

Tailings flow characteristics

Newtonian vs. non-Newtonian flow

Analysis of the flow of tailings slurry is generally more complex than the flow of water. Depending on the solids concentration of the slurry, the flow can possess Newtonian (e.g., water) or non-Newtonian (e.g., mud or tailings) characteristics. For Newtonian fluids, the ratio of shear stress to shear rate is constant for varying shear rates, resulting in constant viscosity. For non-Newtonian fluids, (e.g., tailings) and other fluids that do not obey Newton's Law of Viscosity, the relationship is not constant; as such, this relationship is called apparent viscosity, where viscosity changes with shear rate. This is illustrated in Figure 2 for five typical fluid types (Kilgore and Cotton, 2005).

Tailings typically exhibit yield-pseudoplastic (shear thinning) behavior, where apparent viscosity decreases with increasing shear rate. Additionally, these fluids require a minimum shear stress (yield stress) before flow is initiated. As these characteristics are dependent on the type of tailings and the concentration of solids present, the tailings can exhibit very different behavior to water at increased shear rates and should therefore be considered when modeling the flow of tailings in hydraulic analyses.

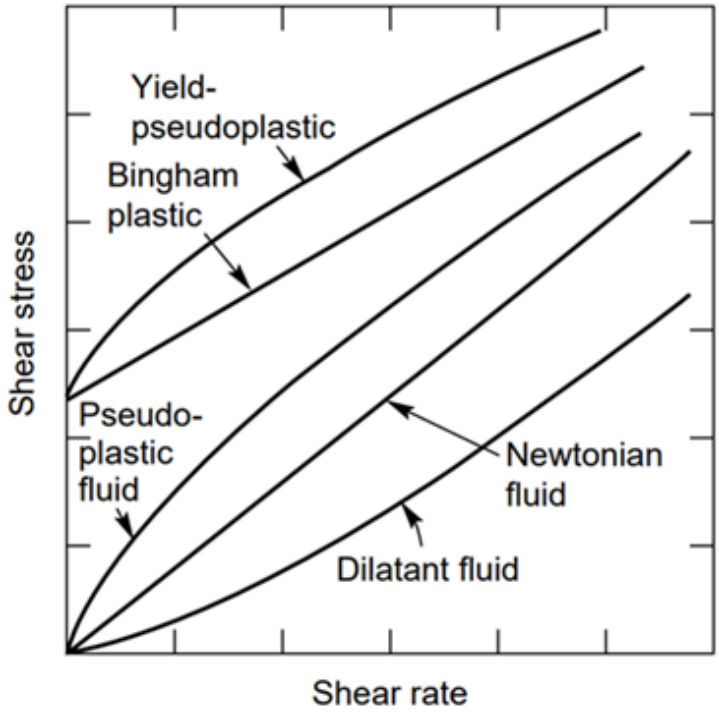

Figure 2: Illustration of shear stress as a function of shear rate (Chabbra and Richardson, 1999)

Tailings slurry rheology data

Tailings slurry rheology parameters adopted for analysis are summarized in Table 4.

Table 4: Tailings slurry rheology data

Parameter	Tailings rheology
Solids particle density, ρ_s (kg/m^3)	3,300
Process water density, ρ_{pw} (kg/m^3)	1,070
Bingham yield stress, τ_0 (Pa)	$\tau_0 = 16{,}100\ C_m^{13.5}$
Bingham plastic viscosity, μ_{BP} (Pa.s) (Note)	$\mu_{BP} = 2.08\ C_m^{8.45}$
Tested range of slurry solids concentrations, C_m (% w/w)	50.4% to 68.8%
Slurry solids concentration adopted, C_m (% w/w)	63%

Note: μ_w refers to the viscosity of water at 24° C (0.000916 Pa.s)

Yield stress (τ_y) and plastic viscosity (μ_0) data for the tailings are presented for a range of solids concentrations by mass in Figure 3. The fit lines included represent the equations noted in Table 4 for Bingham yield stress and Bingham plastic viscosity, respectively.

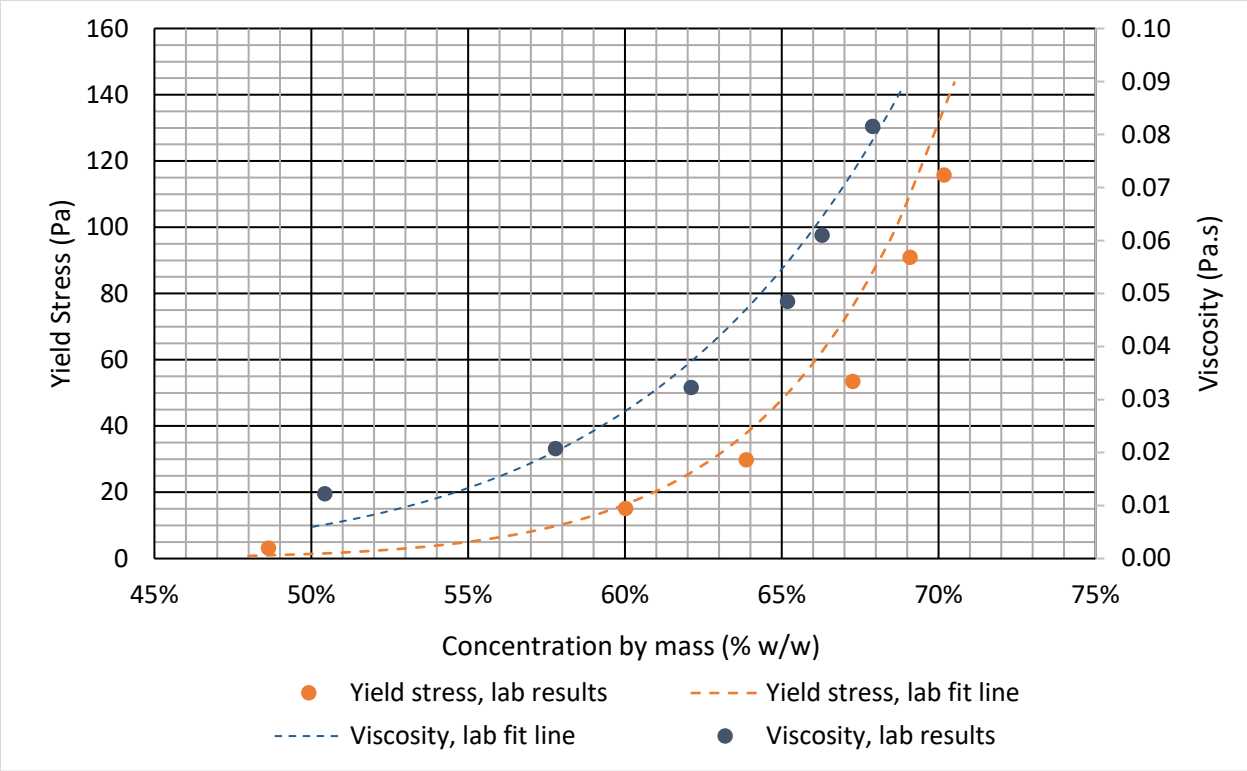

Figure 3: Yield stress vs. mass concentration, and viscosity vs. mass concentration for tailings slurry sample

Adopted tailings rheology model

The Bingham plastic model was adopted to model the tailings slurry in this assessment. In the Bingham model, the fluid is assumed to have a yield stress, which must be exceeded before the fluid will flow. Once this stress is met the fluid will flow with a constant viscosity. Mathematically, the Bingham plastic model can be expressed as the following:

$$\tau = \tau_0 + \mu_{BP}\gamma$$

Where:

- τ is shear stress (Pa)
- τ_0 is the yield stress (Pa)
- μ_{BP} is the Bingham plastic viscosity (Pa.s)
- γ is the shear rate (s^{-1})

The Bingham plastic viscosity represents the constant viscosity exhibited by the fluid once the yield stress has been exceeded.

Adopted tailings rheological parameters

Tailings rheological properties for the samples were obtained via the relationships presented in Table 4 and are presented in Table 5.

Table 5: Adopted tailings rheology parameters for the pipe break erosion analysis

Parameter	
Slurry solids concentration adopted, C_m (% w/w)	63
Slurry density, ρ_{slurry} (kg/m^3)	1,830
Yield stress, τ_0 (Pa)	31.5
Bingham plastic viscosity, μ_{BP} (Pa.s)	0.042

Hydraulic modelling

Software selection

Hydraulic modeling was completed using the FLOW-3D Hydro (Version 22.1.1.01) (Flow-3D) software package developed by Flow Science Inc (Flow Science Inc., 2022). Flow-3D is a commercially available three-dimensional (3D) computational fluid dynamics software package that includes a physics-based modeling package. It is suited to modeling the complexities of both Newtonian and non-Newtonian flows, such as tailings. An overview of the settings used for these models is presented below.

The governing equations behind the hydraulic modeling of scour erosion are empirical, and as such these models contain uncertainty and require consideration when interpreting the results.

Model geometry, mesh, and terrain extents

A digital model of a portion of the embankment surface was created for use in Flow 3D. Fine and coarse mesh sizes were adopted based on optimization of model accuracy and simulation time, as well as resolution of flow behavior. The extents of the surface analyzed for the model, as well as the mesh arrangements, are summarized in Table 6, with the respective directions indicated in Figure 4.

Table 6: Description of mesh used for analyses

Mesh direction/element	Fine mesh	Coarse mesh
Lateral extent (x direction) (m) (**Note A**)	5	9
Length (y-direction) (m) **(Note B)**	5.5	8.5
Vertical extent (z direction)	3	4.2
Cell size (cm)	10	20
Total no. cells	82,500	39,690

Notes:

(A) The lateral extent of mesh is parallel to the crest.

(B) Length of mesh parallel to embankment slope

(C) Distance measured along embankment, includes crest, face, and toe.

(D) Directions for mesh alignment are shown in Figure 4.

Model setup

General

Modeling was performed using a three-dimensional mesh, to simulate erosion of the embankment crest edge at the location of the pipe break. Due to the computationally intensive nature of the assessment, the assessment was limited to the upper portion of the embankment, rather than the entire upstream face between the crest and tailings beach, and the entire crest. Extrapolations were then made to estimate the duration for erosion through the embankment and down to the tailings surface.

In addition to the inputs and assumptions discussed in the sections above, the following model inputs and assumptions were adopted in the hydraulic modeling:

- Inflow boundary at the location of the pipe at a constant flowrate of 0.17 m^3/s.
- Outflow boundaries were adopted at the sides of the modeled region (refer to Table 6).
- Models were compared at 30 minutes (1,800 seconds) of simulated time to balance computational time and assessment of risk of scour. A longer period of simulated time was run for the coarse mesh size model (about 75 minutes of simulated time), due to shorter overall computational time.
- Turbulence was modeled using the Renormalized Group model (RNG), which is equipped to model turbulence in flows near solid surfaces.

Sediment transport

The following were adopted for the sediment transport model:

- The critical shields number for erosion, calculated via the Soulsby-Whitehouse equation (Soulsby and Whitehouse, 1997).
- The Meyer-Peter and Muller equation for bed load transfer rate, a simple excess shear relationship (Meyer-Peter and Müller, 1948).

Erosion assessment results

Erosion profiles, total eroded depths, and erosion extents into and along the embankment crest were obtained from the analysis.

General erosion behavior

The embankment profile prior to erosion is shown in Figure 4, and the surface following 30 minutes of simulated erosion is presented in Figure 5. The tailings slurry is shown as a semi-transparent surface and the extent of erosion is summarized in the section below entitled "Change in scour extent with time." For the following figures, the x-axis is along the embankment crest, the z-axis is vertical, and the y-axis is perpendicular to the embankment alignment. Note, the upstream crest edge (pre-erosion) is located at y = 0, and z = 6.5 (arbitrarily).

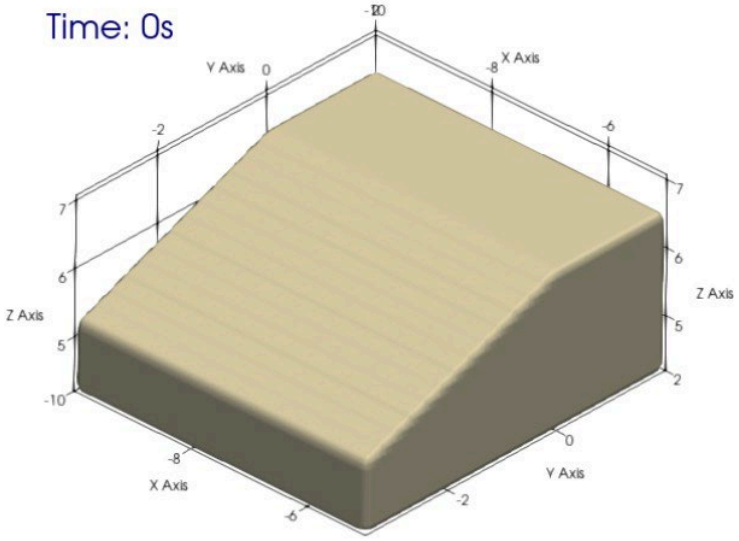

Figure 4: TSF embankment profile before pipe break simulation

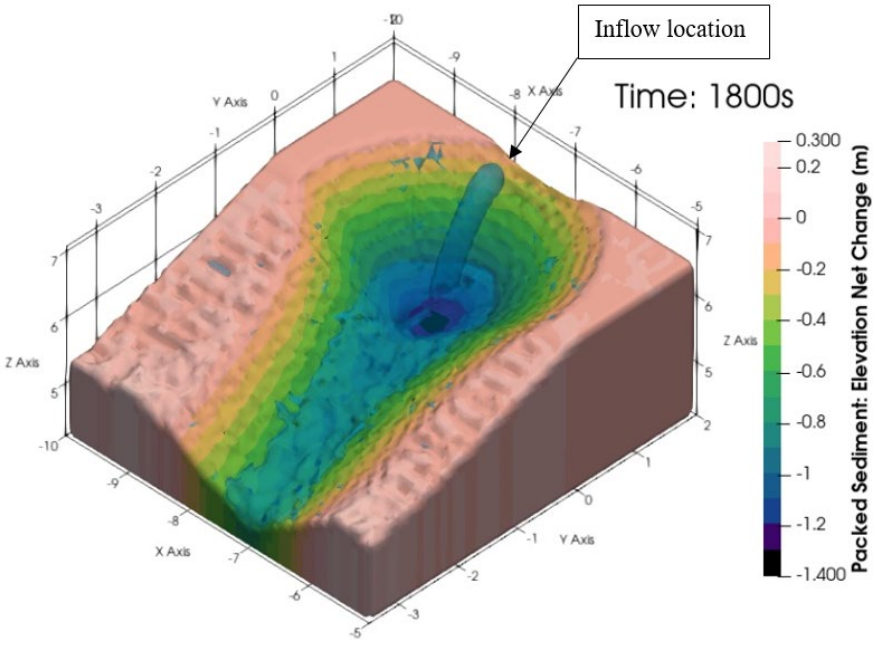

Figure 5: Flow 3D results for tailings slurry, 30 minutes of simulated erosion

Cross-sections showing the erosion profiles after 30 minutes of simulation are presented in a long section in Figure 6 along the embankment crest, and in a cross-section in Figure 7, offset from the upstream crest edge by 20 cm (approximate location of maximum eroded depth). The red dashed line indicates the original embankment crest surface prior to erosion.

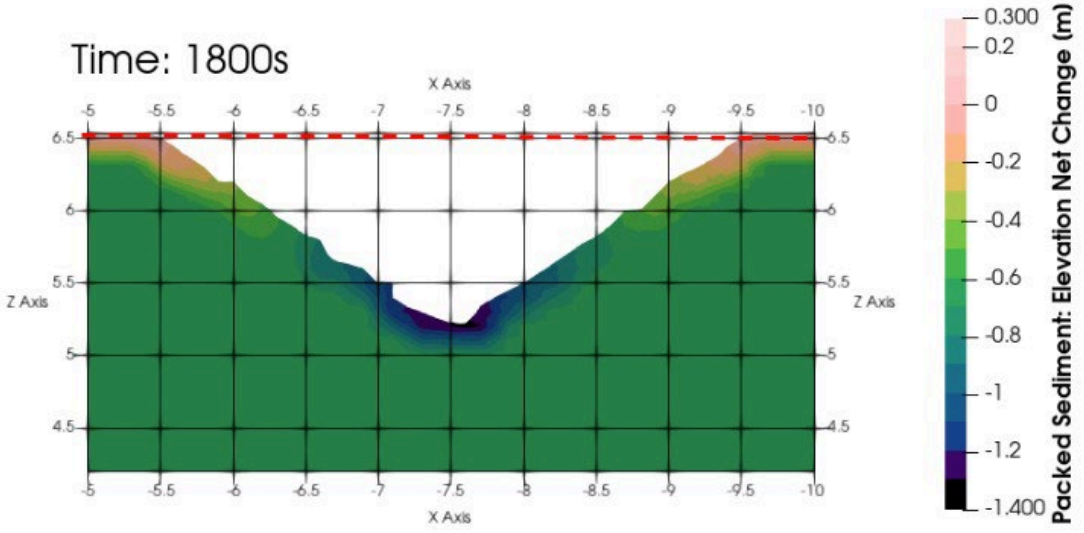

Figure 6: Flow 3D results after 30 minutes of simulated erosion, 20 cm from the upstream crest edge

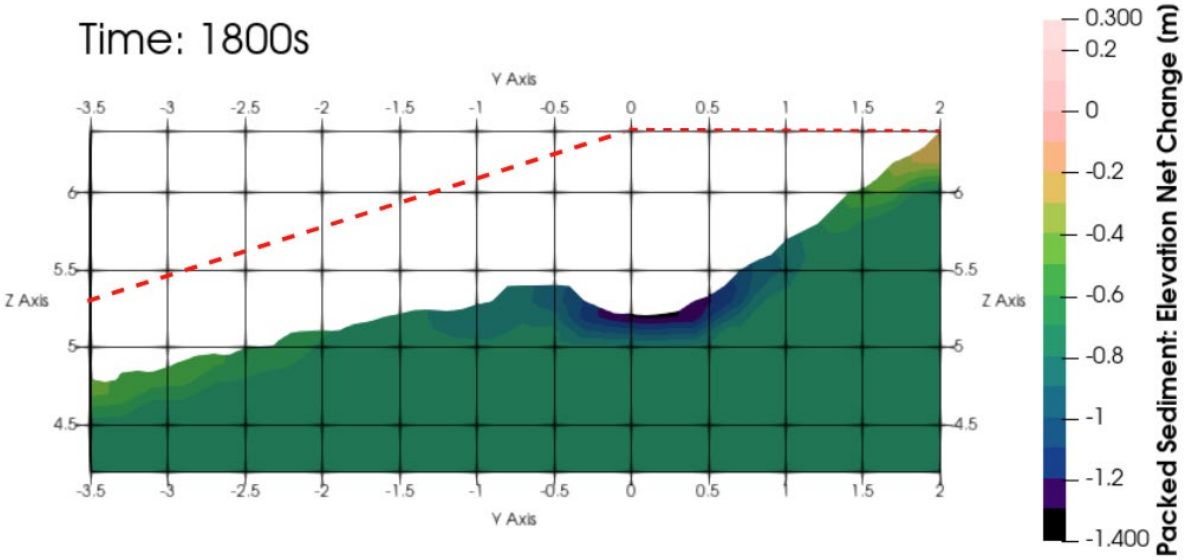

Figure 7: Flow 3D results after 30 minutes of simulated erosion, cross-section at x = -7.5 m

A top-down view of the embankment after 30 minutes of simulated erosion is presented in Figure 8, with the original upstream crest edge marked as a dashed red line.

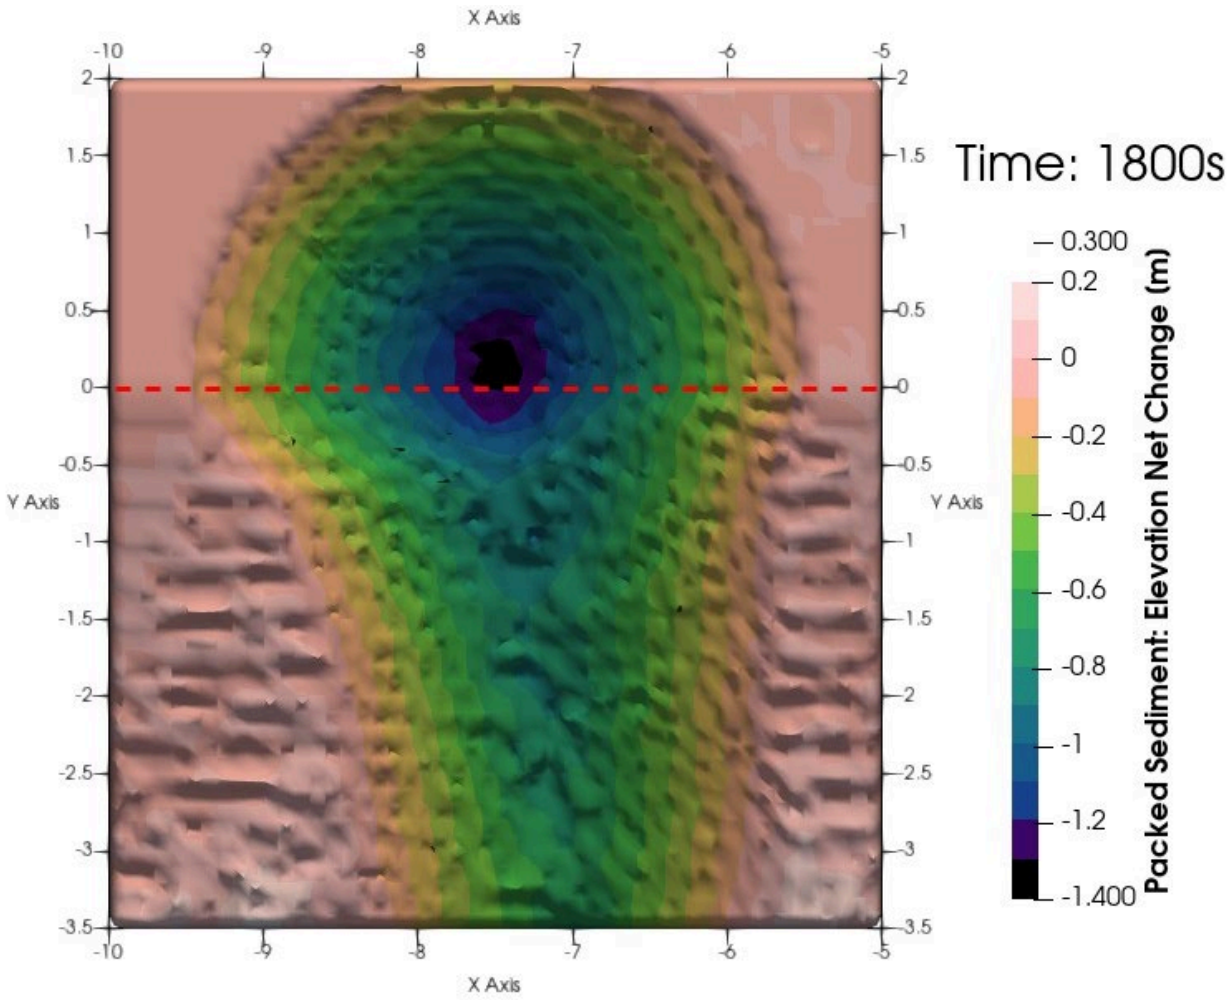

Figure 8: Flow 3D results for the embankment after 30 minutes of simulated erosion, top-down view

Change in scour extent with time

Scour estimates were linearly extrapolated to estimate the time at which the embankment crest (8 m wide) is eroded. Coarse mesh model results are also presented to give a further indication of the model behavior over time.

The rate of retreat of the erosion scarp is indicated in Figure 9, with a linear extrapolation marked as a dashed line. The extrapolation for the fine mesh model indicates erosion through the 8 m wide embankment crest over about 3.5 hours, whereas extrapolation for the coarse mesh model indicates erosion through the crest occurs over about 5.3 hours.

Note, retreat distance is in the positive y-direction indicated in Figure 7 and Figure 8. Also note that the estimated minimum scarp failure time is marked as a red dashed line.

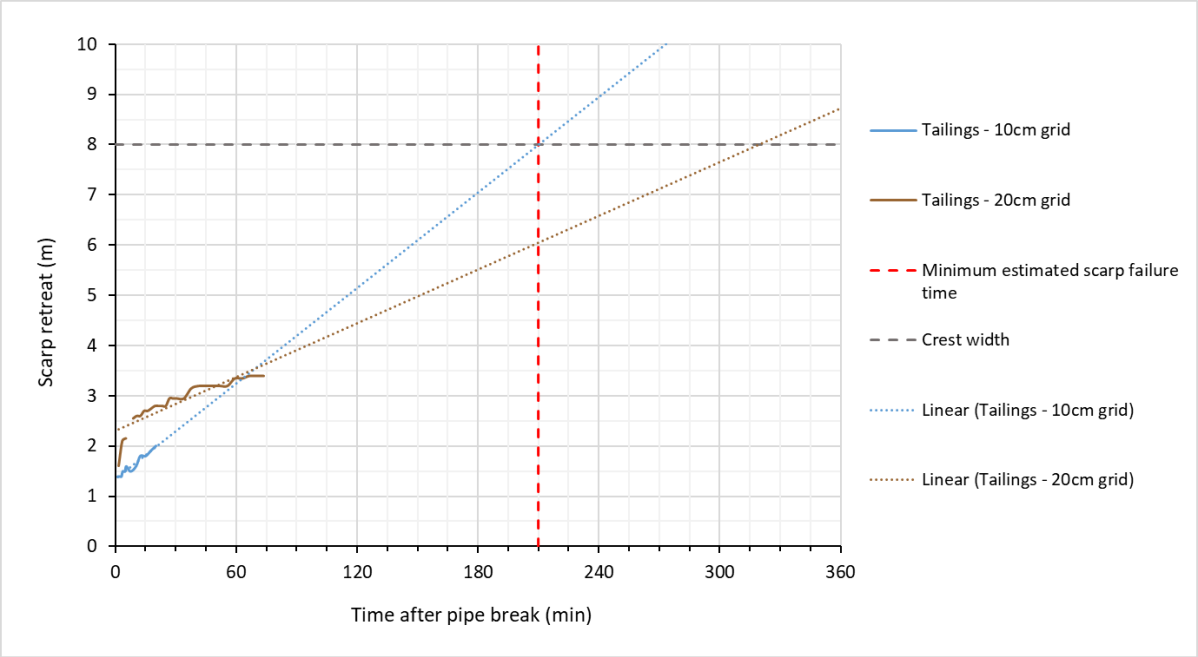

Figure 9: Flow 3D modeled scour distance through the embankment crest

Total vertical scour over time is presented in Figure 10. The estimated shortest duration for the crest to be eroded 6.5 m vertically down to the tailings beach is about 3.5 hours (see Figure 9), as shown by the red dashed line.

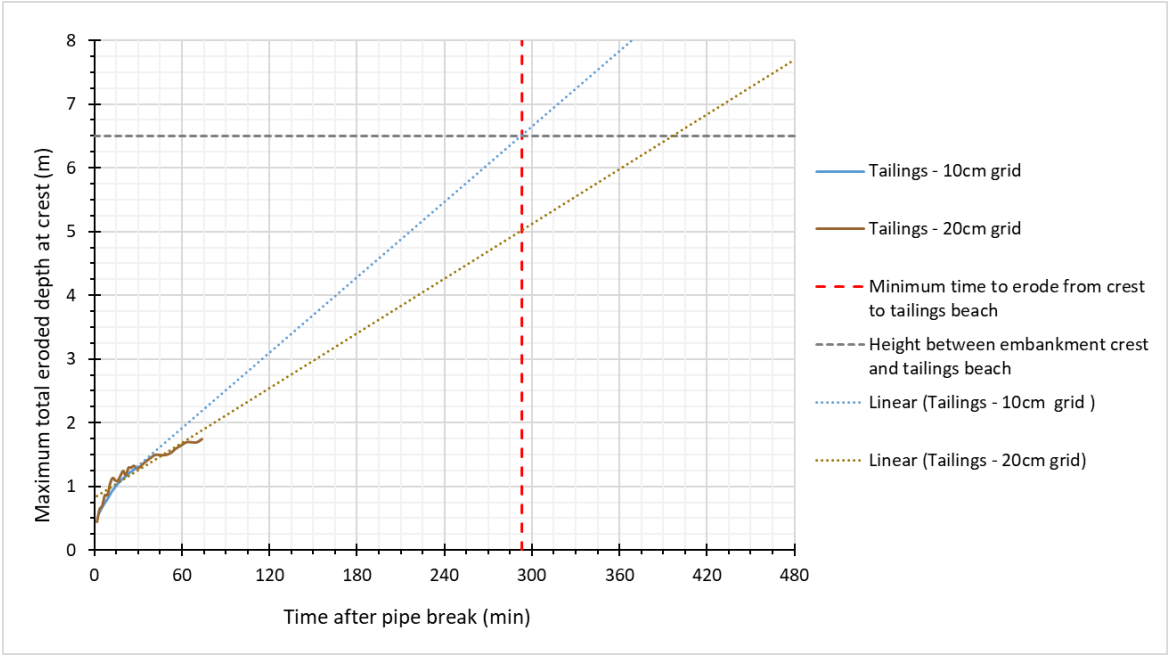

Figure 10: Maximum vertical scour comparison for Flow 3D tailings, with failure time of the scarp

Discussion

In summary, the results from the Flow 3D simulations of pipe-break induced flow of tailings slurry onto the embankment, and the linear extrapolations of these results over time, indicate the following:

- Erosion of 50% of the embankment crest width (4 m) occurs in about 90 minutes.
- Erosion of the crest width (8 m) occurs between about 3.5 and 5 hours.
- Once the erosion scarp retreats through the embankment crest (in 3.5 hours), the estimated lateral erosion extent (along the embankment alignment) is about 16 m.
- Erosion down to the intermediate tailings surface, i.e., a depth of 6.5 m from the upstream crest edge of the embankment occurs after about 4.8 hours.
- Development of a pool of tailings liquid underneath the pipe outlet location, dissipating energy from the outflowing tailings and slowing the overall rate of vertical scour.

The following considerations are provided for the interpretation of the model results:

- The analysis for the fine mesh (10 cm) was limited to a simulation time of 30 minutes for computational efficiency. A coarser mesh model (25 cm) was run for a longer simulation time (70 minutes) for comparison.
- Due to the computationally intensive nature of modeling sediment erosion, the analysis of erosion was limited to the crest and upper portion of the embankment. Linear extrapolations for duration of erosion were made based on the model results.
- Current sediment transport rate equations are empirical and were developed for water. As such there are limitations when applying these to the flow of tailings and other fluids.
- The Meyer-Peter Muller equation for bed load transport rate is empirically derived and was developed for gravel sized particles in the flow of water.

Conclusion

A pipe break event for a tailings delivery pipeline on a hypothetical embankment and slurry flow onto the upstream slope of the embankment was modeled in the Flow 3D Hydro computational fluid dynamics modeling package.

Flow from the break in the tailings delivery pipeline was assessed to estimate the rate of erosion through the embankment crest. Tailings slurry was modeled at a solids concentration of 63% w/w solids and flowing at a rate of 600 m^3/hour. Following the pipe break and slurry flow onto the upstream face of the embankment, the model showed a pool of slurry forming on the crest underneath the pipe break location. Linear extrapolations for results from a fine mesh model indicate the potential to erode through the 8 m

wide embankment crest in about 3.5 hours if flow continues without detection and without cessation of pumping. After 3.5 hours, the maximum erosion depth was estimated to be about 5 m.

Abstract

Liquefaction is a major failure mechanism in upstream tailings dams, as evidenced by the Fundão (2015) and Brumadinho (2019) disasters. This phenomenon occurs in loose and saturated materials and is triggered by destabilizing processes that induce shear in the soil, causing pore volume reduction with associated rapid excess pore pressure generation, and significant drops in effective stress and shear strength, resulting in fluid-like behavior of the material. Traditional stability analyses using the limit equilibrium method are inadequate to model liquefaction, as they fail to capture the post-peak behavior of the material and only effectively simulate failure triggers. Liquefaction analyses have been developed through the application of numerical modeling that considers stress-strain relationships within the deforming material, which requires the use of constitutive models capable of capturing liquefaction. The main constitutive models capable of representing liquefaction are based on critical state soil mechanics, such as NorSand and CASM (Clay and Sand Model), models applied in recent studies of the rupture of Dam I, Brumadinho, Minas Gerais, Brazil. CASM can simulate fine or granular materials with ductile or brittle behavior, incorporating the concept of critical state and the state parameter in its formulation. Given that CASM does not have a well-defined calibration methodology, this work presents a calibration methodology for the model and applies it to tailings materials. We show that the calibration methodology is robust and simple enough to be used by practitioners and researchers alike, contributing to the potential popularization and usage of CASM in future applications related to liquefaction of geomaterials.

Introduction

Liquefaction has been one of the main failure mechanisms in upstream tailings dams. Among recent cases of failure associated with the phenomenon are the Fundão disaster in 2015 (Morgenstern et al., 2016) and

the Brumadinho disaster in 2019 (Robertson et al., 2019; Arroyo and Gens, 2021).

The phenomenon of liquefaction involves a significant reduction in the shear strength of soil subjected to undrained loading due to the generation of excess pore pressure. This occurs because the total stress remains constant while the effective stress decreases due to the excess pore pressure (Sternik, 2014), which increases until it reaches a value equal to the normal stress component.

It is important to note that saturated, loose, granular soils are more prone to liquefaction because they exhibit contractive behavior (Been and Li., 2009). Tailings, which share similar characteristics to soils, are also susceptible to liquefaction because of their often-times loose state.

In geotechnical projects, stability analyses of dams are commonly performed using the limit equilibrium method, where the soil is assumed to exhibit a rigid failure region, and to exhibit perfectly plastic behavior along a well-defined failure surface. This assumption does not represent the mechanism of liquefaction, in which the material shows significant deformations after peak strength is reached. Additionally, limit equilibrium analyses are limited to the simulation of triggers. Given these limitations, liquefaction analyses have been developed through the application of numerical stress-strain modeling. These models are mostly developed using a continuum approach, requiring constitutive models that can capture the phenomenon of liquefaction.

The main constitutive models capable of representing liquefaction are based on critical state soil mechanics and plasticity theory concepts, such as the NorSand model (Jefferies and Been, 2016) and the Clay and Sand Model (CASM) (Yu, 2006). These models have been applied in recent studies of the rupture of Dam I in Brumadinho, Minas Gerais, Brazil (Robertson et al., 2019; Arroyo and Gens, 2021).

The NorSand model can reproduce contractive (volume reduction) or dilative (volume increase) behaviors in sands during shear loading, and originated from observations of sand behavior in large-scale hydraulic fills (Shuttle and Jefferies, 2005). Various works have introduced modifications and improvements to this model (Been and Jefferies, 1985; Jefferies, 1993; Jefferies and Shuttle, 2002; Jefferies and Shuttle, 2011). However, one can only simulate granular materials, and many parameters are required, some of which are difficult to calibrate from test specimens in the laboratory.

CASM, on the other hand, can simulate fine or granular materials with ductile or brittle behavior, incorporating the concept of critical state and the state parameter in its formulation. Given that CASM does not have a well-defined calibration methodology, this work proposes a calibration methodology for the model parameters, with applications to tailings materials.

CASM formulation

Figure 1 shows a schematic representation, on the v-ln(p') plane, of some of the parameters used in CASM, where e is the void ratio and p is the mean normal stress.

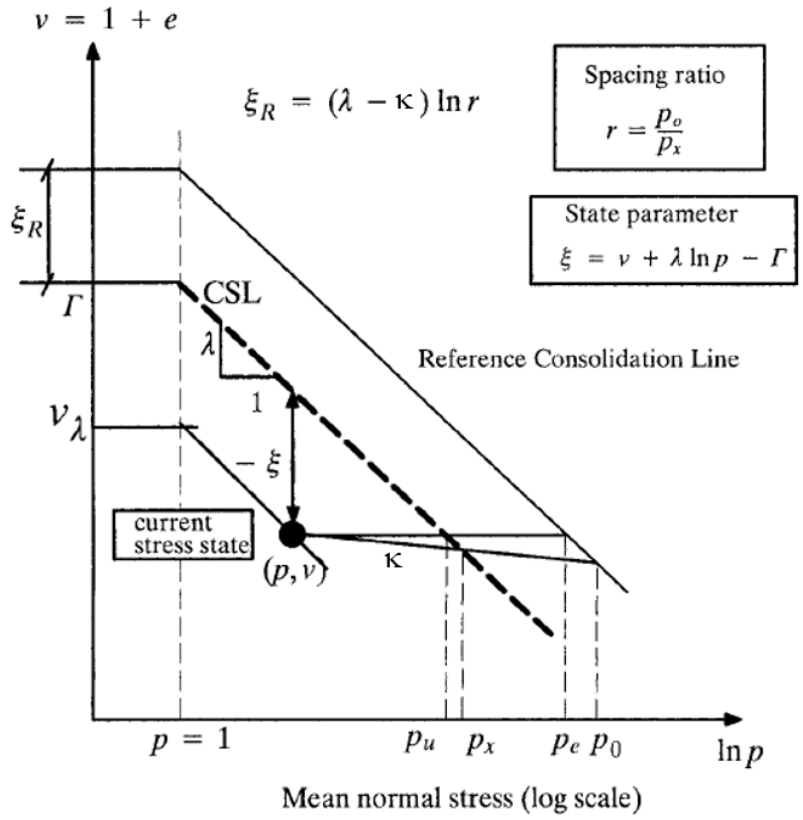

Figure 1: Schematic representation of some parameters of the CASM constitutive model (Yu, 2006)

CASM applies a similar approach to that used in the Cam-Clay constitutive model (Wood, 1990), as it assumes that the consolidation lines are parallel to the critical state line (CSL). Thus, many parameters present in Cam-Clay were retained in CASM.

Unlike the Cam-Clay model, in CASM, the isotropic virgin compression line has been replaced by a reference compression line, assumed to be the loosest probable condition to which the material may be subjected. This change was made because, according to Yu (2006), the isotropic virgin compression line of sands, unlike clays, is only reached at high stress states, higher than those commonly applied in engineering problems.

The reference consolidation line in CASM is defined based on the reference state parameter (ξ_r) or the spatial ratio (r). Both parameters represent ways to measure the distance between the critical state line and the reference line, and are, therefore, changeable parameters related by Equation 1.

$$\xi_r = (\lambda - \kappa) \ln r \qquad \text{(Equation 1)}$$

Where λ is the slope of the CSL, and κ is the elastic compressibility. Given the assumed parallelism between the critical state line and the reference consolidation line, the state parameter is directly related to the overconsolidation ratio (OCR) by Equation 2. Thus, it is observed that to represent dilative materials, it is necessary to use OCR > 1.

$$\xi = (\lambda - \kappa) \ln r \, (1 + \frac{\ln p'/p'_0}{\ln r}) \quad \text{(Equation 2)}$$

To represent elastic behavior, the CASM model uses the following input parameters: Poisson's ratio (ν) and the unloading line slope (k). The parameter k is related to the bulk modulus (K) by Equation 3.

$$K = \frac{(1 + e)\, p'}{k} \quad \text{(Equation 3)}$$

From Equation 3, the bulk modulus is not a constant value, as it tends to vary with mean stress and void ratio. Given that the model assumes a constant value for Poisson's ratio, the shear modulus consequently varies with mean stress and void ratio as well.

The yield function adopted in the model is presented in Equation 4 as a function of the state parameter, and in Equation 5 as a function of preconsolidation stress. It is noteworthy that the ratio p'_0/p' is referred to as the OCR.

$$f = (\frac{q}{M_\theta p'})^{n} + \frac{\xi}{\xi_r} - 1 \quad \text{(Equation 4)}$$

$$f = (\frac{q}{M_\theta p'})^{n} + \frac{1}{\ln r} \ln (\frac{p'}{p'_0}) \quad \text{(Equation 5)}$$

Where q is the Von Mises deviatoric stress, n is a parameter that controls the shape of the surface and M_θ is the slope of the CSL in the p'-q plane.

Arroyo and Gens (2021) modified Yu's original formulation (1998) by incorporating the effects of intermediate principal stress variation (captured by the change in Lode angle, θ into the value of M_θ. They applied the relationship presented in Equation 6, proposed by Sheng et al. (2000).

$$M_\theta = M_{TC} \, (\frac{2\,\alpha^4}{1 + \alpha^4 + (1 - \alpha^4)\, sin3\theta})^{1/4} \quad \text{(Equation 6)}$$

Where M_{TC} is the slope of the CSL under triaxial compression conditions (θ=30°), and α is a parameter that controls the shape of the function. Both are defined based on the critical state friction angle (ϕ_{cs}) by Equations 7 and 8, respectively.

$$M_{TC} = \frac{6\ sin\ \phi_{cs}}{3 -\ sin\ \phi_{cs}} \quad \text{(Equation 7)}$$

$$\alpha = \frac{3 -\ sin\ \phi_{cs}}{3 +\ sin\ \phi_{cs}} \quad \text{(Equation 8)}$$

As presented in Equation 5, the size of the elastic domain is controlled by the preconsolidation stress p'_0. In CASM, a hardening law based on plastic volumetric strains (ε_{vol}^{p}) is assumed, similar to Cam-Clay, and as shown in Equation 9.

$$\frac{\partial p'_0}{\partial \varepsilon_{vol}^{p}} = \frac{(1+e)\ p'_0}{\lambda - \kappa} \quad \text{(Equation 9)}$$

It should be noted that since the hardening law does not depend on shear deformations, the CASM model in the version applied by Arroyo and Gens (2021) cannot capture the increase in material strength after reaching the critical state line, a situation typically observed in materials with state parameter values close to zero.

Finally, the plastic potential function adopted by Arroyo and Gens (2021) also differs from Yu's original formulation (1998). The authors reported that this modification improved the numerical convergence of the model. The plastic potential applied is presented in Equation 10, proposed by Mánica et al. (2021).

$$g = \left(\frac{q}{M_\theta p'}\right)^{m} + \mathrm{m} - 1 - \frac{p_c\ (m-1)}{p'} \quad \text{(Equation 10)}$$

Where m is a parameter that controls the shape of the plastic potential, and p_c is the preconsolidation stress, given by Equation 11, which must be solved for the current stress state.

$$p_c = \frac{p}{m-1}\ \left[\left(\frac{q}{Mp'}\right)^{m} - 1\right] \quad \text{(Equation 11)}$$

It is observed that the plastic potential function is different from the yield surface (Equation 5), and therefore CASM does not have an associated flow.

Calibration methodology

For the calibration of CASM, eight input parameters are required, as presented in Table 1.

Table 1: Parameters of CASM

Component		Parameters
Critical State Line – CSL	G	CSL void ratio at p' = 1 kPa
	l	Plastic compressibility
	Mtc	Critical state slope in p'-q space
Elasticity	n	Poisson's ratio
	k	Elastic compressibility
Plasticity	m	Plastic potential shape
	r	Spacing ratio
	n	Yield shape

The methodology for determining the required input data for the constitutive model will be divided into 5 steps:

Step 1 – Determination of parameters M, Γ and λ

To determine parameters *M, Γ*, and λ, triaxial tests are conducted to establish the CSL on the *p'-q* plane (Figure 2-a), and the ln(*p'*)-*e* plane (Figure 2-b). In the *p'-q* plot, parameter *M* is obtained from the slope of the CSL, while in the ln(*p'*)-*e* plot, *Γ* corresponds to the CSL void ratio at *p'* = 1 kPa, and λ represents the slope of the CSL.

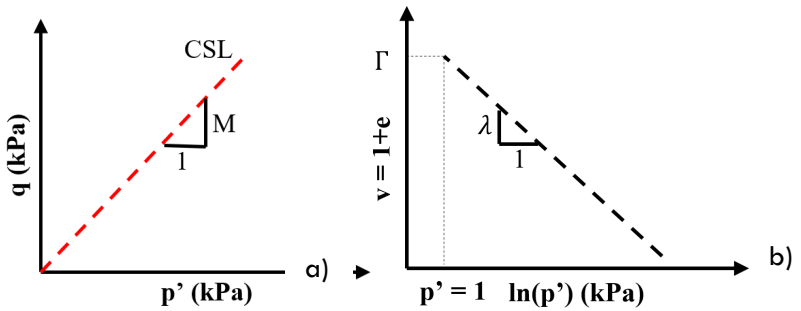

Figure 2: a) Plot to obtain parameter *M*. b) Plot to obtain parameters *Γ* and λ

Step 2 – Determination of the elastic parameters ν and κ

Parameter ν can be obtained through data from triaxial tests by plotting the axial strain (ε_a) versus radial strain (ε_r) and determining ν from the slope of the line. Alternatively, this parameter can also be obtained from literature references, as in Arroyo and Gens (2021), as it does not vary significantly.

To obtain *k*, consolidation oedometer tests are conducted and the ln(*p'*)-*v* graph is plotted (Figure 4). The value of *k* corresponds to the slope of the recompression line, as illustrated in Figure 3.

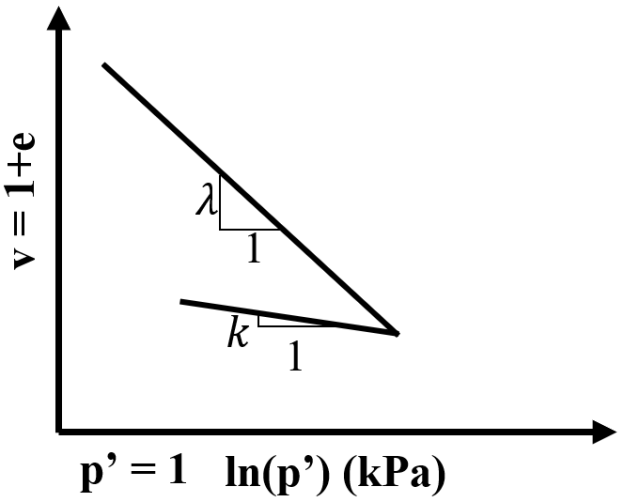

Figure 3: Graph to obtain parameter *k*

According to Mánica et al. (2021), since the parameters *v* and *κ* do not vary much, they can be estimated.

Step 3 – Determination of the plastic parameter – *m*

The parameter *m* controls the shape of the plastic potential and can be used to adjust the model's response in oedometer tests, ensuring that the coefficient of earth pressure at rest (K_0) remains at a specified value without changes due to plastic deformations. The relationship between K_0 and *m* is given by Equation 15.

$$\frac{3\,(\lambda-\kappa)}{2\,\lambda}=\left[\frac{M}{m}-M\right]\left[\left(\frac{1}{M}\frac{3(1-K_0)}{1+2K_0}\right)-\left(\frac{1}{M}\frac{3(1-K_0)}{1+2K_0}\right)^{1-m}\right] \quad \text{(Equation 15)}$$

The equation requires data related to the CSL (*M* and *λ*), determined in Step 1, and the elastic parameter (*κ*), determined in Step 2, and K_0, which can be obtained through pressuremeter tests.

Step 4 – Determination of the plastic parameter – *r*

The parameter *r* allows control of the distance between the CSL and the virgin compression line on the horizontal axis and is related to residual undrained strength (S_{ur}), determined by Equation 17.

$$r=\left[\frac{M}{6}\,(1+2K_0)\left(\frac{\sigma'_{vini}}{S_{ur}}\right)\right]^{\frac{\lambda-\kappa}{\kappa}} \quad \text{(Equation 16)}$$

The equation requires data related to the CSL (M and λ) (Step 1), the elastic parameter (κ) (Step 2), K_0 (Step 3), and the residual undrained strength of the material ($\frac{S_{ur}}{\sigma'_{vini}}$), which can be obtained through triaxial or CPTu tests.

Step 5 – Determination of the plastic parameter – *n*

The parameter n controls the shape of the yield surface and is related to peak undrained strength (S_{up}), determined by Equation 17.

$$\exp\left[\left(\frac{1}{\sqrt[n]{n\ln r}}\right)^n \ln r\right] = \frac{M}{2\frac{\sigma'_v}{S_{up}}\sqrt[n]{n\ln r}} \exp\left[\left(\frac{q_{ini}/p'_{ini}}{M}\right)^n \ln r\right] \exp\left[\frac{\lambda-\kappa}{\kappa}\ln\left(\frac{M}{2\frac{\sigma'_v}{S_{up}}\sqrt[n]{n\ln r}}\right)\right] \quad \text{(Equation 17)}$$

To determine parameter n, Equation 17 is used. The equation requires data related to CSL (M and λ) (Step 1), the elastic parameter (κ) (Step 2), the plastic parameter (r) (Step 3), and the peak undrained strength of the material ($\frac{S_{up}}{\sigma'_{vini}}$), which can be obtained through triaxial or CPTu tests.

Calibration for tailing materials

Below is presented an application of the methodology to calibrate CASM parameters for tailings materials. After obtaining the input data, p'-q and ε_{ax}-q graphs will be illustrated, comparing the calibration results with the tested material.

Step 1 – Determination of parameters *M*, *Γ* and *λ*

To determine parameters M, Γ, and λ, triaxial tests were conducted to establish the critical state line on the p'-q plane (Figure 4), and the ln(p')-e plane (Figure 5). In the p'-q graph, parameter M = 1.32, from the slope of the CSL. In the ln(p')-e graph, the values obtained were Γ = 1.79 and λ = 0.035.

It should be noted that Figure 5 presents the critical state line in the ln(p')-v plane, using only the three undrained loading confining pressures shown in Figure 4, which, in turn, presents the critical state line in the p'-q plane. However, the authors acknowledge and advise that critical state lines are more accurately represented with a minimum of eight tests, incorporating both drained and undrained loading conditions.

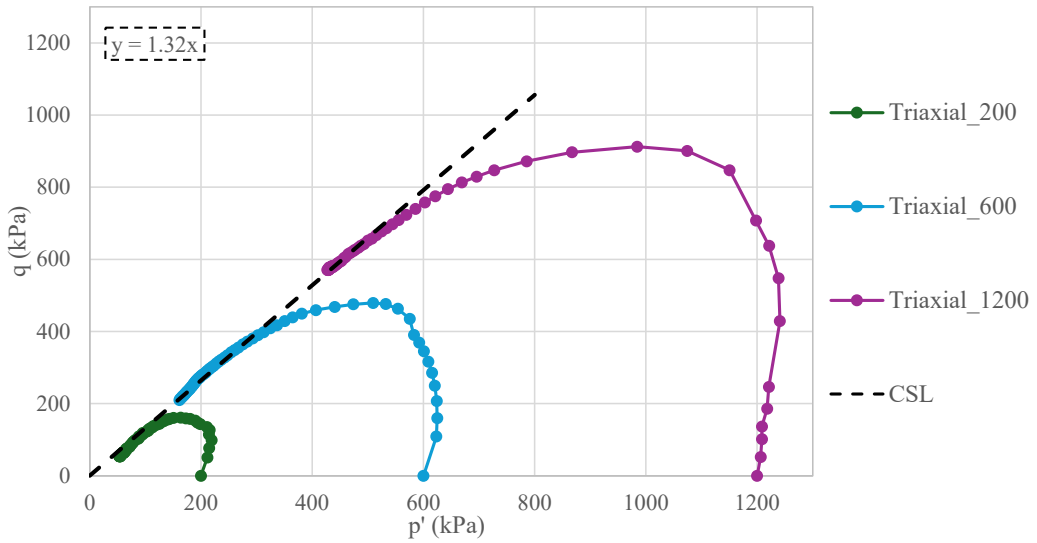

Figure 4: Critical State Line – *p'-q* plot

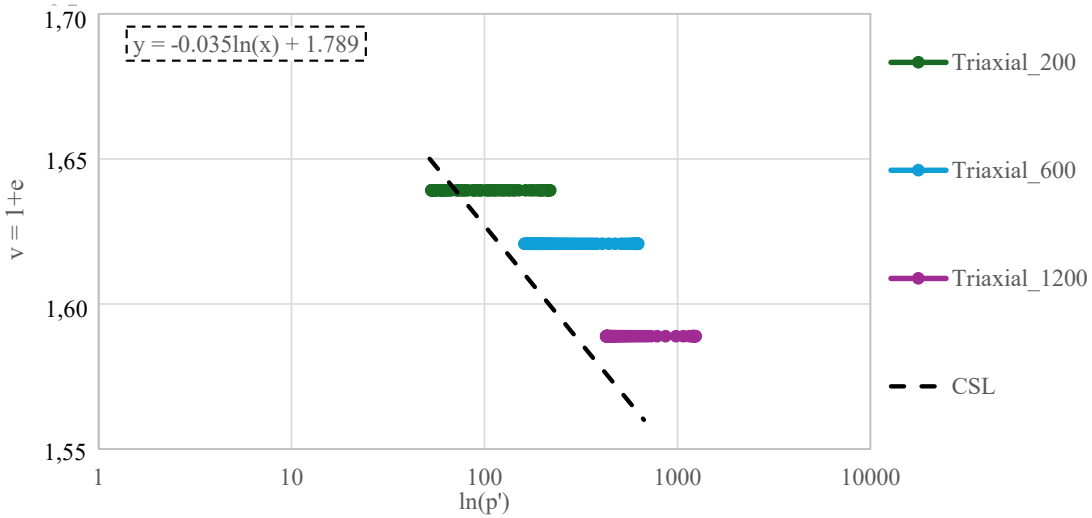

Figure 5: Critical State Line – ln(*p'*)-*v* plot

Step 2 – Determination of elastic parameters ν and κ

The parameter $\nu = 0.3$ was obtained from Arroyo and Gens (2021), as it shows little variation. Due to the lack of oedometer consolidation tests, $\kappa = 0.02$ was assumed.

Step 3 – Determination of the plastic parameter – *m*

Equation 15 requires CSL data, determined in Step 1: $M = 1.32$ and $\lambda = 0.035$, the elastic parameter determined in Step 2: $k = 0.02$, and K_0, which can be obtained through pressuremeter tests; in this case, $K_0 = 0.6$ was used. Applying these parameter values to Equation 15 yielded $m = 1.5$.

Step 4 – Determination of the plastic parameter – *r*

To determine the parameter *r*, the following values were considered: M = 1.32 and λ = 0.035 (Step 1), k = 0.02 (Step 2), and K_0 = 0.6 (Step 3). For the undrained residual strength of the material $\left(\frac{S_{ur}}{\sigma'_{vini}}\right)$, correlations were performed using the methodologies of Olson and Stark (2003) and Sandrekarime (2014) with the CPTu test data, resulting in $\frac{S_{ur}}{\sigma'_{vini}}$ = 0.13. By applying the parameter values to Equation 16, r = 20.0 was obtained.

Step 5 – Determination of the plastic parameter – *n*.

To determine the parameter n, the following values were considered: M = 1.32 e λ = 0.035 (Step 1), k = 0.02 (Step 2), and r = 20.0 (Step 4). For the undrained peak strength of the material $\left(\frac{S_{up}}{\sigma'_{vini}}\right)$, correlations were performed using the methodologies of Olson and Stark (2003) and Sandrekarime (2014) with the CPTu test data, resulting in $\frac{S_{up}}{\sigma'_{vini}}$ = 0.27. By applying the parameter values to Equation 17, n = 5.5 was obtained.

Table 2 presents a summary of CASM parameters obtained from the calibration for the tailings material.

Table 2: Parameters of CASM

Component		Parameters
Critical State Line – CSL	G	1,79
	I	0,035
	Mtc	1,32
Elasticity	n	0,30
	k	0,02
Plasticity	n	5,5
	r	20,0
	m	1,5

Once the input data resulting from the calibration were obtained, the p'-q (Figure 6) and ε_{ax}-q plots (Figure 7) were compared with the laboratory test results.

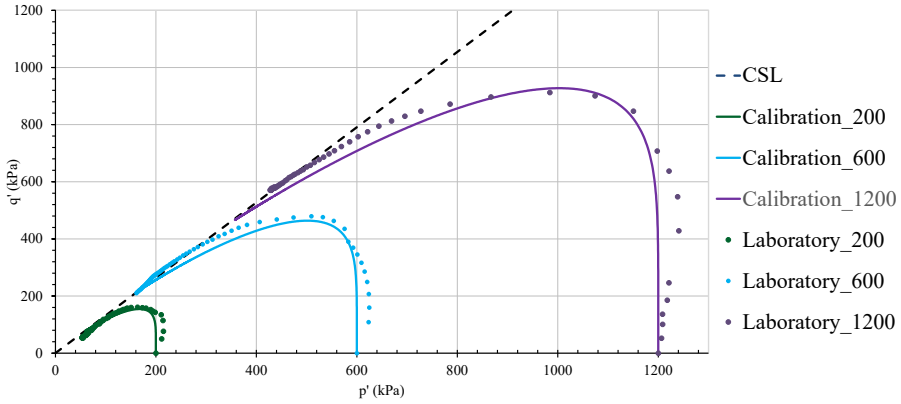

Figure 6: Calibrated versus laboratory p'-q curves

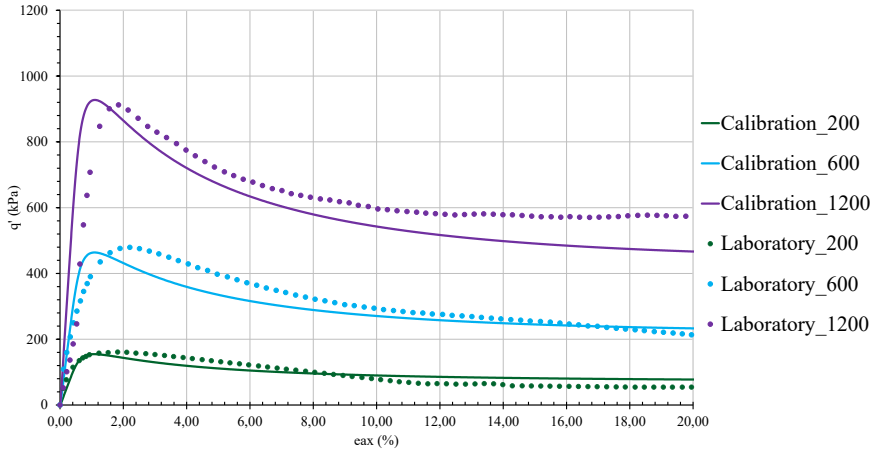

Figure 7: Calibrated versus laboratory ε_{ax}-q curves

Since the calibration should approximate the behavior of the materials simulated in the laboratory tests, it is shown that in the present example case, a consistent calibration is observed when applying the calibration methodology presented in this work.

Conclusion

This work presented the methodology for the calibration of the CASM constitutive model, illustrating the field and laboratory tests considered to obtain the input data required by the model and the necessary equations for the calibration process. Additionally, an application of the proposed calibration methodology to a tailings material was performed, and the results of the calibrated model in p'-q and ε_{ax}-q spaces agree very well with results from laboratory tests. The methodology proposed in this work results in accurate and consistent calibration of the behavior of the material. Hence, we envision that the proposed calibration methodology will serve as a reference for practitioners and researchers alike when using CASM to model

liquefaction-prone materials, such as those in tailings dams applications.

The authors assert that the calibration of the CASM constitutive model should prioritize meeting the criteria of the critical state line, ensuring its alignment both in the p'-q plane and the ln(p')-e plane. While attempts to calibrate the mechanical behavior of tailings are valid, it is challenging to replicate field conditions accurately in the laboratory. Consequently, complete convergence between the numerical simulation and the mechanical behavior observed in laboratory tests is unlikely, as stress paths may not fully align with each other.

Drained Laboratory Vane Shear Testing to Characterize Nonplastic Tailings

Alvino Bezuidenhout, University of the Witwatersrand, South Africa
Luis A. Torres-Cruz, University of British Columbia, Canada and University of the Witwatersrand, South Africa

Abstract

The peak and residual undrained strength of tailings are of paramount importance when assessing their geotechnical stability. Accordingly, efforts have been made to use vane shear testing (VST) to assess the undrained strength of tailings. However, these efforts have been hindered because tailings are often nonplastic and thus exhibit relatively high permeability, making it difficult to attain undrained conditions during a VST. While much attention has focused on how to achieve, and verify, undrained VSTs in low-plasticity soils, in this paper we hypothesize that drained VSTs can provide information about the contractiveness of a soil and thus give insights into their undrained strength. We present results from a series of laboratory VSTs performed on a fine-grained angular silica sand that we use as a proxy for nonplastic tailings. Besides exploring the repeatability of the VST, the experiments also explore the effects of specimen diameter, pore medium (air vs. water), and angular velocity. We used these results to establish a test configuration that led to drained results in dry specimens and that eliminated undue interference due to an insufficiently large mold diameter. This configuration was then used to investigate the effect of the initial void ratio. The behavior of the specimens at large shearing deformations (360 vane rotations) was also investigated. Initial void ratio, and therefore potentially contractiveness, has a distinct effect on the results. This supports the possibility of using drained VSTs to assist assessments of the undrained shear strength of nonplastic tailings. We discuss additional research directions that should be addressed.

Introduction

Assessment of the peak and residual strength of tailings is a major consideration when assessing their geotechnical stability. The vane shear test (VST) has been identified as a method that can aid the characterization of the undrained strength of tailings (Hogan et al., 2022; Reid, 2016; Reid et al., 2023). During a vane shear test (VST), a vane with four blades is pushed into the ground and rotated to measure the shearing resistance of the soil (Figure 1). VSTs have several features that make them attractive as a geotechnical investigation tool:

1. A relatively simple geometry amenable to analysis.
2. The possibility of obtaining a full force vs. displacement (torque vs. rotation angle) curve to characterize the soil at any particular depth. This is unlike the cone penetration test (CPT), which provides only one reading of tip resistance, friction sleeve, and dynamic porewater pressure for any particular depth.
3. The VST can be performed both in the field at full scale (e.g. ASTM D2573) or in the laboratory at a reduced scale (e.g. ASTM D4648). This has the potential of facilitating the interpretation of the field version of the test.
4. The angular velocity of the vane can be adjusted within a wide range to promote drained or undrained conditions.

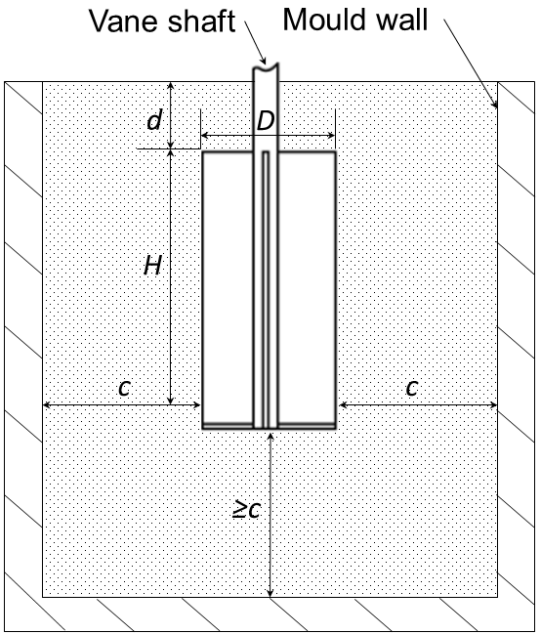

Figure 1: Setup of a laboratory vane shear test

However, a major difficulty in using VSTs to measure the undrained strength of nonplastic soils, such as many types of tailings, is that the greater permeability of these soils makes it challenging to attain undrained conditions. So far, attempts to overcome this difficulty have focused on increasing the angular velocity of the vane to promote undrained conditions (Hogan et al., 2022; Reid, 2016; Reid et al., 2023). However, regardless of how fast the vane is rotated, the situation remains challenging for at least two reasons. Firstly, drainage begins as soon as the vane reaches its target depth and before it even begins to rotate. During an in-situ testing campaign in which a deliberate effort was made to reduce the time between insertion and rotation, the average measured time was ~3 minutes (Reid et al., 2023). Clearly, significant

drainage can occur in the tailings surrounding the vane during this time. A second difficulty is the lack of a reliable criterion to determine when a VST is undrained or not (Reid et al., 2023).

Given these difficulties in performing and verifying undrained VSTs in nonplastic tailings, in this paper we focus on using drained VSTs to assess the shearing characteristics of nonplastic soils. Naturally, the undrained strength cannot be inferred directly from a drained VST. However, we show that the torque vs. rotation curve produced by a drained laboratory VST reflects the density of the specimen and thus has the potential to also reflect its contractiveness. We hypothesize that because the contractiveness of a soil is fundamentally correlated to its undrained shear strength (Jefferies and Been, 2015), it may be possible to estimate the undrained strength of low plasticity soils using the results of drained VSTs. While the data presented herein is insufficient to validate our hypothesis, it does suggest that this is a possibility worth exploring.

Materials and methods

We tested a narrowly graded silica sand with angular particles (Figure 2) as a proxy for nonplastic tailings. The sand had a maximum and minimum void ratio of e_{max} = 1.12 and e_{min} = 0.68, determined as per ASTM D4254-16 and the procedure proposed by Torres Cruz (2016), respectively. The mean particle density was ρ_s = 2.67 g/cm^3 (BS 1377).

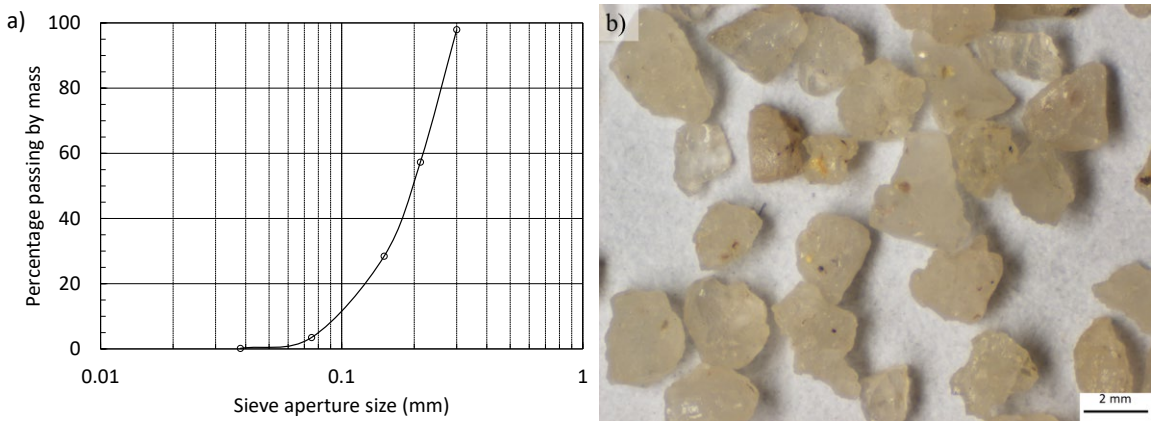

Figure 2: a) Particle size distribution and b) micrograph of the silica sand

We performed laboratory vane shear tests, generally abiding by ASTM D4648. All tests were done with a square vane with a width and height of 12.7 mm. We used a fully automatic vane shear tester capable of logging torque against angle of vane rotation. The VST device comprised a control panel and test frame that housed strain sensors (used to measure torque), a removable vane, a fully threaded spindle and handle that allowed the vertical displacement of the vane (and sensor housing unit) and a mold support bracket fixed to the base of the test frame. The control panel was connected to a desktop computer from which each

test was configured. The VST device could measure torques of up to 3 Nm, at a resolution of 0.001 Nm and operate at angular velocities from 0.06 to 1,200°/min.

Table 1 shows the features of the test that we varied during the experimental program, as well as the values or options that such features took on. We performed a total of 19 tests. Table 2 indicates their purpose and their characteristics in terms of specimen (or mold) diameter in mm (D), pore medium (M), angular velocity in °/min (V) and initial void ratio (e_0).

Table 1: Features of the VSTs that varied within the testing program

Test feature	Values or options tested
Specimen diameter *D* (mm)	37, 75.5, 101, 105
Pore medium *M*	Air (dry), water (saturated)
Angular velocity *V* (°/min)	0.15, 1.5, 4.7, 15, 47, 150
Maximum vane rotation θ_{max} (°)	150, 1,080, 3,220, 14,400, 129,600
Initial void ratio e_0	0.68 = e_{min}, 0.89, 1.11 ≈e_{max}

Table 2: Summary of the testing program

Test no.	Characteristics (D/M/V/θ_{max}/e_0)	Aspect explored
1	101/air/15/1080/0.68	Repeatability and benchmark
2	101/air/15/1080/0.68	Repeatability
3	101/air/15/1080/0.68	Repeatability
4	101/air/15/1080/0.68	Repeatability
5	37/air/15/1080/0.68	Effect of specimen diameter
6	75.5/air/15/1080/0.68	Effect of specimen diameter
7	105/air/15/1080/0.68	Effect of specimen diameter
8	101/water/15/3220/0.68	Effect of pore medium
9	101/water/0.15/150/0.68	Effect of pore medium
10	101/water/0.15/150/0.68	Effect of pore medium
11	101/air/1.5/1080/0.68	Effect of angular velocity
12	101/air/4.7/1080/0.68	Effect of angular velocity
13	101/air/47/1080/0.68	Effect of angular velocity
14	101/air/150/1080/0.68	Effect of angular velocity
15	101/air/15/1080/0.89	Effect of void ratio
16	101/air/15/1080/1.11	Effect of void ratio
17	101/air/150/129,600/0.68	Behavior at large rotation
18	101/air/150/129,600/0.89	Behavior at large rotation
19	101/air/150/129,600/1.11	Behavior at large rotation

Test 1 served as a benchmark test. As described below, for most of the remainder of the tests, different aspects of test 1 were systematically varied to isolate the effect of changes on D, M, V and e_0. However, tests 2 to 4 were set up identically to test 1 to investigate repeatability. We assessed repeatability by computing the coefficient of variation (CoV) of the torque measured by the tests 1 to 4 at any given rotation angle. The CoV was computed by calculating the standard deviation of the sample of the torque readings and dividing them by the mean torque reading.

Tests 1, 5, 6, and 7 were aimed at identifying a suitable specimen diameter D. There are good reasons both to keep D small and to make it large. On the one hand, a small D implies specimens that use less material and are quicker to form, and in which homogeneity is easier to achieve. On the other hand, if D is too small, the walls of the mold interfere with the results and can artificially increase the measured torque (Barros and Barros, 1989). An adequate D must thus be established through testing. For our benchmark configuration (test 1) and, consequently, for most of the remaining tests, we adopted $e_0 = 0.68 = e_{min}$ because we hypothesized that this dense condition was the critical one in terms of identifying a D large enough to eliminate the effect of the mold walls.

Tests 1, 8, 9, and 10 investigated the effect of pore medium, specifically, the difference between dry and saturated specimens. We considered this because, except for tests 8 to 10, all VSTs were performed on dry specimens as they are more easily prepared than saturated specimens. However, it is saturated tailings that are of practical interest as they are prone to undrained loading. We thus assumed that the results from dry specimens are relevant to saturated specimens provided that the VSTs in the saturated specimens are fully saturated. The tests on saturated specimens were designed to verify this assumption.

With tests 1, 11, 12, 13, and 14 we investigated the effect of the angular velocity V of the vane. In saturated soils, V has a significant effect because low velocities promote drained conditions while high velocities promote undrained conditions. Presumably, the effect of V on dry soils, and particularly on a sand like the one tested herein, is much smaller because the lower viscosity and greater compressibility of air may prevent the development of any air pressure (i.e., prevent the development of fully or partially undrained conditions) even when the vane is rotated relatively quickly. Notwithstanding, we ran tests to ensure that changes in V did not affect the results.

Tests 1, 15, and 16 investigated the effect of the initial void ratio e_0. Because the peak friction angle of a sand is directly correlated to its initial void ratio e_0, the peak torque during a VST is also directly correlated to e_0. We investigated this effect by running tests at e_0 close to e_{min}, close to e_{max} and close to an intermediate value.

Finally, tests 17, 18, and 19 explored the behavior of VSTs with different e_0 at large values of vane rotation. For these tests the vane was allowed to complete 360 revolutions ($\theta_{max} = 129{,}600°$). Regardless of initial density, soils attain the same critical friction ratio at large shear strains for a given mode of shearing

(Jefferies and Been, 2015). Accordingly, we hypothesized that tests with different e_0 would eventually reach the same torque values. Tests 17, 18, and 19 were run to explore this hypothesis. Given the large number of vane rotations involved in these tests, their vane rotation velocity was 150°/min.

The specimen preparation method depended on the target e_0 and pore medium. Except for tests 16 and 19, all specimens were prepared by dry tamping ten sand layers of equal mass and height. The mass of each layer was calculated as a function of the target e_0. Tests 16 and 19 were prepared at $e_0 = 1.11 \approx e_{max}$. Accordingly, these tests were prepared by gently pouring the sand into the specimen container without any tamping.

Tests 8 to 10 involved saturated specimens. Accordingly, after dry tamping, a plastic disc with 1 mm diameter holes was placed on top of the specimen. Distilled water was then poured on top of the disc, and it flowed through the 1 mm diameter holes. The disc protected the specimen from disturbance by the pouring of the water. Weighing the specimen before and after pouring the water enabled the estimation of the saturation (S), with the method typically achieving $S > 95\%$. While not perfectly saturated, herein we refer to these specimens as saturated.

For all tests, the vane was positioned in the center of the cylindrical mold (Figure 1), ensuring uniform lateral clearance that was verified using a Vernier caliper. The vane was lowered into the specimen at approximately 6 mm/min. The clearance between the bottom of the vane and the bottom of the mold was at least equal to the lateral clearance. For all dry specimens prepared at $e_0 = 0.68$, the height of soil above the upper edge of the vane (distance d in Figure 1) was equal to 25.4 mm, that is, twice the height of the vane. This resulted in a vertical effective stress of $\sigma'_v = 0.50$ kPa at the mid-height of the vane, a value that was computed using:

$$\sigma'_v = \gamma\left(d + \frac{H}{2}\right) \qquad \text{(Equation 1)}$$

$$\gamma = \left(\frac{G_s}{1 + e_0}\right)\gamma_w \qquad \text{(Equation 2)}$$

Where γ is the total unit weight, d and H are as defined in Figure 1, G_s is the specific gravity of the solids, and γ_w is the unit weight of water (9.81 kN/m^3). We increased the soil height d (Figure 1) for tests 8, 9, 10, 15, 16, 18, and 19 to achieve the same initial nominal $\sigma'_v = 0.50$ kPa at the mid-height of the vane for all tests.

Results

Figure 3 presents the results of the tests done to assess repeatability. The four curves exhibit a peak torque of ~0.045 Nm at a rotation angle of ~20° followed by a sharp drop in strength between $20° \leq \theta \leq 80°$ and a slower drop at $\theta > 80°$. The reduction in T was still ongoing at $\theta_{max} = 1080°$ when T reached ~0.014 Nm.

The CoV begins at relatively high values of ~50% but reduces quickly to <5% as T increases to its peak value. After the peak the CoV increases again to ~15% until the end of the test. The mean CoV of 13.5% is similar to the mean CoVs reported for undrained triaxial compression, direct shear, and laboratory VST performed on plastic soils and drained shear tests in sand (Phoon and Kulhawy, 1999). Overall, tests 1 to 4 suggest that the laboratory VST can perform a reliable characterization of the silica sand.

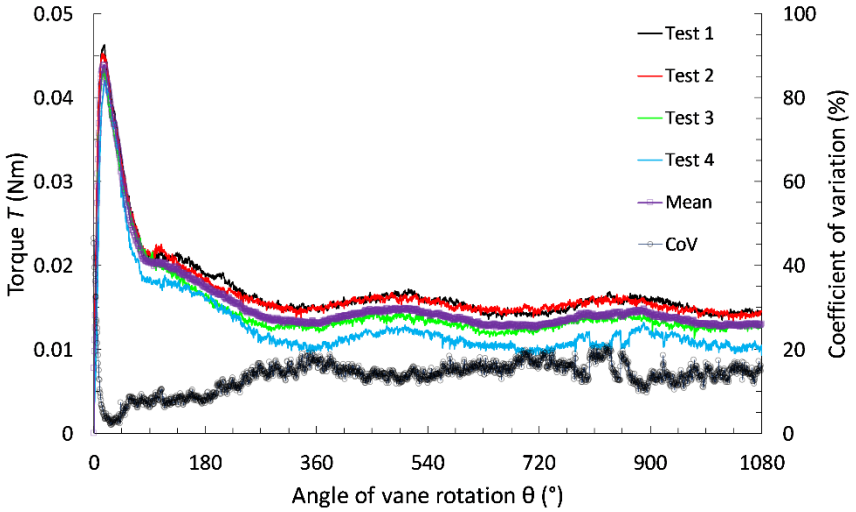

Figure 3: Repeatability assessment of the vane shear test

Figure 4 presents the results of the tests that explored the effect of specimen diameter D. For D values of 37, 75.5, and 101 mm there is an inverse correlation between D and the torque at any given value of θ. However, the curves for D = 101 mm and D = 105 mm are virtually indistinguishable suggesting that, for the sand used herein, D = 101 mm is adequate to eliminate interference from the walls of the mold.

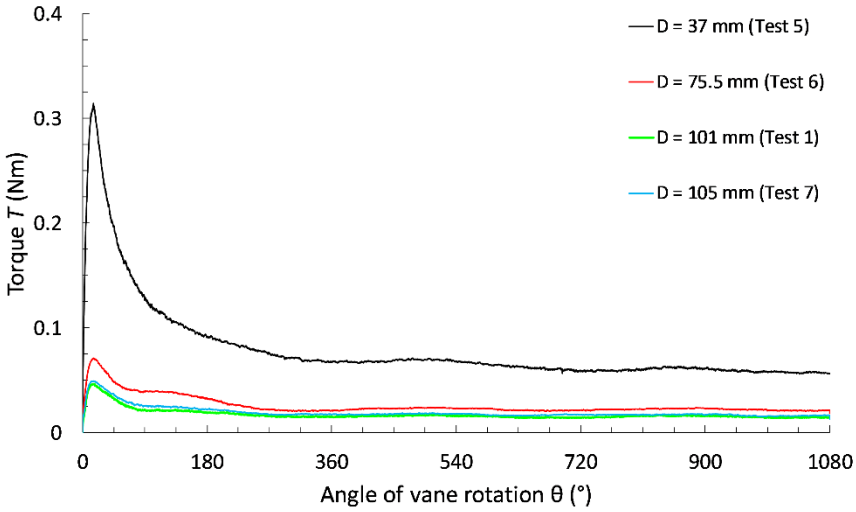

Figure 4: Effect of specimen diameter

Figure 5 presents the results of the tests done to assess the effect of pore medium. The saturated specimens (tests 8, 9, and 10) yielded torque values that are significantly larger than those measured in the dry specimen. As mentioned previously, the expectation was that the tests on dry and saturated specimens would yield the same results provided that the tests on saturated specimens were drained. Test 8 was the first test on a saturated specimen and yielded torque values that were significantly higher than the benchmark test 1. We initially attributed this difference to test 8 not being fully drained. That is, we suspected that since test 8 had $e_0 \approx e_{min}$, dilation of the dense sand was generating negative pore water pressures that were increasing the effective stress levels and therefore the shear strength. To improve drainage, for test 9 we brought down the angular velocity by two orders of magnitude from 15 to 0.15°/min. Surprisingly, test 9 yielded even higher torque values than test 8 (Figure 5). We believe the results of test 9 are spurious and that the high torque values are due to the vane shaft deviating from verticality during insertion.

Test 10 is a repetition of test 9, taking care to prevent the vane shaft from deviating from verticality. The torque values of test 10 are still significantly larger than those of test 1 that was dry (Figure 5). It is not clear to us what is causing the large difference between tests 1 and 10 since both have $e_0 = e_{min}$, D = 101 mm, initial σ'_v = 0.50 kPa at the mid-height of the vane and, presumably, both tests are fully drained. We believe that further testing is required to clarify this matter. It is also interesting to note the similarity between tests 8 and 10 despite their large differences in V (Figure 5). This apparent independence of the torque values from V is similar to a finding reported by Wilson (1963).

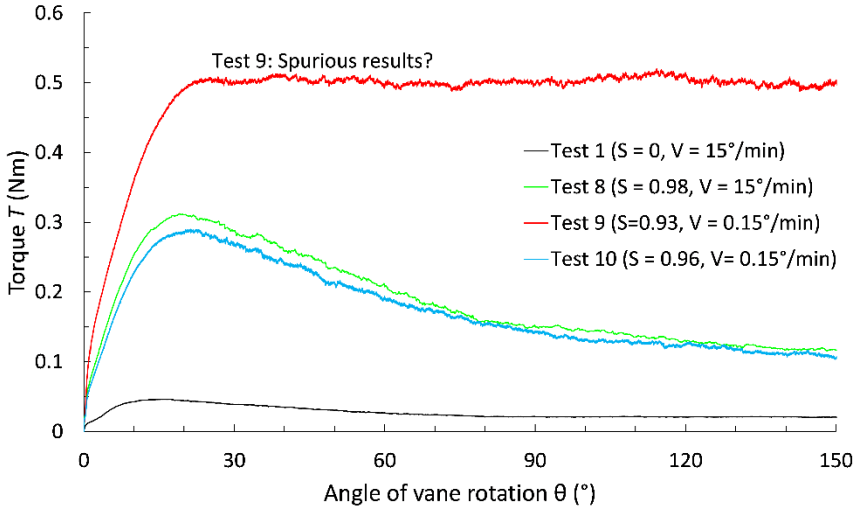

Figure 5: Comparison of specimens with air or water as a pore medium

Figure 6 shows the effect of changing the angular velocity over two orders of magnitude from 1.5 to 150°/min. While there are differences between the five curves (Figure 6a), these differences do not seem to

be systematic. That is, there appears to be no clear direct or indirect correlation between V and T at a given angle of rotation (Figure 6b). Furthermore, beyond $\theta = 360°$ the five curves are largely indistinguishable. We interpret the similarity of the results to mean that, despite differences in V, all five tests were fully drained. The similarity in results could also mean that all five tests are fully undrained. However, we believe this is unlikely considering that all specimens were dry (M = air) and that the slowest test was run at V = 1.5°/min.

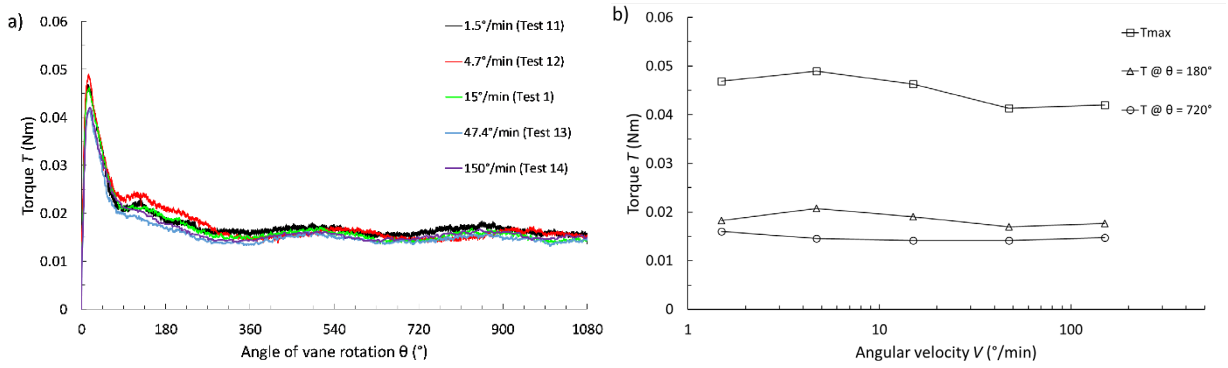

Figure 6: Effect of angular velocity

Figure 7 illustrates the effect of changes in e_0. These tests were done with D = 101 mm because this diameter proved to be adequate to eliminate the effects of the mold walls (Figure 4). The results show a clear inverse correlation between e_0 and peak torque (Figure 7a), a finding that is consistent with previous investigations (Barros and Barros, 1989; Park et al., 2016; Park et al., 2018). The ratio of the peak torque (T_{max}) to the end-of-test torque (T_{EoT}) is also significantly affected by e_0 (Figure 7b).

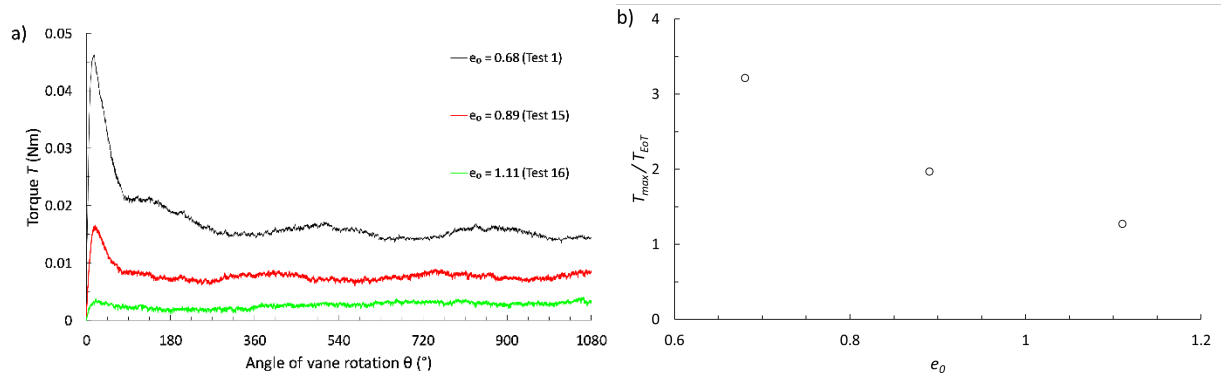

Figure 7: Effect of e_0 on a) Full torque vs. rotation curves and b) T_{max}/T_{EoT}.

Figure 8 shows the results of tests ran to 360 vane revolutions. Figure 8a suggests that tests 17 and 18 reached a steady residual torque after ~160 vane revolutions. Conversely, it appears that, despite the large number of revolutions, test 19 did not reach a truly steady residual torque, with the torque still increasing at the end of the test. Figures 8a and 8b also show that, contrary to our expectation, the three tests did not

reach the same residual torque at large strains. Instead, the residual torques are inversely correlated to e_0. We suspect this is due to a cavity that developed around the vane shaft during rotation in each test (Figure 9). This cavity reduces the shaft friction and the vertical effective stress around the vane. The geometry of the cavity appears to be influenced by e_0. Specifically, the looser the soil, the higher its susceptibility to disturbances, and the larger the diameter and depth of the cavity. In turn, this leads to a lower σ'_v around the vane and therefore lower torque values. These results highlight the experimental challenges of attaining truly constant σ'_v across tests with different e_0.

The inset in Figure 8a shows that the two denser tests (17 and 18) approached a peak torque at $\theta \approx 20°$ and then reduced to a residual torque. Conversely, test 19 shows a nearly monotonic increase in strength.

Figure 8b, which focuses on the last ten revolutions, shows that all three tests exhibit a well-defined sinusoidal shape with a periodicity of one revolution. This may be indicative of a non-uniform strength distribution along the shear surface. Although Figure 8b only shows the last ten revolutions of the tests, the periodic nature of the torque response is established much earlier, in some cases as early as in the second revolution (Figures 3, 6, 7, and inset in Figure 8a). It also appears that the amplitude of the sinusoidal response increases with specimen density.

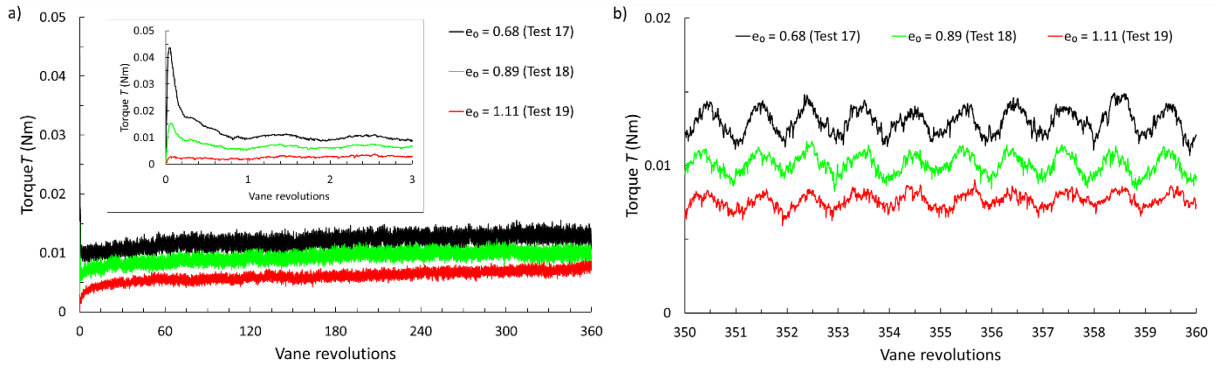

Figure 8: Tests run to 360 revolutions. a) Full results with inset showing enlargement of the first three revolutions and b) last ten revolutions

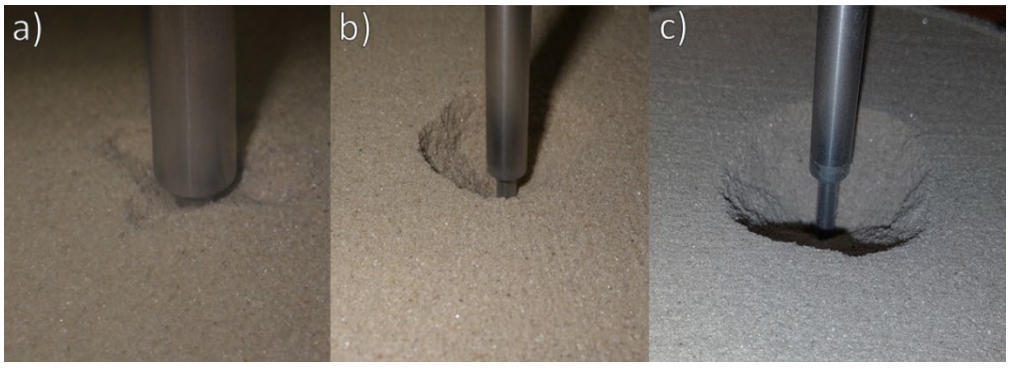

Figure 9: Cavity around the vane shaft at the end of a large deformation vane shear test. a) $e_0 = 0.68 = e_{min}$, b) $e_0 = 0.89$ and c) $e_0 = 1.11 \approx e_{max}$.

Discussion

The initial void ratio e_0 of the tests affects T_{max} and the ratio T_{max}/T_{EoT} (Figure 7). We hypothesize that these effects are related to whether the specimen is contractive or dilative. Accordingly, drained VST results appear to have the potential of aiding in the assessment of the volume change characteristics of tailings. Such characteristics are correlated to the undrained strength of tailings, suggesting that drained VSTs can ultimately assist with the assessment of undrained strength. There are several practical issues to address before these observations can be translated into a robust methodology to assess undrained strength.

Firstly, while Figure 7 shows that e_0 affects VST results, it is very likely that there is also an effect of horizontal effective stresses (not measured herein). The magnitude of these horizontal stresses also affects the contractiveness of the soil, and therefore its undrained strength, because it is the combination of void ratio and mean effective stress that controls contractiveness (Been and Jefferies, 1985).

Assuming that it is indeed possible to establish a correlation between VST results and the volume change characteristics of the soil, it is crucial to determine whether such a correlation is affected by the particle size distribution. This is relevant to hydraulically deposited tailings because they exhibit intense layering with particle size distribution varying from one layer to the next.

Another consideration is ensuring that the field VST is indeed drained. This is probably not as challenging as ensuring that the VST is fully undrained which, as mentioned in the introduction, is an approach adopted in other works. However, ensuring fully drained conditions is not necessarily straightforward because neither laboratory nor field VST probes are typically fitted with piezometers. The addition of piezometers would be a welcome enhancement. Furthermore, because of the aforementioned layering in tailings deposits, the angular velocity required to achieve drained conditions is likely to vary significantly both laterally and vertically. It is also necessary to consider the implications that these velocities will have on the duration of field VSTs.

We encountered an unexpected difference between tests in dry and saturated specimens (compare tests 1 and 10 in Figure 5) and were unable to explain them satisfactorily. Resolution of this matter is crucial to the interpretation of VST results because it is ultimately saturated or nearly saturated tailings, and not dry tailings, which mostly contribute to stability concerns of tailings deposits.

All tests presented herein were performed at a very low σ'_v of 0.50 kPa at the mid-height of the vane. Additional testing is required to investigate VST results obtained at σ'_v levels that are more representative of in-situ conditions.

Our laboratory VST results exhibited a sinusoidal pattern with a periodicity of one revolution. It appears that the amplitude of the sinusoidal response is affected by e_0. We are not aware of a similar pattern having been reported for field VSTs. We believe this is worth exploring as well as assessing the effect that the amplitude may have in result interpretation.

Finally, VST-based assessment of the in-situ undrained strength of tailings may require pairing VST results with a laboratory test, such as triaxial testing or direct simple shear, in which undrained (or constant volume) conditions can be easily imposed. Again, further research is needed to determine whether it is possible to correlate VST results with the undrained strength measured in laboratory tests.

Conclusion

We presented the results of a laboratory VST program that explored repeatability as well as the effect of specimen diameter, pore medium (dry vs. saturated), angular velocity, and initial void ratio e_0. The testing program also investigated the behavior of VSTs at very large strains (360 revolutions). Results on a clean angular silica sand show that the laboratory VST is generally repeatable, with a representative CoV of ~13%. A mold diameter of 101 mm was adequate to eliminate interference from the mold walls. For undetermined reasons, dry and saturated specimens yielded different results. We will carry out further testing to clarify this issue. On dry specimens, varying the rotation velocity from 1.5 to 150°/min did not affect the results. The results are affected by e_0, with denser specimens resisting higher torques. Cavities formed on the surface of the specimens appear to hinder efforts to run tests at different e_0 while maintaining a constant σ'_v. VSTs yield a periodic response that may begin as early as in the second revolution, but which is particularly noticeable when running tests to a large number of revolutions.

The effect of e_0 on drained VSTs suggests that it is worth exploring the possibility of using such results to estimate the in-situ undrained strength of nonplastic tailings. However, several issues discussed herein must be addressed to develop a robust methodology.

Modeling Assumptions and Implications during Closure Assessments on Legacy Tailings Facilities

Benjamin Kramka, Stantec, USA
Erin Dunn, Stantec, USA
Lauren Meyer, Stantec, USA
Jason Cumbers, Stantec, USA

Abstract

Moving a legacy tailings storage facility (TSF) toward closure under the Global Industry Standard for Tailings Management (GISTM) involves comprehensive assessment and understanding of construction history, site management, and post-operation activities and procedures. Some legacy TSFs that have undergone steps toward closure prior to the GISTM may not meet the GISTM requirements for closure. Consequently, mining companies that are working toward GISTM compliance for legacy TSFs in their portfolios are having to re-evaluate previously closed or partially closed facilities with limited historical documentation on the site and dam construction, under more rigorous standards. Assumptions are often made on how a facility was built based on historical as-built information and previous consultants' investigation work, leaving data gaps in the conceptual TSF zonation and geometry used for detailed geotechnical stability analysis. Further complicating these types of modeling exercises is the presence of material property data gaps, outdated management techniques during operation, and construction field adjustments made with minimal documentation.

This paper provides recommendations for approaching stability analyses and assessing needs for further site investigation, specifically for legacy mine sites seeking closure with critical data gaps related to TSF as-built conditions. Not only are supplemental investigations to close gaps costly and time intensive, but gaining access for site investigations can be challenging and require modifications to partially closed facilities, which Owners often prefer to avoid. As stakeholders drive the industry toward more stringent requirements and better management to avoid failures, it can be more efficient to use conservative models and sensitivity analyses to evaluate data gaps and inform stakeholder decisions than to proceed with targeted investigations or closure planning. By approaching modeling with an emphasis on data gap driven sensitivities developed using case study analogies, site closure designers can effectively implement solutions more quickly.

Introduction

Achieving closure of a legacy TSF to meet current-day standards such as the GISTM can be a lengthy process. TSF liability is not only controlled by ongoing maintenance costs, but is more closely tied to risks involving embankment and dam stability under a wide range of loading conditions that could lead to a catastrophic failure event. To satisfy closure requirements and achieve critical risk-reduction measures, a common approach often involves site investigations to resolve major unknowns and attempt to fully characterize a TSF before moving forward with a closure design. While this approach seeks to minimize risk from all angles, there are drawbacks as well, specifically the amount of time and capital investment required to reach the final closure implementation.

This paper outlines the steps a closure design team can take to assist an Owner with identifying the closure status of a legacy TSF and beginning to assess the approach to design for closure. This approach seeks to identify data gaps up front and rule out factors contributing to potential instability, or identify those that can remain unknown with minimal risk. This process can be iterative and includes the following steps:

- Identifying site-specific closure criteria based on relevant standards, regulations, Owner goals and appetite for risk.
- Assessing available historical documentation, publicly available information, and data for the site and identifying data gaps and uncertainties with respect to necessary parameters for closure design.
- Developing conceptual models and sensitivity analyses for the TSF.
- Using the results of the conceptual models to update data gaps and make a decision to either revisit data needs or move forward with closure design, balancing cost and time constraints with the criticality of remaining gaps.

TSF closure criteria

TSF closure criteria typically relies on governing regulations set by states or national government agencies with jurisdiction over the TSF in addition to state-of-the-practice guidelines published by professional organizations. Since it was published in late 2020, many mining companies have aligned with the guidance from the GISTM for establishing minimum design criteria for closure of TSFs. GISTM design criteria for active TSFs are based on consequence classification. The criteria for closure are consistent for all TSF consequence classifications due to the design life or period of performance of the facility, with design for the 10,000-year recurrence interval for both seismic and hydrologic analyses (GISTM, 2020). Alternative guidance exists from various national dam associations (non-regulatory entities) such as the Canadian Dam Association (CDA) and the Australian National Committee on Large Dams (ANCOLD), among others.

These associations form the basis for guidelines or state-of-the practice standards which can also be considered and adopted by mining companies and closure design teams as deemed appropriate. Other governmental regulatory agencies may have design requirements, such as the Nuclear Regulatory Commission or Environmental Protection Agency in the United States. The GISTM has become the industry standard for TSF closure design criteria with required compliance for member organizations of the International Council on Mining and Metals (ICMM) because of its comprehensive approach that seeks to consider all stakeholders.

The key drivers for site closure generally pertain to perceived and inherent risks associated with failure of a TSF and potential impacts to the people and environment within the neighboring communities. Although all sites are different and will have their own site-specific risks (geohazards, nearby waterways, wildfires, avalanches, seasonal flooding, etc.), several apply across the board. These risks include:

- Static failure due to poor construction techniques, foundational weakness, phreatic surface changes, static liquefaction, or piping.
- Seismic failure due to liquefaction and/or material strength reduction.
- Dam breach and inundation due to hydrologic events.

Assessment of these potential failure modes is typically explored through a multi-disciplinary risk assessment and used to inform the design. For legacy TSFs, where as-built documentation is lacking, this commonly means making conservative assumptions regarding as-built conditions, construction techniques, material properties (particularly for liquefiable tailings and foundation conditions), water levels within the TSF, and identification and understanding of the known unknowns. This information is typically gathered through a thorough assessment of existing historical data.

Historical data assessment

The first step in assessing the closure status and/or planning for closure design of a legacy TSF in reference to GISTM or other regulatory criteria is to complete a desktop study and assessment of the available historical data. The engineer of record (EOR) typically completes a historical data assessment for the site. The desktop study is especially important for Owners and EORs that were not responsible for the legacy facility during operations, construction, or closure, and are not familiar with site history or its documentation. Though mining companies and EORs that were responsible for historical operations and closure should also complete a thorough review of historical data prior to developing closure designs. Documents and information that should be compiled and reviewed to support or develop a thorough historical site knowledge base include:

- Geotechnical investigation field and laboratory data.

- Design documentation.
- Operational data.
- As-built construction documentation.
- Instrumentation and monitoring data.
- Regional and site geology, geomorphology, and hydrogeology.
- Geochemistry.
- Climate data.
- Seismicity.
- Photographs (construction, aerial, site inspection).

A site visit should also be conducted by the EOR as a part of the review, to gain a better understanding of the TSF configuration and current status.

Document review

Evaluating historical site information that was collected prior to closure allows for review of key design elements with respect to critical risks and failure modes identified during a risk assessment. The document review should organize data to align with identified risks and closure criteria. Data should also be organized into the components needed to build an overall conceptual site model (CSM). For example, data should be organized by material type such as tailings, cover, embankment fill, and foundation materials. Data should also be organized to show which data may be used for planned analyses, such as liquefaction, stability, scour/erosion, or dam breach analyses. Organizing data this way allows for efficient review of data trends and identification of data gaps.

An important step of the document review is to identify data that can be used for the analyses needed to assess closure criteria conformance, the associated data gaps for the analyses, and the complete TSF knowledge base. For example, material property testing on samples collected from presumed dam raises can support general understandings for how a dam may have been initially constructed. Historical documentation, such as photographs of TSF construction and operations, should be cross-referenced and evaluated for discrepancies, and it is not uncommon to find conflicting information or data which can be challenging to navigate as a data gap.

How the data is assessed in historical documentation also matters, since the circumstances around why it was collected, or how, may by biased, or are often not fully known to the EOR or current Owner. Data should be assessed qualitatively to evaluate the level of certainty for specific parameters in the available data set. For instance, laboratory testing such as triaxial shear strength tests should be reviewed to evaluate the test methods used and overall quality of the results. If incorrect test methods were used, or if reporting of the results does not include enough information (for example, stress path plots) to evaluate

the test results in detail, this should be flagged as uncertain in the desktop review for additional evaluation during model parameter development. Additionally, historical lab data and drill log information regarding conditions of sample collection should be assessed and weighed with the tested values to see if the results are representative of broader conditions or should be discounted appropriately. Data should also be assessed quantitatively. If a dataset is too small for a specific parameter, it should be noted as uncertain in the desktop review. For example, many historical data sets lack information about the TSF foundation material properties; if there are few, to no, historical borings or laboratory tests for foundation materials, it is challenging to assess the potential for liquefaction, or identify weak foundation layers, that could pose a risk to overall stability. In this case, review of regional datasets may provide clues as to heterogeneity or continuity of native foundation layers.

Public reference information

Paired with existing site knowledge, data pulled from publicly available literature can improve the understanding of historical data and provide useful information for closing data gaps. Historical closure designs for legacy TSFs will have been developed on a set of assumptions that fit the overall TSF closure plan at that given time, requiring new EORs to conduct an independent review of the historical information to establish assumptions in line with new closure goals. Part of weighing the applicability of the site data is incorporating regional characteristics, stratigraphy, hydrogeology, and other publicly available information. This is also a good time to review relevant case histories, for example those with similar location, operational aspects, tailings composition, construction methods, or other factors where important assumptions can be drawn from the key outcomes of another closure design. Both successful closure designs and past failures should be considered in a case history review when evaluating assumptions for the TSF models.

Generally, the CSM will incorporate detailed local information and become more granular with wider uncertainty as site boundaries are reached, but there still needs to be an understanding of how the conditions of the boundary materials affect model results. An example of information to be considered while developing the CSM includes reviewing geologic studies for materials that could affect stability, hydrogeology, geochemistry, or liquefaction potential near or beneath the TSF. Data collected from the surrounding area should be organized similarly to the site-specific data, by specific model inputs as well as more general groupings. One may be easily drawn to previous assumptions and assertions regarding factors controlling TSF stability from observed historical data trends. For example, concluding that excess seepage observed through toe drain water present in a dam adjacent to a lake is from the lake, when it could be coming from the surrounding hillslope or elsewhere. A proper CSM will develop assumptions that are based

on available reference information to highlight the known and unknown information for a particular TSF equally.

Conceptual models and sensitivity analyses

Compiling a thorough site knowledge base allows for development of a more comprehensive conceptual site model (CSM), which provides a framework for assessing potential risk of failure. The key focus when transitioning from evaluating site data categorically to building the site model is revisiting the main components of the risk assessment under GISTM to prioritize details that inherently make the greatest difference in modeling and associated results. For example, a data gap for shallow bedrock strength may be less relevant than whether overlying fine-grained loess deposits were left in place over bedrock and directly below the TSF footprint. Though it is important to accurately capture all available data to build out a conceptual site model that can be relied on for a closure assessment, it is also important to incorporate quality data into the main components of the CSM that may impact closure criteria being met.

Additionally, once a framework has been created for a TSF, professional assumptions and observations that feed into the CSM should be evaluated in the field by experts in that area of practice to visualize how the closure criteria objectives are being incorporated. A basic approach is to build a database from historical information and use linear interpolation combined with statics to derive site information that is defensible and reflective of the onsite behavior; however, comparing that to the regional setting and case studies will make a CSM and modeling approach more informative on the driving factors for long-term TSF stability. This step of the closure process requires outside-of-the-box thinking to weigh the knowns with the unknowns and establish evaluation criteria that will allow identification of the data gaps needing to be addressed vs. those that can be designed around with less certainty.

Preliminary model development should be approached as a directional study intended to address the following questions:

1. Does the site meet the closure criteria for known site conditions (developed based on available data), and satisfy critical risks?
2. Does the site meet the closure criteria for worst-case conditions for model inputs with insufficient data or unknowns?

Addressing these questions may require model refinement and additional data input.

Knowns: stability model development using available historical data

The data identified for the CSM and general site history tend to be the primary focus, since most of the information on how a TSF was constructed and its general performance provides information on current TSF conditions. Model development should begin by identifying the critical areas within the TSF. For

stability analyses, this may include areas with the tallest or steepest embankment slopes, or areas with known layers of weaker materials or higher water levels. In some cases, the selected portion of the TSF used as the base case model, may externally appear to be a critical slope based on topography or dam height but may not be an area with the most critical subsurface conditions. For these conditions, one efficient approach is to develop a single model that is a hybrid of the two conditions, pairing the critical topography or geometry from one portion of the TSF with the critical subsurface conditions from another area to create a worst-case model that checks both conditions for stability. This is an example where model refinement is anticipated, but if the results meet the closure criteria, additional model refinement may not be necessary. If the results do not meet the criteria, more detailed, separate models for each condition should be prepared to evaluate and compare whether they meet criteria on their own.

Starting with generalized conservative models that qualitatively evaluate a range of conditions for legacy sites with data gaps and uncertainties, and refining the models in later iterations is an efficient way to develop preliminary models and identify key risks and closure objectives for the site. For example, if multiple data gaps for material properties important to the model are assumed to have low strength and no failure surfaces pass through these materials, it may be an indication that the known data is needing more refinement compared to the unknowns. These models should start with high level, general expected conditions, and be refined after preliminary analyses with more granular data inputs and newly collected information. Selected model inputs should be compared to expected/published values to draw comparisons against different data sets for the same parameters.

For example, strength parameters from triaxial or direct shear laboratory test results compared with calculation of strength parameters using field data tests or correlations for standard penetration tests (SPTs). These lab and calculated values should be compared to typical empirical values for similar materials. At this stage, the modeling team needs to evaluate what is an appropriate minimum or representative lower bound for model inputs to select, which will change for each parameter and sometimes for each material depending on the data reviewed. Either the most conservative value of the site data and typical comparison values can be selected for analysis, or the highest quality or quantity data could be used, even if it's not the most conservative option. This will either lead to very conservative base case models, or less conservative with additional sensitivity analyses to evaluate more conservative parameters. Regardless of the approach, it is important to evaluate each model parameter holistically by cross-checking each parameter with overall site knowledge and asking the following questions:

- Is there agreement between multiple data sources for each parameter? (e.g., field data, laboratory data, and typical values)
- Does each model input fit with the overall site understanding? (e.g., does model geometry align with known construction methods such as upstream, centerline, or downstream)

Additional data gaps may be identified in this step as data is reviewed in detail for development of the base case models. If the stability analysis results meet the closure criteria, it is important to run additional sensitivity analyses to check for potential site conditions that may not meet the criteria. Alternatively, if the results of base case analyses do not meet the criteria, back-calculation analyses can be used to identify site conditions that would meet the criteria.

Unknowns: model sensitivity analyses or back-calculation

After development of a CSM using available site data, sensitivity stability analyses should be prepared to evaluate data gaps, limited data sets, or other uncertainties identified during the historical data assessment and base case model development process. Sensitivities should evaluate key risks identified for the site. For example, if seismic liquefaction of tailings is a key risk, sensitivity analyses for post-earthquake stability should encompass potential worst-case scenarios, such as a reduced liquefied residual strength or increased saturation levels leading to more liquefiable tailings. If there is not enough data to complete a liquefaction analysis for the tailings, or if the liquefaction analysis is inconclusive, sensitivity analyses should also evaluate a maximum extent of liquefied materials or lower-bound liquefied residual strengths for tailings as well. The scale of the sensitivity analysis should be relative to the level of uncertainty for the model parameter that is being adjusted in the analysis. For parameters with high levels of uncertainty it is most efficient to model a lower bound worst-case scenario, rather than modeling a less conservative but more realistic scenario. This approach allows the modeler to quickly identify whether the parameter with a high level of uncertainty controls stability.

In some cases, sensitivity results meet the design criteria. For these scenarios the sensitivity analysis helps increase the level of confidence in meeting design criteria, even when data gaps may be present for the TSF. The results of the sensitivity analyses that do not meet closure criteria should be used to identify critical data gaps; if a change to a specific parameter results in an analysis that does not meet the closure criteria, that data gap is a critical data gap. Identification of critical data gaps can inform a targeted field investigation to fill the critical data gaps, or focused conceptual closure design alternatives, depending on whether the Owner decides to collect more data or proceed with closure design. For the data with a higher degree of confidence, the decision on addressing this sensitivity for closure will look different than for gaps where there is limited confidence for which back-analysis may better inform on feasibility of achieving satisfactory results.

If the base case does not meet the closure criteria, the components of the model should be reviewed to identify which component is most critical in causing the analysis to not meet the closure criteria. The identified component can then be back-calculated for a minimum input that would result in the analysis meeting the criteria. The back-calculated parameter should be checked against the available data or typical

values to verify it is a realistic value that could exist for the site, if more data were available. This check can help inform whether additional field investigation could be used to fill data gaps and run updated analyses that have the potential to meet the closure criteria or not. If the back-calculated parameter appears to be unrealistic for the existing conditions at the site, it may be more prudent to begin developing a conceptual closure design that would modify the TSF to meet the criteria.

Moving ahead: design or assessment of data needs

Once uncertainties and the impacts on stability are known, effective management for the end goal of closure can proceed. Comfort with the range of results derived from sensitivity analyses will inform the path forward. If conservative modeling within a reasonable range of parameters shows the TSF meets closure criteria, and the closure design team is comfortable with the results, additional steps may not be necessary. Alternatively, if modeling leaves results that are marginal or insufficient, in most cases the engineer will recommend that more data collection will be necessary to reach a place of confidence with models that represent reasonably true conditions. Data collection may include updated surface topography, geotechnical test pitting, drilling, sampling, or laboratory testing to verify assumptions or expand existing data sets.

In most cases, the key considerations for an Owner are the estimated costs and schedule for detailed data collection. GISTM compliance typically proceeds based on a set schedule based on the Owner's risk profile for sites. Depending on the cost and other risks associated with field investigations, an Owner may weigh this against simply designing stabilization measures using conservative stability model parameters to forgo the cost and delays associated with prolonged geotechnical investigation and analyses. For example, a gap showing global stability failure of foundation material could be potentially mitigated by laying back slopes at shallower angles instead of trying to characterize the foundation material in more detail. Large field programs coupled with follow-on data collection and updates to analyses can have significant impacts on schedule targets for overall compliance. Another consideration for field investigations is evaluating whether the data that could be collected in the field is likely to change the conservative model outcome which is where the back analysis plays an important role. If back-analysis results are unrealistic compared to expected or typical TSF properties, it is unlikely that field investigation will provide value in meeting closure criteria, and stabilizing measures will be necessary, regardless of the data gaps.

For the purposes of the planning an investigation, the engineering team must think strategically about the key data that will most benefit the gaps in the current stability models. The team should think long-term about questions that may arise not only during the next revision phase of the analyses but also details that may become critical during a future design phase. In many cases, questions around remaining saturation of old tailings deposits are key because this influences both static and post-earthquake stability. Estimates for

undrained strengths of saturated tailings also tend to be a key parameter for development of stability models. This process of using the field collected data can be iterative with multiple rounds of investigation and analysis updates necessary to address gaps satisfactorily prior to beginning closure design. However, as described above, the Owner should consider the option of beginning closure design with conservative models, even when some data gaps may remain. It is sometimes more efficient to develop a conservative closure design instead of completing additional field investigations until all data gaps are filled.

Risk tolerance and specific site goals dictate how this last step is addressed, and a collaborative effort between the TSF management team (Owner's) and the engineering team is critical to shaping the most efficient closure path to reach the closure objectives. Better and more information is always preferred, but professional judgement informed by a thorough analysis approach can help move a site to completion if all parties are motivated to answer the key questions within the framework of what needs to be resolved and what can remain unknown.

Conclusion

Closure of legacy TSFs can be a lengthy process with limited historical data, but to comply with GISTM, many sites have a limited timeframe to achieve compliance. These timelines can be challenging to meet when questions arise that were not anticipated or built into the analysis approach. In particular, TSF embankment stability is among critical closure risks. Closure planning for legacy sites should begin with identification of the closure criteria based on relevant guidelines, regulations, and Owner goals. After identification of the closure criteria, historical data is collected and assessed to identify data gaps prior to developing preliminary CSMs. CSMs should be developed using site data identified during the historical assessment, and sensitivity analyses should be completed to evaluate the potential range of conditions that meet closure criteria and identify critical data gaps. The CSM and sensitivity analyses may show that the site meets the closure criteria and does not require additional action.

If the CSM does not meet the closure criteria, parameters that would meet the criteria should be back-calculated to set expectations and objectives for field investigation or stabilization measures. Results of the conceptual model, sensitivity analyses and back-calculations, if completed, should then be used to decide whether to conduct targeted field investigations, or to begin closure design with conservative assumptions. If completion of additional field investigation and updates of analyses are warranted, it may be an iterative process depending on closure objectives and available schedule.

Although some stakeholders may want to know every TSF site detail, this may not always be the best and most efficient path to effective risk mitigation for site closure. TSF closure designed to mitigate the worst-case scenario in a cost-effective and timely manner to meet GISTM compliance goals is also a viable path forward. As we advance the state of practice and follow new Best Practice guidelines, filling

critical data gaps or demonstrating closure with thorough and conservative analyses should be a primary focus ahead of filling all data gaps for legacy TSFs.

Enhancing the Safety of Tailings Dams: An Updated Approach in Fault Tree Analysis and Probabilities

Geinfranco Villalta, Stantec, Peru
Raquel Borja, Stantec, Peru

Abstract

The complexity and scale of tailings dams, along with recent catastrophic failures, highlight the need for advanced risk assessment methodologies. This study presents an updated probabilistic analysis of tailings dam failures using fault tree analysis (FTA), incorporating recent data from failure incidents and integrating contemporary failure probabilities.

A comprehensive review of tailings dam failure databases was conducted to identify prevalent failure modes and critical vulnerabilities. A sensitivity analysis was applied to the updated FTA model, identifying key events that significantly influence the overall failure probability and providing a dynamic risk assessment framework adaptable to changing conditions.

The research concludes with strategic recommendations for enhancing dam stability, including design innovations, structural modifications, and improved monitoring protocols. The methodology's effectiveness is demonstrated through a case study, advancing the field of tailings dam risk assessment and contributing to the prevention of future failures.

Introduction

Tailings dams are critical in mining operations, storing byproducts from mining processes. However, their potential for catastrophic failure poses significant environmental and economic risks. Recent failures, such as the 2015 Bento Rodrigues and 2019 Brumadinho disasters in Brazil, underscore the urgent need for enhanced risk assessment methodologies.

This paper enhances tailings dam safety through an updated FTA integrated with recent probabilistic data. By recalibrating risk factors with current incident data and applying sensitivity analysis, the study offers a dynamic risk assessment framework that identifies key vulnerabilities and informs better design and management practices.

Through a comprehensive review of failure databases, the updated FTA model systematically maps potential failure mechanisms, providing insights that guide strategic recommendations for improving dam

stability. This research advances the field by offering a robust methodology for predicting and preventing failures, contributing to the long-term safety and reliability of tailings storage facilities.

Background

Tailings dams are vital structures in mining, designed to store byproducts of operations. Their failure can result in catastrophic consequences, including loss of life, environmental damage, and significant economic costs. Historical data, such as the 2015 Bento Rodrigues and 2019 Brumadinho disasters, highlight the frequency and severity of these failures, emphasizing the need for rigorous risk assessment and management practices. Databases like the WISE-Uranium Project provide continuous updates on major failures, underscoring the ongoing risks.

Traditional risk assessment methods, like deterministic approaches, evaluate dam stability under specific conditions but often overlook uncertainties in geotechnical properties and loading. Probabilistic Risk Assessment (PRA) offers a more advanced approach by incorporating variability and uncertainty, allowing for a comprehensive understanding of risks through statistical analysis and probability distributions.

FTA is a prominent risk assessment technique for complex systems like tailings dams. It uses a top-down approach to identify and quantify the causes of failure, providing valuable insights into critical components and weak points. Studies by Hartford and Baecher (2004), along with recent advancements by Taguchi (2014) and De La Cruz (2017), demonstrate FTA's effectiveness in improving safety protocols. By focusing on primary failure modes such as earthquake-induced failures, overtopping, and slope instability, FTA supports the development of robust mitigation strategies, advancing the safety and reliability of tailings storage facilities.

Failure tailings dam events

The history of tailings dam failures is marked by numerous catastrophic events with significant environmental and human impacts. According to the International Commission on Large Dams (ICOLD), the primary causes of these failures – overtopping, slope instability, earthquakes, foundation issues, seepage, and structural failures – have evolved over decades.

Recent analyses using databases like the CSP, WISE Uranium Project, and World Mine Tailings Failures database offer detailed records on incidents, including mine locations, dam types, and failure causes. These resources, though not exhaustive, are critical for identifying trends and risk factors. By integrating data from these comprehensive sources, this research aims to develop targeted mitigation strategies and improve safety standards in the mining industry, thereby reducing the risks of future catastrophic events.

Understanding the historical context and evolving nature of tailings dam failures is essential for enhancing the safety and reliability of these structures. This research contributes to the ongoing effort to prevent future incidents and strengthen risk management practices in the mining sector.

Main failure modes identified

The classification of tailings dam failure modes has evolved significantly, incorporating a deeper understanding of their causes and interactions. Taguchi (2014) refined this classification into five key failure modes: overtopping, static liquefaction, internal erosion, static slope instability, and seismic slope instability. This classification aligns with previous studies while adding nuanced perspectives on event triggers and interrelations.

Rico et al. (2008) expanded the database on tailings dam failures, identifying additional factors such as mine subsidence, unusual rain, snowmelt, and poor management practices. They emphasized the prominence of slope instability, overtopping, and earthquakes, especially in upstream-constructed tailings facilities. This highlights the need for comprehensive risk management approaches.

Stark et al. (2022) and De La Cruz (2017) further corroborated these findings. Stark et al.'s (2022) analysis emphasized the importance of robust seismic design and ongoing monitoring to mitigate seismic instability risks. De La Cruz illustrated the complex interplay between design flaws, operational practices, and environmental factors contributing to failures. These studies underscore the necessity for advanced risk assessment methodologies like FTA to enhance the safety of tailings dams. Therefore, this paper focuses on the three main failure modes: earthquake-induced failures, overtopping, and slope instability.

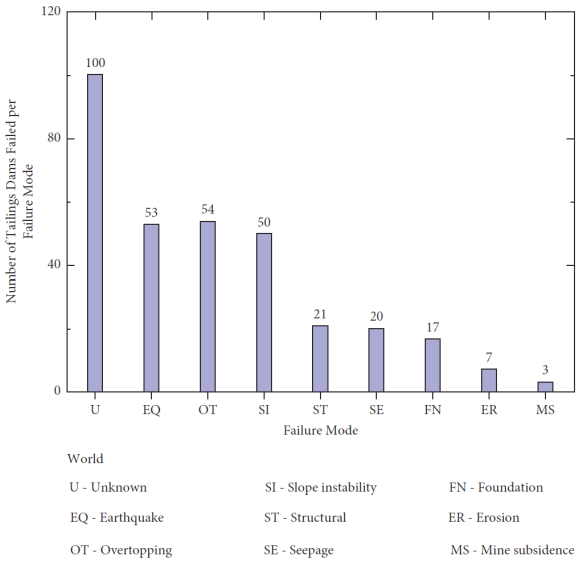

Figure 1: Updated number of tailings dam failed per failure mode in the world (Stark et al., 2022)

Figure 1, adapted from Stark et al. (2022), illustrates the number of tailings dam failures by failure mode. The most frequent causes are unknown (100 incidents), followed by earthquake-induced failures (EQ, 53 incidents), overtopping (OT, 54 incidents), and slope instability (SI, 50 incidents). Other failure modes include structural issues (21 incidents), seepage (20 incidents), foundation problems (17 incidents), erosion (7 incidents), and mine subsidence (3 incidents). This data emphasizes the need for robust design and risk assessment practices to mitigate these common failure mechanisms. For this reason, this paper will focus on discussing the three main failure modes: earthquake-induced failures, overtopping, and slope instability.

Probability of tailings dam failures

The probability of tailings dam failures has evolved significantly with advancements in engineering practices and risk assessment methodologies. Historical failure rates, as reviewed by Silva et al. (2008), have shown a trend towards lower probabilities in well-designed and managed facilities, underscoring the importance of robust engineering and comprehensive safety practices.

De La Cruz (2017) methodology integrates historical data, expert judgment, and advanced probabilistic techniques. Extensive historical failure data provides a foundation for understanding the frequency and types of basic events leading to failures. Expert opinions are elicited to estimate probabilities for events with limited data, based on their experience and understanding of failure mechanisms.

In Taguchi (2014), probabilities of basic events were estimated through historical data analysis, expert judgment, and probabilistic modeling. Historical failure data provided a basis for understanding the frequency and nature of basic events, refined through expert elicitation. Appendix A summarizes the estimated probabilities of basic events for the three main failure modes (static instability, overtopping, and seismic instability).

By integrating historical data, expert insights, and probabilistic techniques, the methodologies developed by De La Cruz and Taguchi provide a robust framework for understanding and mitigating the risks associated with tailings dam failures. This approach ensures probability estimates are reflective of real-world conditions, enhancing the reliability of risk assessments for tailings dams.

Fault tree analysis

FTA is a systematic, deductive failure analysis technique used to identify and evaluate the possible causes of a predefined undesired event, such as a failure in a tailings dam. It involves creating a fault tree, a graphical representation that uses logical gates to map out the pathways leading to the failure (Baecher and Christian, 2003). Each pathway traces back from the top event (the undesired event) to the basic events that contribute to it, allowing for a thorough examination of potential failure causes.

Procedure

The procedure begins by identifying a critical failure, known as the "top level" event, and placing it at the top of the fault tree diagram. From this top event, the possible intermediate causes leading to it are identified and analyzed. Each failure is examined step by step to identify its potential causes, moving to successively lower levels of the system until further analysis is deemed unproductive (ISO/IEC, 2009). Boolean logic is used to combine these lower-level events into the fault tree. A schematic FTA is shown in Figure 2, along with conventional logic gate symbols, is typically used to illustrate the main concepts, although some symbols specific to mechanical systems may be excluded for simplicity.

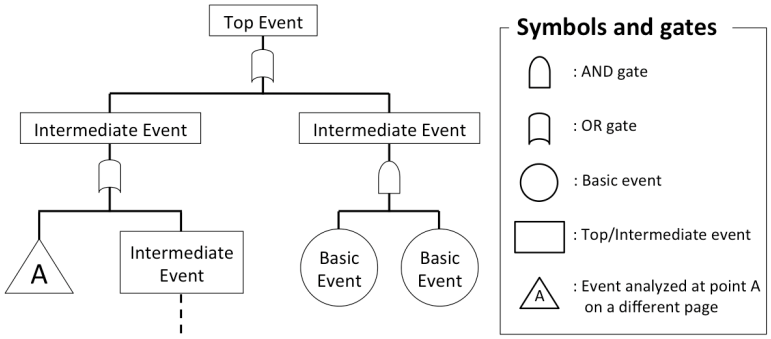

Figure 2: Example of fault tree analysis (Taguchi, 2014)

Boolean algebra for calculation of top event probability

Boolean algebra is used to combine the probabilities of basic events to calculate the total probability of the top event. The process involves using logical gates, primarily AND and OR gates, to represent how basic events contribute to intermediate events and ultimately to the top event.

AND gate

An AND gate represents a scenario where the higher-level event (output) occurs only if all the lower-level events (inputs) occur simultaneously. The probability of the event represented by an AND gate is calculated as the product of the probabilities of its input events. If E_1 and E_2 are the inputs events, the probability of P of the output event occurring is:

$$P(AND) = P(E_1)P(E_2)$$

OR gate

An OR gate represents a scenario where the higher-level event (output) occurs if at least one of the lower-level events (inputs) occurs. The probability of the event represented by an OR gate is calculated using the sum of the probabilities of the input events minus the product of their probabilities to avoid double counting. If E_1 and E_2 are the inputs events, the probability of P of the output event occurring is:

$$P(OR) = P(E_1) + P(E_2) - P(E_1)P(E_2)$$

Subjective probabilities of basic events

In FTA, assessing probabilities for basic events is crucial, especially given the limited data available. Subjective probabilities, often derived from expert judgment, play a significant role and are based on intuition, past experiences, and qualitative beliefs. However, these probabilities are prone to biases such as overconfidence, anchoring, and representativeness, which can affect the accuracy of risk assessments (Baecher and Christian, 2003; Villalta and Borja, 2023). Experiments by Fischhoff et al. (1977) and studies in geotechnical engineering by Folayan et al. (1970) and Baecher (1972) highlight the risks of overconfidence in subjective estimates. Therefore, careful elicitation and consideration of expert judgments are essential. The probabilities in Appendix A, originally defined by Taguchi (2014) and updated by Stark et al. (2022), should be applied with caution, considering site-specific variability.

Application of FTA to analyze the failure of tailings dams

The application of FTA to tailings dam failures involves constructing fault trees for different failure modes, such as seismic slope instability (SS), overtopping (OT), and static slope instability (SI). Appendix B presents the fault trees constructed for these primary failure modes. Table 1 shows the probability of failure for each mode, calculated based on the probabilities established in Appendix A and applying Boolean algebra within the FTA framework.

Table 1: Outcomes for probabilistic analysis of FTA

Failure mode	Probability of top event
Static Instability (SI)	1.7×10^{-4}
Overtopping (OT)	1.1×10^{-4}
Seismic Stability (SS)	2.3×10^{-6}

These results highlight the likelihood of failure for each mode, providing a quantitative basis for understanding the risks associated with tailings dam operations. By constructing detailed fault trees and systematically analyzing the probabilities of basic events, FTA enables a comprehensive assessment of potential failure scenarios and their impacts. This methodical approach is essential for identifying critical vulnerabilities and implementing targeted risk mitigation strategies to enhance the safety and reliability of tailings dams.

Sensitivity analysis

Sensitivity analysis is a critical component of the probabilistic risk assessment framework, providing insights into which basic events have the most significant impact on the overall probability of failure. By systematically varying the probabilities of basic events and observing the resulting changes in the top event

probability, we can identify critical factors that should be prioritized in risk management strategies.

Methodology for sensitivity analysis

The sensitivity analysis in this study involves the following steps:

1. **Identify basic events**: Determine the basic events from the fault tree models for overtopping, seismic instability, and static instability.
2. **Vary probabilities**: Systematically vary the probabilities of each basic event within a realistic range based on historical data and expert judgment.
3. **Recalculate top event probability**: For each variation, recalculate the overall probability of the top event (i.e., failure of the tailings dam).
4. **Analyze impact**: Assess the impact of changes in the basic event probabilities on the overall failure probability. This is typically visualized using Tornado plots, which show the relative influence of each basic event.

Define variation ranges

The selection of variation ranges for sensitivity analysis, as detailed in Table 1, was strategically designed to evaluate the fault tree model's sensitivity to changes in basic event probabilities. The chosen ranges (-90%, -50%, -20%, -10%, +10%, +20%, +50%, +90%) cover a broad spectrum of realistic scenarios, from minor adjustments to significant shifts, ensuring the analysis reflects potential real-world conditions (Hartford and Baecher, 2004).

These diverse variation magnitudes help identify non-linear effects and threshold points critical in complex systems like tailings dams. By including both negative and positive variations, the analysis accounts for overestimations and underestimations, providing a balanced risk assessment (Taguchi, 2014; Bowker and Chambers, 2015). The incremental steps ensure comprehensive coverage, capturing both subtle and extreme influences while maintaining probabilities within logical bounds to preserve the integrity of the analysis (Piciullo et al., 2022). These ranges, supported by historical data and expert judgment, enhance the credibility and relevance of the sensitivity analysis results (Stark et al., 2022).

Outcomes

The sensitivity analysis of tailings dam failure probabilities focused on three primary failure modes: static instability, overtopping, and seismic instability. The results provide detailed insights into how variations in basic event probabilities influence the overall failure probability, highlighting critical factors that significantly impact tailings dam stability.

Static Instability

The sensitivity analysis for static instability in tailings dams identified several key basic events that significantly influence the overall probability of failure. The findings emphasize the importance of managing these events to prevent static instability. Figure 3 shows the tornado plot for the sensitivity analysis.

Critical events

- **Over-steepened slope (SI10)**: This event demonstrates substantial sensitivity, particularly at higher positive variations (+50% and +90%). The significant increase in the total probability of static slope instability with higher probabilities of an over-steepened slope underscores the importance of maintaining safe slope parameters. Effective slope monitoring and management are essential to mitigate this critical risk (Stark et al., 2022).
- **Change in material behavior (SI3)**: Like SI10, SI3 shows a notable impact on the overall failure probability, especially at higher variation levels. This finding highlights the necessity of monitoring and managing changes in material behavior to prevent static instability. Understanding and controlling material properties are crucial (Taguchi, 2014).

Moderate impact events

- **Pore pressure increase (SI4)** and **high pool (SI5)**: These events exhibit considerable sensitivity, particularly at higher positive variations. Proper management of pore pressure and water levels within the dam is crucial to maintaining stability. Regular monitoring and proactive measures to control pore pressure and water levels can significantly reduce the risk of static instability (Hartford and Baecher, 2004).
- **Long term degradation (SI6)** and **poor pool management (SI7)**: These events display moderate sensitivity across the variation range, indicating a steady influence on the overall failure probability. Consistent maintenance practices and effective pool management strategies are necessary to mitigate these risks. Ensuring the long-term integrity of the dam structure and proper pool management can prevent gradual degradation (Piciullo et al., 2022).

Lower impact events

- **Susceptible Features in foundation (SI1)**, **unsuccessful detection (SI2)**, **runoff leading to increased water elevation (SI8)**, and **poor management of increased pool (SI9)**: These events show relatively lower sensitivity compared to others. However, they still contribute to the overall

risk, and their probabilities should be carefully monitored and controlled. Addressing these events through targeted risk management practices can further enhance dam stability.

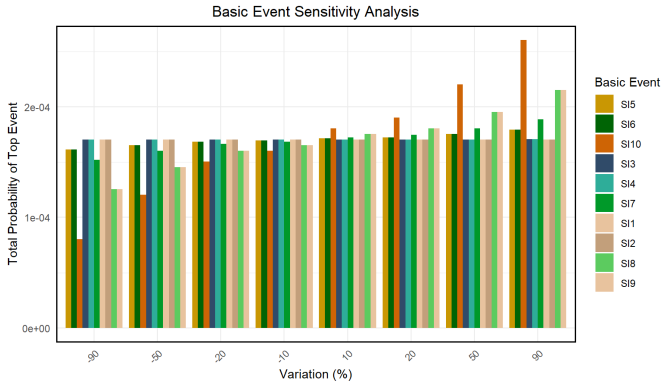

Figure 3: Tornado plot for static instability sensitivity analysis

Overtopping

The Tornado plot for the sensitivity analysis of overtopping in tailings dams provides essential insights into how variations in the probabilities of basic events influence the overall probability of overtopping failure. Figure 4 shows the tornado plot for the sensitivity analysis.

Critical events

- **Head cut advances to upstream surface (OT1)**: This event shows substantial sensitivity, particularly at higher positive variations (+50% and +90%). The significant increase in the total probability of overtopping with higher probabilities of head cut advancing to the upstream face underscores the importance of maintaining the structural integrity of the dam's upstream face. Effective monitoring and intervention are essential to mitigate this critical risk (Stark et al., 2022).
- **High pool (OT4)**: Like OT1, OT4 shows a notable impact on the overall failure probability, especially at higher variation levels. This finding highlights the necessity of maintaining adequate freeboard and effective water management practices to prevent overtopping. Proper management of water levels within the dam is crucial to maintaining stability (Taguchi, 2014).

Moderate impact events

- **Slurry inflow exceeds design capacity (OT5)** and **natural ore variability (OT6)**: These events exhibit considerable sensitivity, particularly at higher positive variations. Proper management of slurry inflow and understanding the variability of ore properties are critical to maintaining stability. Regular monitoring and proactive measures to control these factors can significantly reduce the risk of overtopping (Hartford and Baecher, 2004).

- **Design error (OT7)** and **exceedance of design criteria (OT8)**: These events display moderate sensitivity across the variation range, indicating a steady influence on the overall failure probability. Robust design standards and thorough review processes are necessary to mitigate these risks. Ensuring that the dam is designed to withstand expected loads and operational conditions can prevent design-related failures (Piciullo et al., 2022, 2022).

Lower impact events

- Runoff leading to increased string wind (OT12), earth / rockslide (OT13), high pool (OT14), unsuccessful intervention (OT11), and rapid thaw (OT10): These events show relatively lower sensitivity compared to others. However, they still contribute to the overall risk, and their probabilities should be carefully monitored and controlled. Addressing these events through targeted risk management practices can further enhance dam stability.

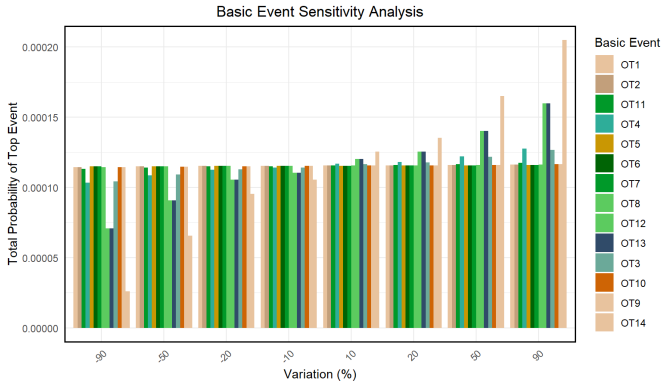

Figure 4: Tornado plot for overtopping sensitivity analysis

Seismic Instability

The sensitivity analysis for seismic instability identified the critical factors that significantly impact the failure probability during seismic events. Figure 5 shows the tornado plot for the sensitivity analysis.

Critical events

- **Ground motion exceeding design parameters (SS9)**: This event demonstrates substantial sensitivity, particularly at higher positive variations (+50% and +90%). The significant increase in the total probability of seismic instability with higher probabilities of ground motion exceeding design parameters underscores the importance of designing dams to withstand expected seismic loads and conducting regular seismic risk assessments (Stark et al., 2022). Ensuring the dam's structural integrity against seismic loads is paramount for preventing seismic instability.

- **Liquefaction (SS3)**: Similar to SS9, SS3 shows a notable impact on the overall failure probability, especially at higher variation levels. This finding highlights the necessity of implementing measures to improve soil stability and prevent liquefaction in seismically active regions (Taguchi, 2014). Effective soil stabilization and reinforcement techniques are essential to mitigate this critical risk.

Moderate impact events

- **Slope steepness (SS4)** and **pore pressure increase (SS5)**: These events exhibit considerable sensitivity, particularly at higher positive variations. Proper management of slope steepness and pore pressure is crucial to maintaining stability during seismic events. Regular monitoring and proactive measures to control these factors can significantly reduce the risk of seismic instability (Hartford and Baecher, 2004).
- **Change in material behavior (SS6)** and **tailing water release from pool (SS7)**: These events display moderate sensitivity across the variation range, indicating a steady influence on the overall failure probability. Ensuring that the dam's materials remain stable under seismic conditions and managing the release of tailing water are essential to mitigate these risks (Piciullo et al., 2022).

Lower impact events

- **Undrained situation (SS1)**, **contractive material (SS2)**, **displacement intercepts pool (SS8)**: These events show relatively lower sensitivity compared to others. However, they still contribute to the overall risk, and their probabilities should be carefully monitored and controlled. Addressing these events through targeted risk management practices can further enhance dam stability (Bowker and Chambers, 2015).

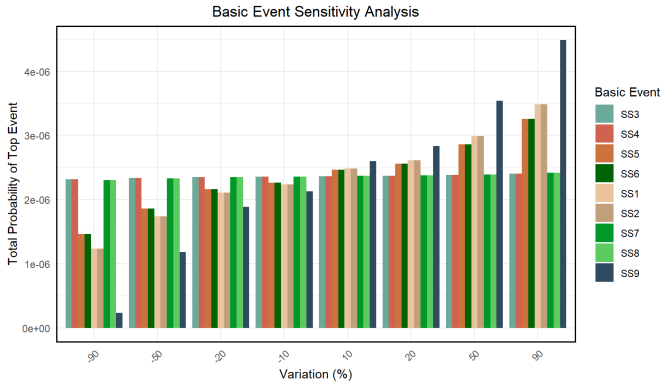

Figure 5: Tornado plot for seismic instability sensitivity analysis

Summary of findings

The sensitivity analysis across the three failure modes – static instability, overtopping, and seismic instability – provides critical insights into the factors that most significantly affect the stability of tailings dams. The key outcomes include:

- The importance of maintaining surface integrity and internal drainage to prevent static instability.
- The necessity of effective water management and drainage maintenance to mitigate overtopping risks.
- The critical need for soil stability measures and robust seismic design standards to address seismic instability.

These findings emphasize the need for targeted risk management strategies that focus on the most influential factors identified through sensitivity analysis. By addressing these critical areas, dam operators can significantly enhance the safety and reliability of tailings dams.

Conclusion

This study offers an in-depth analysis of tailings dam failure probabilities using fault tree analysis (FTA) combined with sensitivity analysis, focusing on static instability, overtopping, and seismic instability. Key findings highlight those specific basic events, such as over-steepened slopes, high pool levels, and ground motion exceeding design parameters, disproportionately impact failure probabilities, emphasizing the need for targeted risk management strategies.

The analysis underscores the importance of maintaining up-to-date probabilistic data, reflecting current conditions for accurate risk assessment. While the probabilities derived from Taguchi (2014) and updated by Stark et al. (2022) provide a foundational basis, their applicability may vary across different sites, necessitating site-specific validation. The study also recognizes that varying one probability at a time in sensitivity analysis may not fully account for interdependencies between variables, suggesting that future research should explore these relationships.

The practical applicability of this methodology is demonstrated through insights into critical risk areas, enabling the development of robust mitigation measures. By implementing these recommendations, the likelihood of catastrophic failures can be significantly reduced, safeguarding human lives, environmental health, and infrastructure integrity. This research advances tailings dam risk assessment by integrating FTA with updated probabilistic data and sensitivity analysis, offering actionable insights for improving dam safety. Future efforts should focus on refining these models and incorporating additional data to enhance the reliability and applicability of the risk assessment framework.

Analysis of the Deformation and Cracking Mechanism of the Itabiruçu Dam – Case Study

Paulo Cella, BVP Geotecnia e Hidrotecnia, Brazil

Felipe Neiva, BVP Geotecnia e Hidrotecnia, Brazil
Laura Rodríguez, Ex-BVP, Brazil

Abstract

This work aims to understand the dominant displacement mechanism that resulted in a set of longitudinal cracks, a few tens of meters long, that affected the Itabiruçu Dam, Conceição Mine, Itabira Complex, Minas Gerais, Brazil The dam is currently 71 meters high and has a crest length of around 920 meters. The appearance of cracks caused the fourth dam raise to be halted for over 2.5 years, starting in mid-2019. A significant number of field and laboratory investigations, as well as a comprehensive monitoring program implemented after construction was halted, produced a rich data set, which in this article is subjected to a careful analysis of the actual displacements caused by differential settlements of the foundation beneath the downstream shell of the dam. In addition to looking into the numerical model results (on which this paper is not specifically focused) as a basis for the monitoring evaluation, a comparison was also made with a finite element classical study (Clough and Woodward, 1967), in which the construction of an idealized dam in several stages is appraised by assigning material deformability within a range of contrasting embankment/foundation stiffness ratios. In the case study presented herein, the vertical-to-horizontal displacement ratio was found to be more likely to correspond to the pattern of components associated with the gravitational dam settlement as an isolated mechanism, rather than a potential underlying foundation shear band development.

Introduction

Loading effects in compacted soil embankments can lead to anomalies that affect the physical stability of a facility during operation and decommissioning. According to Silvera (2006), construction-related issues can develop depending on the rate at which the embankment is built on a saturated foundation or differential stiffnesses occurrence contrasts between the embankment and the foundation.

Clough and Woodward (1967) studied the pattern of displacements induced along the embankment-foundation interface of an earth dam in idealized gravity settlement models, based on different stiffness ratios between these materials, considering incremental and single-stage loading. The results showed that the distribution of horizontal and shear stresses at the embankment-foundation interface, as well as vertical and horizontal displacements, are significantly affected by the stiffness contrast between embankment and foundation.

Poulos and Davis (1972) also arrived at similar conclusions, by normalizing the displacements based on the displacement influence factor concept proposed by Poulos et. al (1972), which differs according to construction stages.

This paper presents the case of the Itabiruçu Dam (Figure 1). The dam has had a history of surface cracks. The study attempted to investigate whether the cracks were due to differential gravitational settlement, or horizontal displacement along a potential deep shear band, at the embankment-foundation interface.

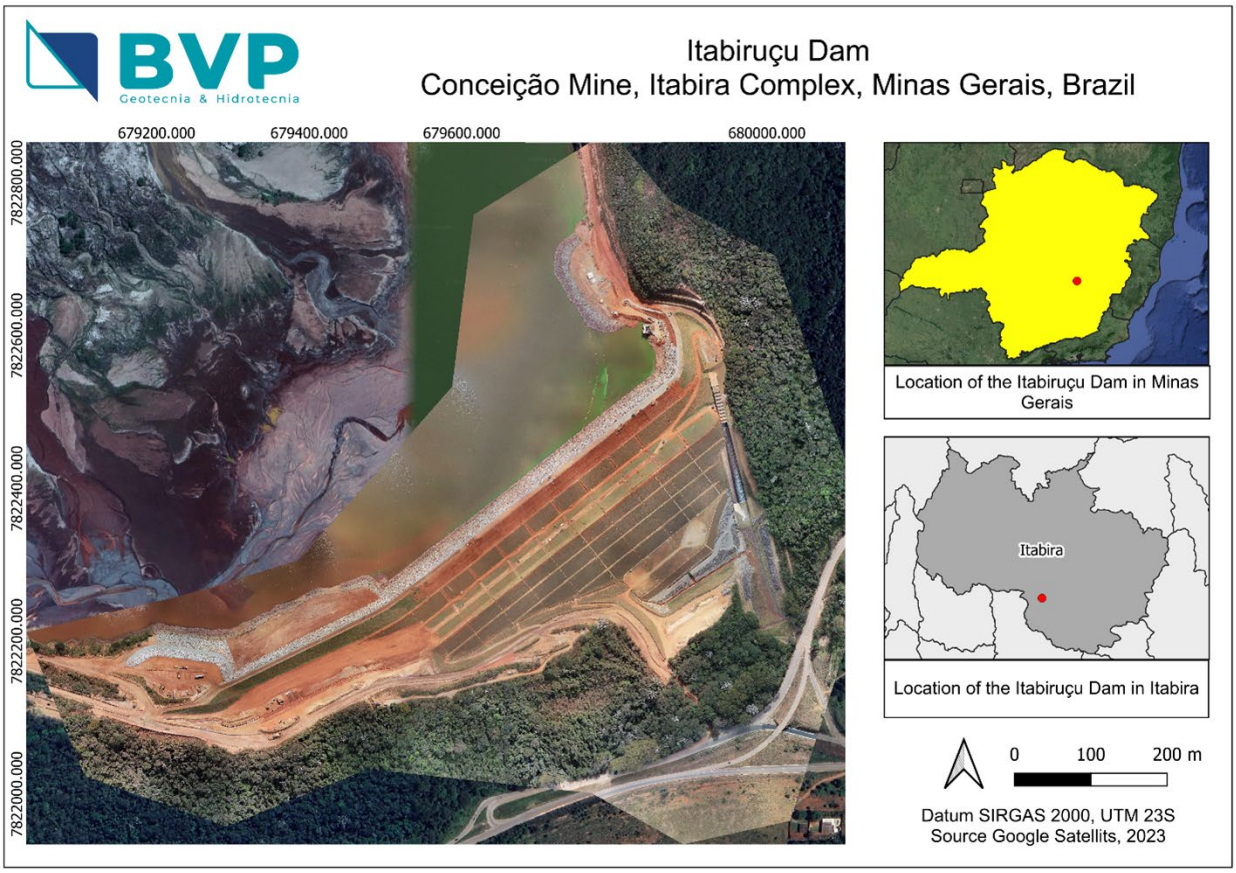

Figure 1: Location of the Itabiruçu Dam (source: Google Satellites)

Key facts about the most recent raise of the dam

Itabiruçu Dam was built at Conceição Mine, Itabira Complex, Minas Gerais, Brazil, to store iron tailings generated and provide water for ore processing. The starter dyke was built circa 1980/1981 to a crest elevation of 812.0 m. During operations, the dam has undergone four downstream raises: in 2004, to elevation 817.5 m; in 2011, to elevation 833.0 m; in 2016, to elevation 836.0 m; and in 2023, to elevation 841.0 m.

The last-mentioned raise was started in 2018, and was planned to reach an elevation of 850.0 m. However, in July 2019, after the crest reached an elevation of 819 m, construction was preventively halted following the appearance of centimetric lengthwise cracks, close to the contact between the previous raise and the new one (see Figure 2), as well as cross cracks at the left abutment. Construction resumed in May 2022 after a comprehensive field investigation program was carried out, monitoring instruments installed, and numerical simulations performed to understand the displacement mechanism. Construction was completed in July 2023, to a modified design crest elevation of 841 m, and guidelines were set out to control the rate of rise, and to establish a threshold settlement for the structure.

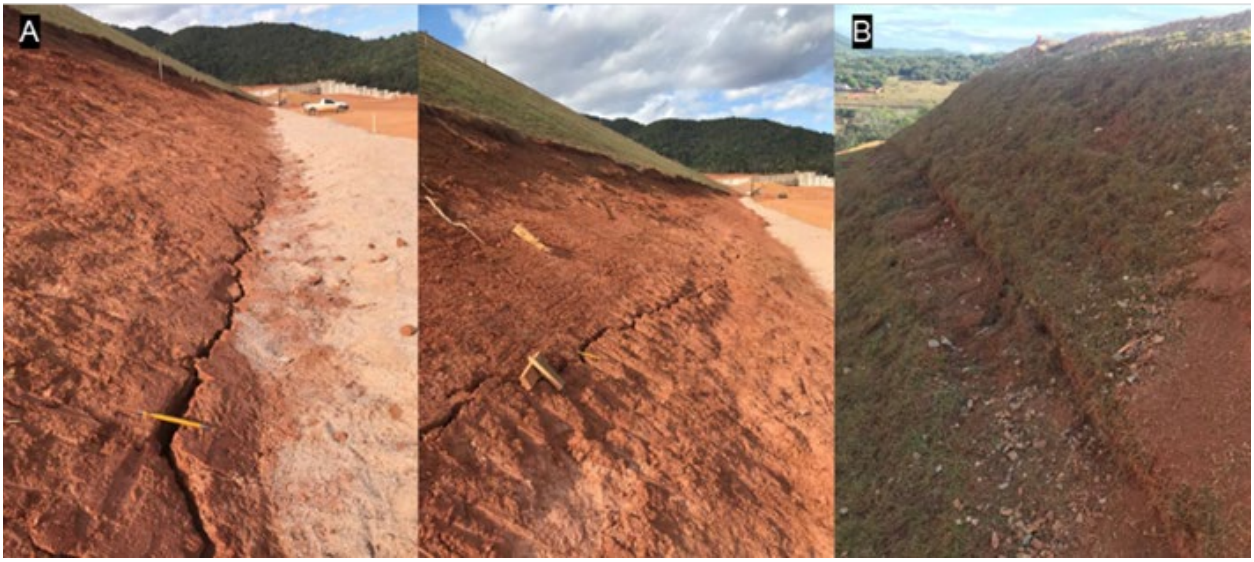

Figure 2: A) Cracks on the downstream dam shell, at the contact between the previous raise and the new one (Berm el. 818 m); B) Left abutment cracks (source: own archive)

A comprehensive field investigation program was carried out, and monitoring instruments installed. This allowed for enhanced knowledge on both foundation conditions and behavior, and evolution and gradual stabilization of facility movements. Among the studies was the numerical simulation of the dam with undrained foundation, in which constitutive model selection, mesh sizes, and medium discretization refinement, as well as important distinctions of geotechnical foundation units sectorization, were thoroughly discussed and enhanced over more than two years of work, with various professionals having

been engaged, including designers, EoR, client, Public Prosecutor's Office auditors. Stiffness, compressibility, and hydraulic conductivity parameters of the embankments were adjusted in several stages, in order to replicate the decreasing settlement rates and the piezometric levels established. The numerical model was accurately calibrated, hence data value and reliability for interpretation of dominant deformational mechanism and facility behavior trend in the medium term, as long as no significant changes occur in the patterns identified to date.

Geological-geotechnical foundation condition

Geological-geotechnical data on Itabiruçu dam is based on several site investigation programs performed during dam design and raise phases (Figure 3).

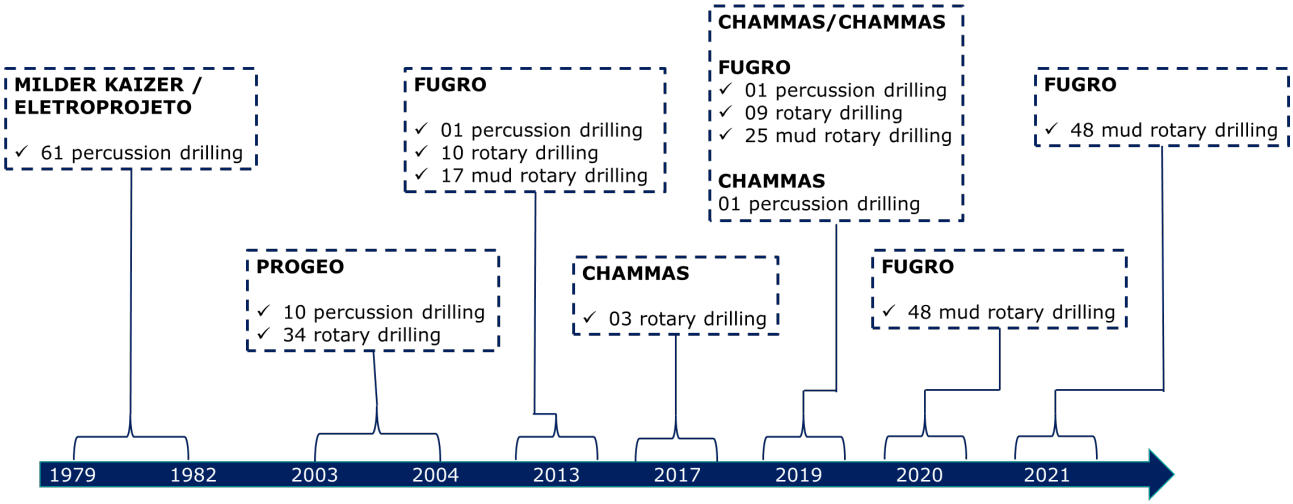

Figure 3: Itabiruçu dam investigations timeline (source: BVP, 2023c)

The dam footprint comprises weathered rocks and soils from Nova Lima Supergroup schists and Guanhães Complex migmatite gneisses. Schists occur predominantly at the dam toe and on the left abutment. They can include mafic schist, steatite, and serpentinite (talc-schist), usually as saprolite, saprolite and residual soil, generally clayey. Gneiss, on the other hand, outcrops mainly as saprolite soil along the right abutment and central portion of the dam. Within this area, large saprolite thicknesses were encountered in the boreholes, underlying clayey-sandy to sandy-clayey saprolite soil, with felsic bands. In total, there are about 7500 meters of boreholes, five CPTs, and over fifty in situ? strength tests.

Geological-geotechnical units

The geotechnical units under the Itabiruçu Dam footprint were carefully characterized following the assessment of the site investigation data. Two gneiss saprolite units were identified: a saprolite soil / young residual soil, referred to as “SAC” underlain by a well-structured saprolite soil, referred to as “SSG”. SAC

is a more compressible and less permeable unit than SSG. It has lower strength parameters and develops excess pore pressure during shear up to the maximum deviatoric stress. SSG has been shown to dissipate partly or totally the excess pore pressures in undrained triaxial tests.

These two subunits were differentiated by applying double corrections to the SPT blow count (N_{SPT}) obtained from drilling programs, especially from 2013 onwards. The corrections were required to account for the significant increase in confinement (due to placement of 40 to 45 m of embankment) compared to in situ testing carried out in 1977, 1983, and 2004, which were drilled on native ground or minor embankments, and also to account for energy losses due to much longer string lengths. Correction due to confining stress used the methodology proposed by Boulanger (2003), specific to low-plasticity silty soils (correction index lower than sand index), in order to obtain NSPT values in conditions comparable to those of the boreholes drilled in earlier investigation phases. On top of these two corrections, an additional factor of 0,7 concerning the energy efficiency. For SAC, $N_{SPT} < 10$. For SSG, $10 \leq N_{SPT} \leq 35$.

The prominent heterogeneity of saprolite horizons, with varying textures (from clayey to sandy soils) and colors, favors the adoption of a correction parameter for N_{SPT}, at the expense of reduced assertiveness in tactile-visual differentiation from the drill cores.

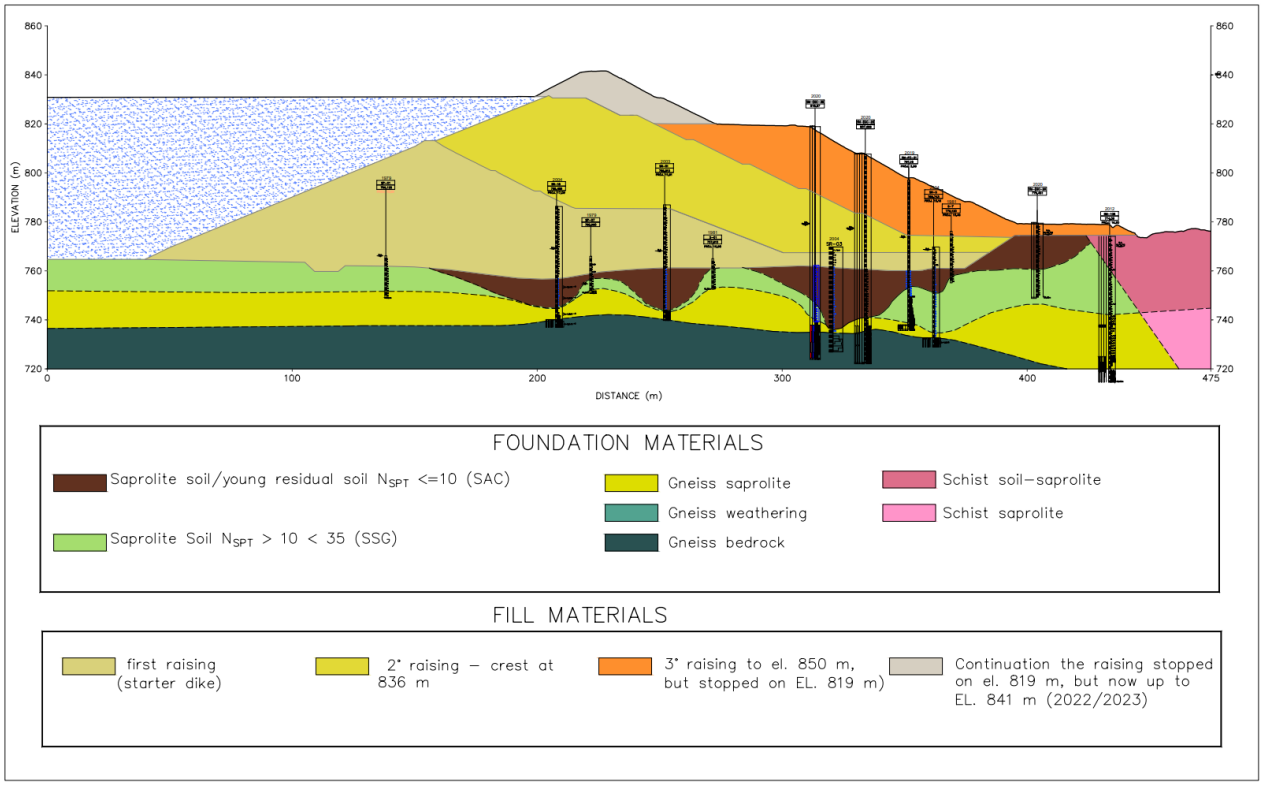

Figure 4: Sections with adjusted NSPT values, differentiating two saprolite soil horizons, one with NSPT <10 and the other with 10> NSPT <35 (source: BVP, 2023c)

The section in Figure 4 identifies the two units, SAC (in brown) overlying the less compressible soils SSG (in green). The thickness of the SAC soil ranges from 5 to 25 m, whereas the SSG ranges from 7 to 30 m. A slightly altered gneiss saprolite underlies the saprolite layer. The thickness of the saprolite ranges from 5 to 15 m. The other foundation materials are also presented.

Settlement basin

The settlements large-scale pattern in the downstream shell, as measured from the prisms/survey monuments, was shaped like a bow (or basin). The center of the basin coincided with the lengthwise crack observed at the contact between the existing embankment and the new raise. Figure 5 plots the vertical displacements over the monitoring period (from 2019 to 2023). Ranges of accumulated vertical displacement (15 to 100 mm; 100 to 300 mm, and greater than 300 mm) are shown in different colors, for reference. A maximum settlement of 420 mm was reached during the stabilization phase, before construction was resumed, and over 500 mm was reached during the final raise to the crest at elevation 841 m, starting from the downstream plateau, halted in 2019 at elevation 819 m. As a result, a 38 m wide berm was shaped along the downstream slope (Figure 4).

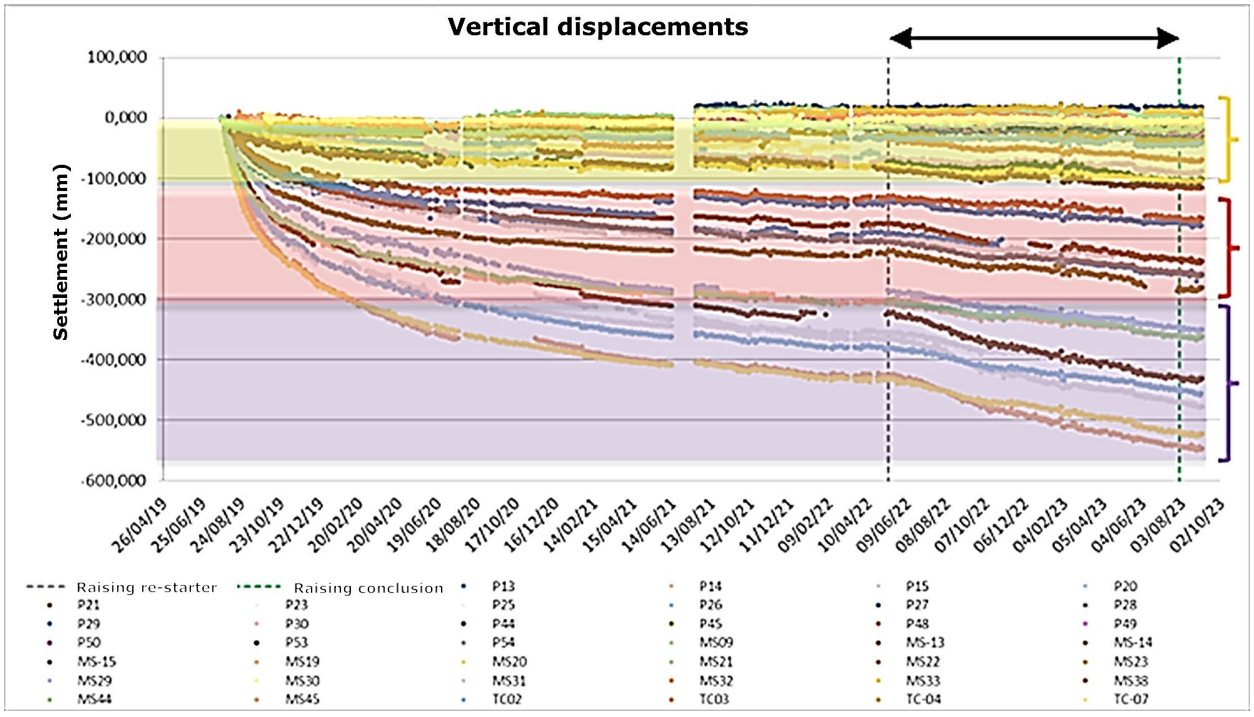

Figure 5: Prisms and survey monuments – full monitoring period – accumulated settlement. double arrow indicates works resume period (source: BVP, 2023c)

The data shows a gradual slowdown in the settlement rate during the first few years of monitoring. The decreasing settlement rate was used to calibrate the numerical model. Note that monitoring only started about two months after construction was stopped, in 2019.

Figure 6 plots contours of accumulated settlement measured from August to October 2019. The arrows plot the direction and magnitude of the horizontal displacement component at each instrument location. The contours and arrow pattern indicate the existence of a settlement basin. Figure 7 shows the settlement basin six months after construction was completed, in July 2023. The instruments MS-19 and MS-20 located at the center of the basin show vertical displacements of 548 mm and 523 mm, respectively, with full stabilization yet to be achieved.

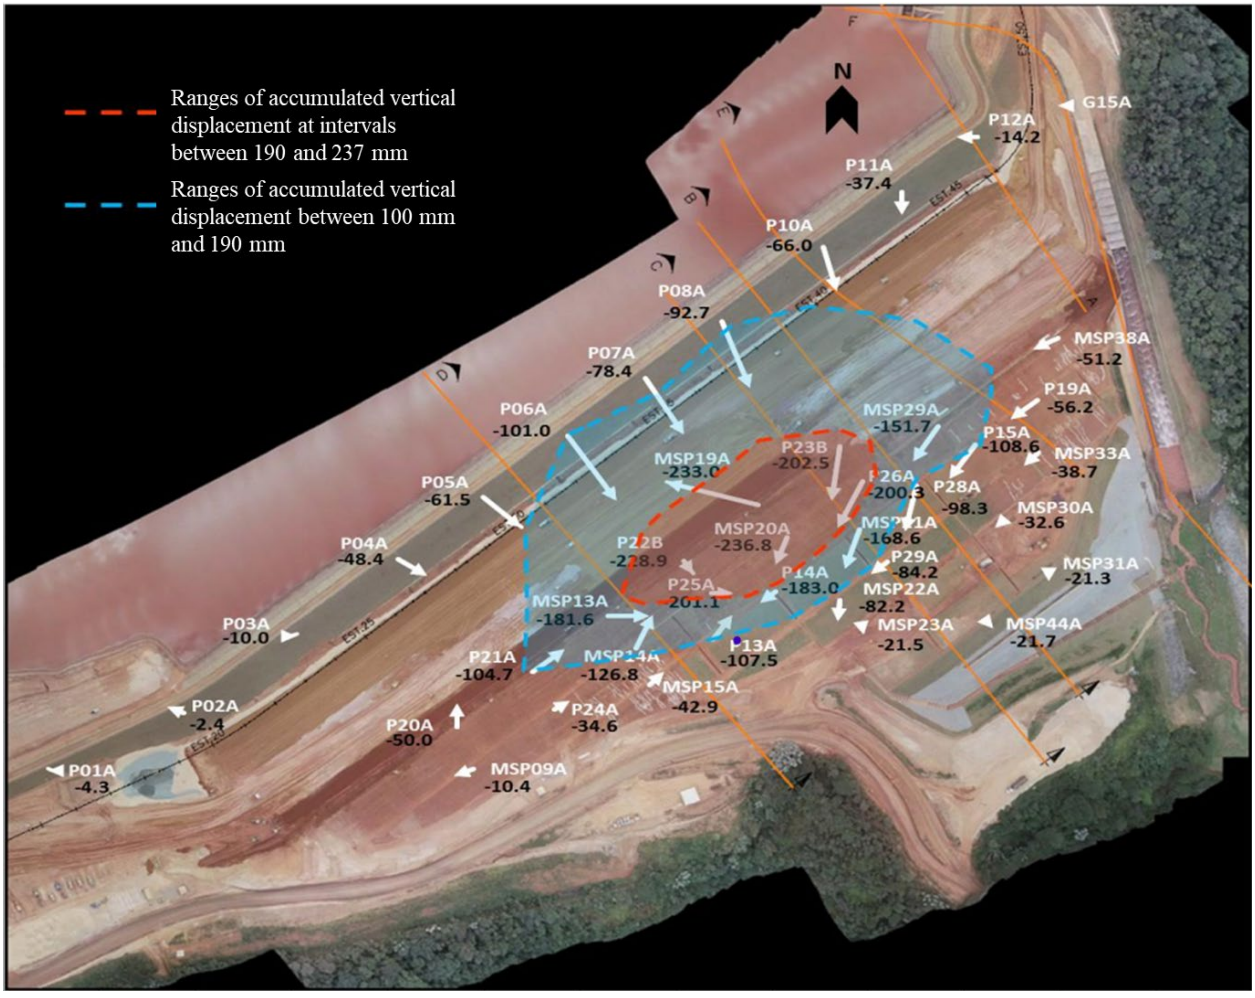

Figure 6: Settlement basin identified, considering monitoring from August to October 2019. The arrows indicate the direction and magnitude of the horizontal displacement component at each instrument location (source: BVP, 2019b)

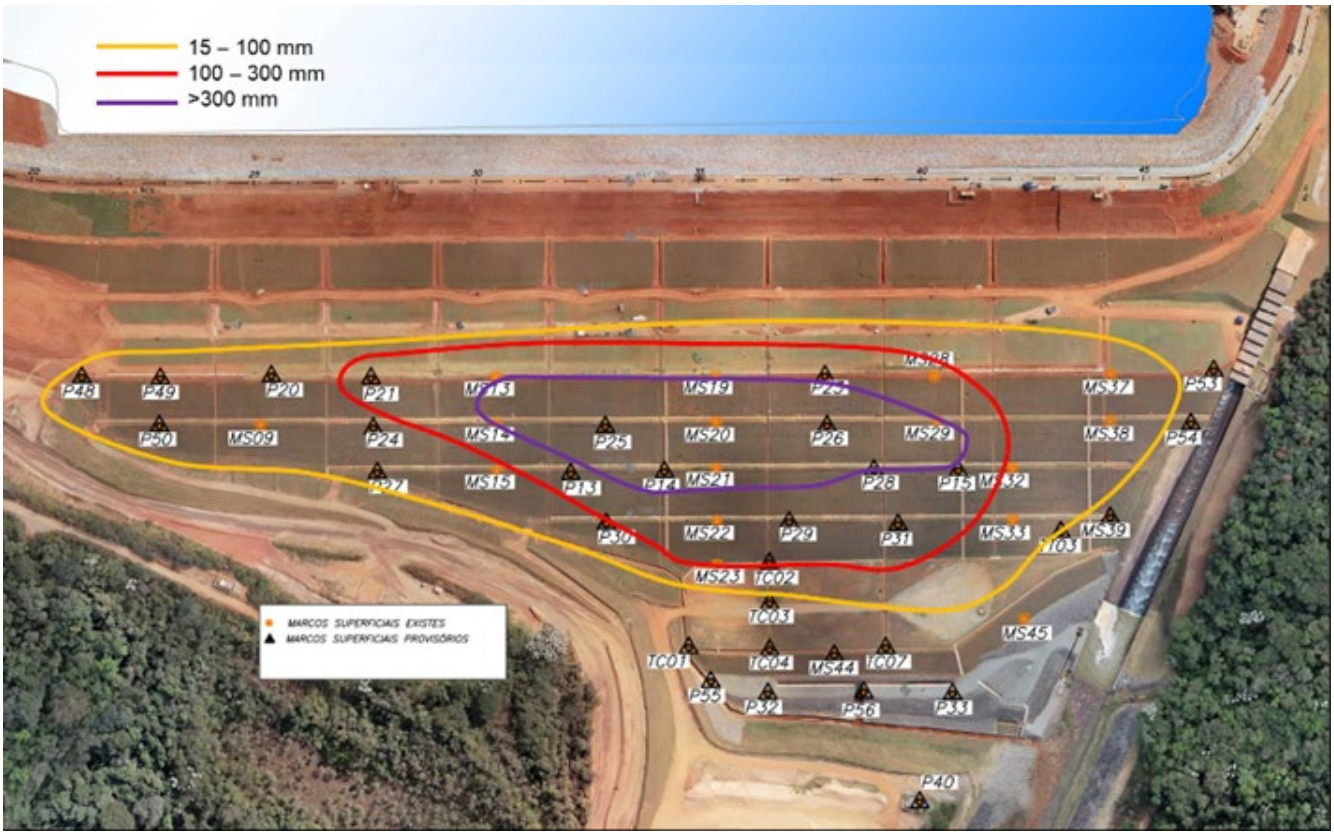

Figure 7: Settlement basin for the monitoring period between 2019 and mid-2023 (source: BVP, 2023c)

Theoretical reference model

Clough and Woodward (1967) developed a theorical model to evaluate the effects of embankment construction rate. They carried out finite element simulations of an idealized dam under construction in stages (or in a single-stage), assuming foundation to embankment stiffness ratios of 1:1, 1:2, and 1:5 (i.e., the embankment is 1×, 2× or 5× stiffer than a homogeneous foundation). For displacement pattern configuration, the theoretical study assumed a single valued embankment deformability. The dam load was applied as a gravity load in ten steps, up to the final height of the structure.

Figure 8 plots the resulting vertical and horizontal displacements at the base of the dam for the three stiffness ratio cases.

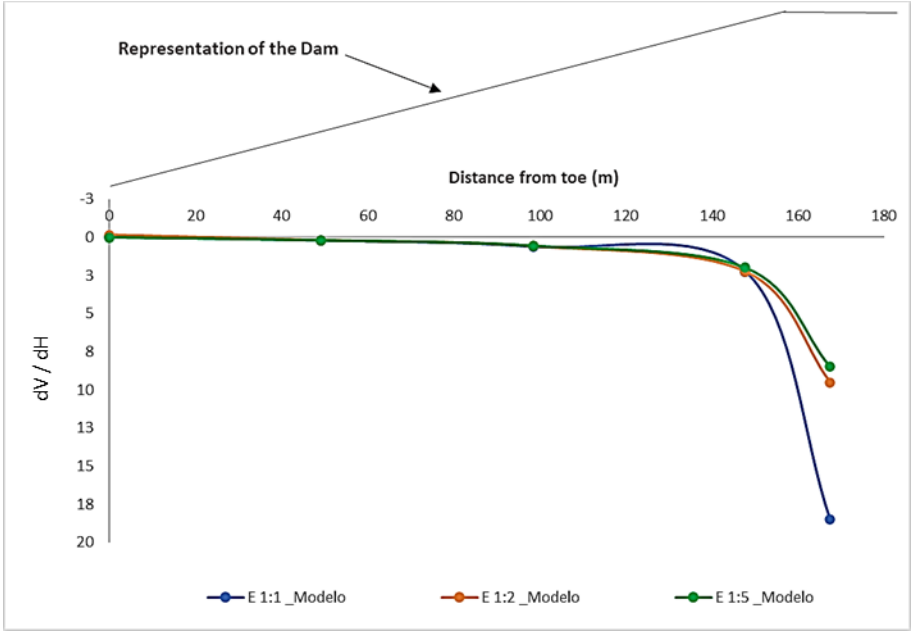

Figure 8: Vertical to horizontal displacement ratio (dv/dh) for different embankment-foundation stiffness ratios (Source: adapted from Clough and Woodward, 1967)

To apply the Clough and Woodward (1967) model to Itabiruçu Dam, the vertical displacements were divided by the horizontal displacements, as shown in Figure 9.

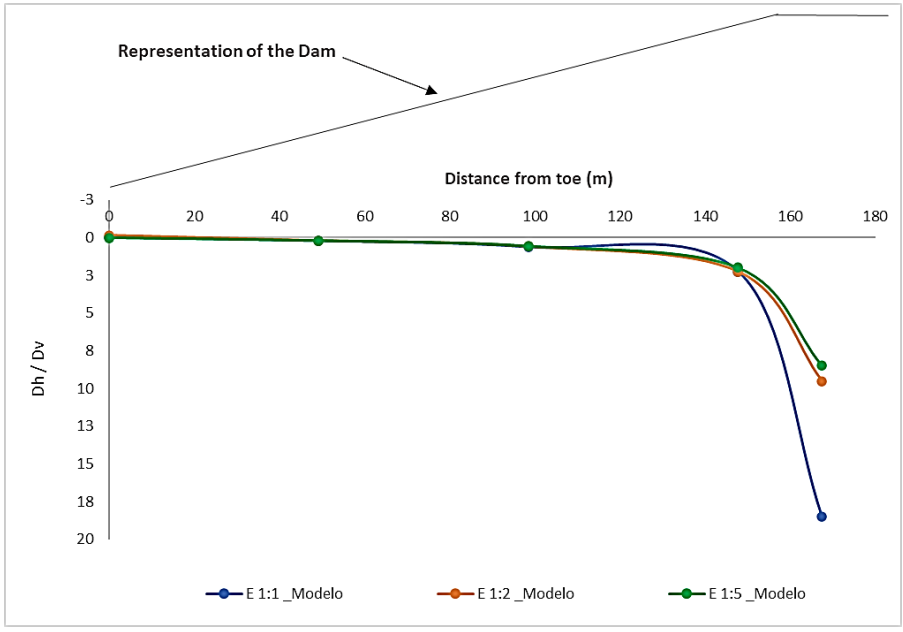

Figure 9: Vertical to horizontal displacement ratio (dv/dh) for different embankment-foundation stiffness ratios (source: adapted from Clough and Woodward, 1967)

The next section compares the model and actual vertical and horizontal displacements obtained from instruments installed near the embankment-foundation interface.

Comparison between field measurement and theoretical model

Inclinometer and settlement gauge data was used to compare field measurements with the model.

Monitoring evaluation mainly focused on checking the displacement profiles over instrument operation history, aiming at identifying any signs of raise-induced shear zone formation and mass movement. The instrumentation used to observe horizontal and vertical displacement behavior at the embankment/foundation contact is shown in Figure 10 for the typical section.

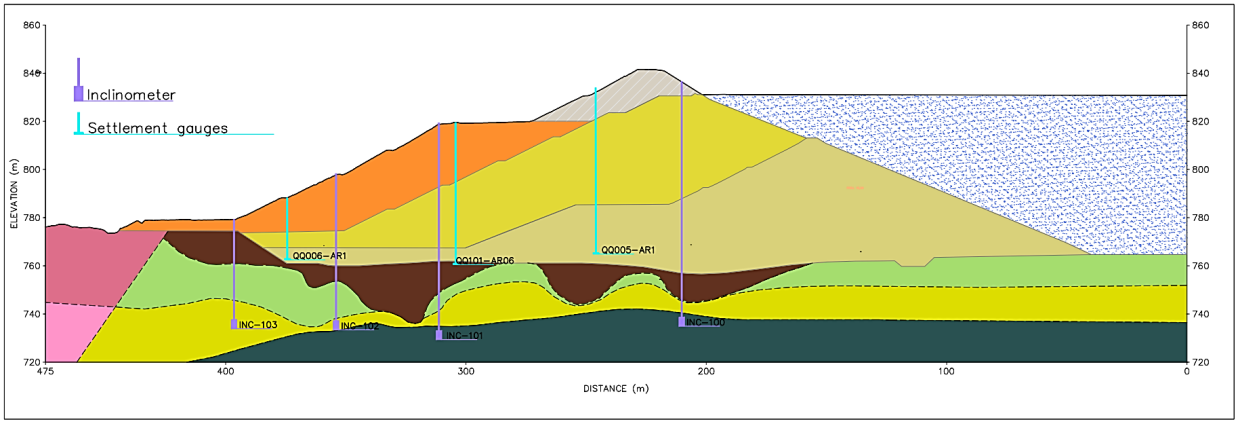

Figure 10: Typical instrumented section of a conventional earth dam. The dam embankment erected in 2022/2023 is indicated in the figure key (source: BVP, 2023c)

Also, four inclinometers anchored in competent rock are shown, from dam crest to toe, as well as three settlement gauges (RA) near the embankment/foundation interface more directly subjected to final works loading.

Figure 11 shows the horizontal displacement (Figure 11 (A)) and vertical displacement (Figure 11 (B)) profile indicated by the instrumentation, whose maximum and minimum distribution and distance from the crest is similar to Figure 9 of the theoretical reference modeling.

It is worth noting that the profiles on Figure 11 correspond to different times during the final dam raise works, making it possible to evaluate the effects of the increased load with the actual embankment and foundation stiffness contrast, conditioned in the actual case by the high SAC unit compressibility against the higher embankment stiffness. Thus, embankment/foundation stiffness relationships addressed in the idealized model are inverted.

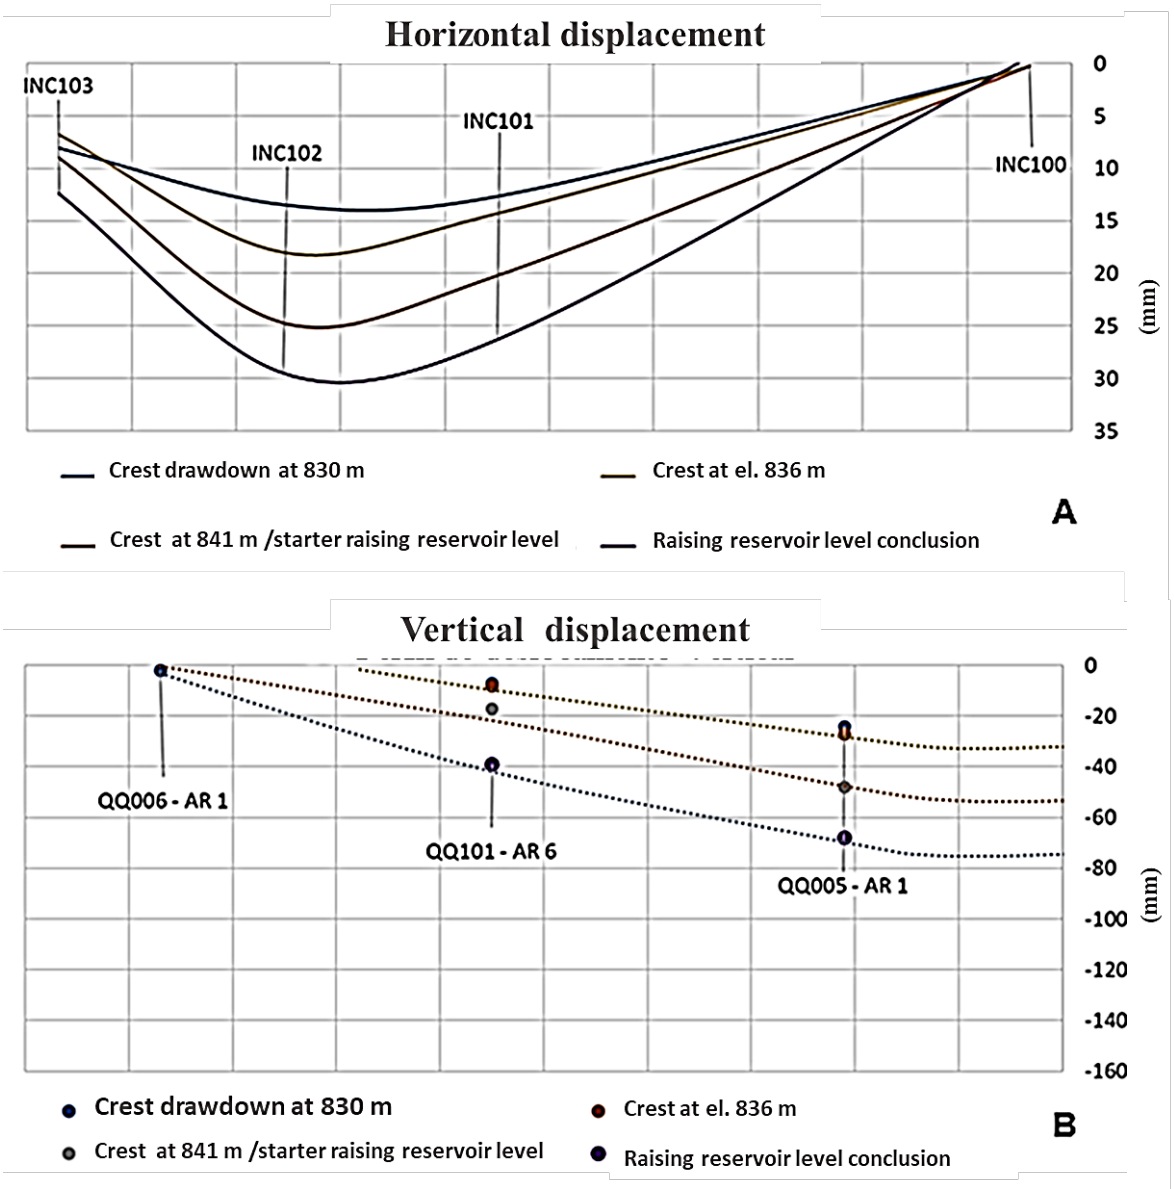

Figure 11: Monitoring data of displacements over time A) horizontal and B) vertical with behavior similar to that proposed in the theoretical model, according to Figure 8

In order to check whether the displacement pattern identified in the selected section replicates the idealized model, but with stiffness ratio inverted, the analysis included monitoring data on vertical and horizontal displacements from instruments installed in a farther section, also at depths corresponding to the embankment/foundation interface. Figure 12 shows the plot plan for additional instruments (an inclinometer and a pressure gauge) included in the comparison basis.

We believe that the considerable distance of the additional instruments from the most instrumented section is strongly significant for a typical downstream shell deformational behavior to be established, in a considerably more complex foundation condition from a geological-geotechnical standpoint.

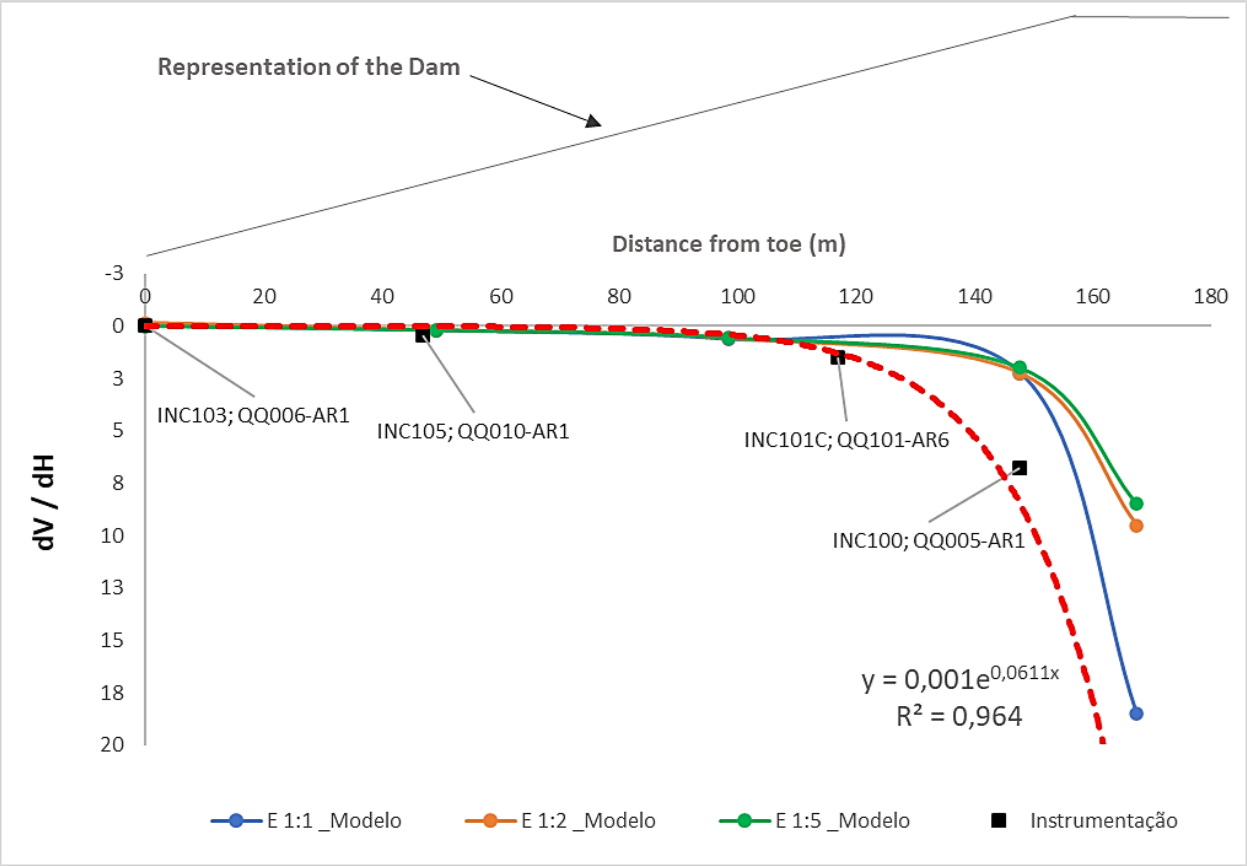

Figure 12: Comparison of site-measured vertical and horizontal displacements (dashed red line) with the theoretical model

Figure 13 shows vertical and horizontal displacement ratios recorded by the instruments considered. The relationship between vertical and horizontal displacements in the actual case (dashed red curve) quite reasonably follows idealized model ratio pattern, but it is on the opposite side to the equivalent stiffness curve (blue curve). This is clearly compatible with the actual case of the foundation being more flexible than the embankment, according to the calibrated numerical model.

The shape of the normalized curve between vertical/horizontal displacements corresponding to the actual measurements shows a similar pattern to the normalized reference model curves, which suggests the actual case behavior, in terms of settlement and horizontal displacement, is in line with deformations associated with the gravitational facility settlement, in which the actual foundation is around 2 to 2.5 times more flexible than the embankment stiffness.

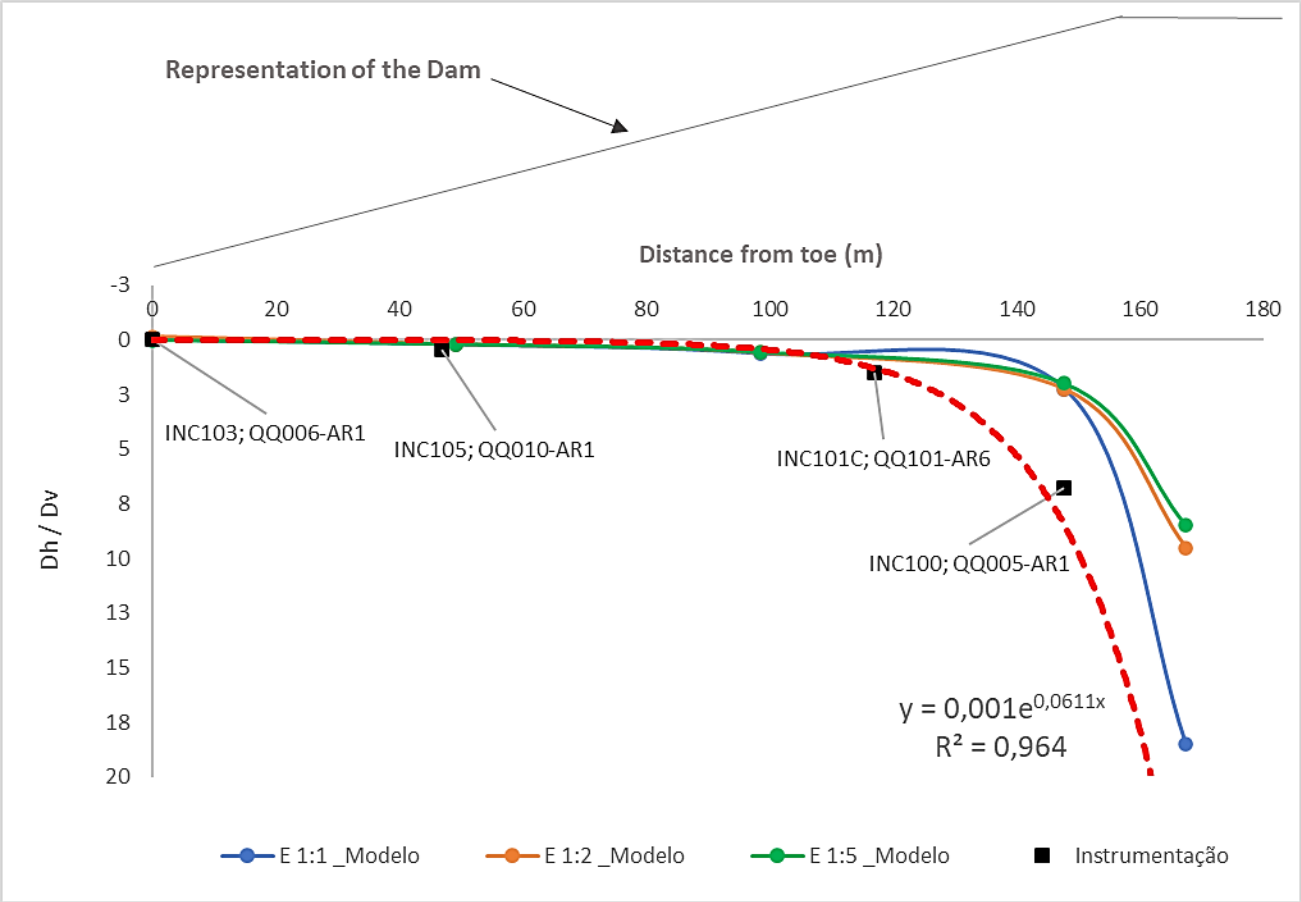

Figure 13: Comparison of site-measured vertical and horizontal displacements (dashed red line) with the theoretical model

Table 1 shows the E50 modules of the Hardening Soil model, Undrained module 'A' applied to the foundation, on the off-the-shelf program PLAXIS. These values led to the best result of comparison between the numerical Itabiruçu Dam simulation and the monitoring data, especially regarding construction pore pressure dissipation rate, as shown in Figure 14, with numerical model and settlement results over time for survey monuments 19 and 20.

Table 1: Average stiffness modulus (E50), embankment phases and foundation materials (source: BVP, 2023a)

Materials	Average stiffness modulus – E50 (kPa)
Embankment, downstream shell	6,475
Foundation	3,600

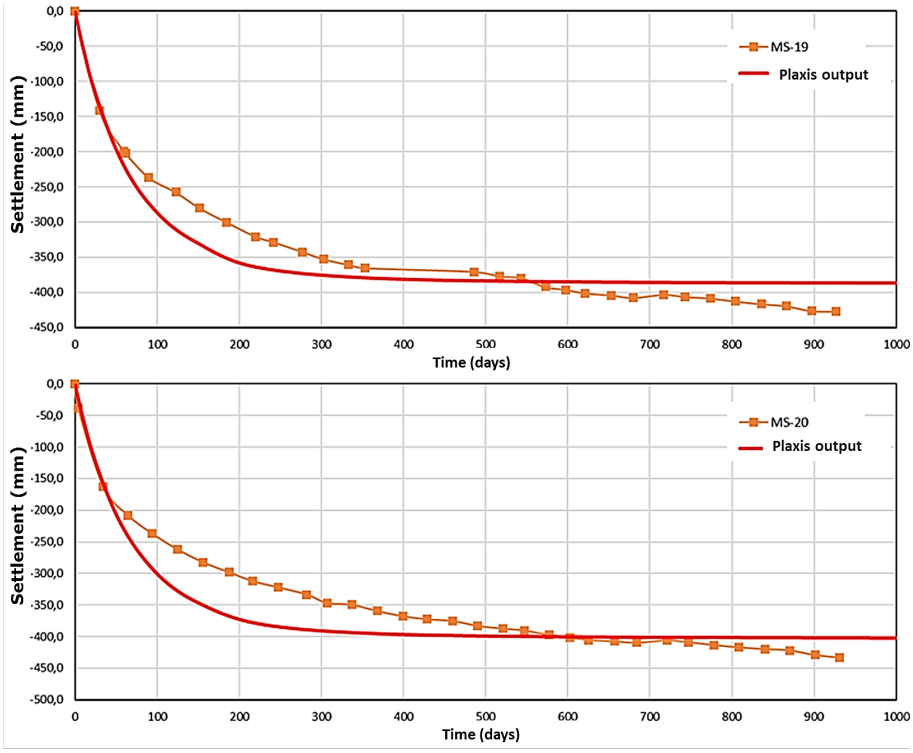

Figure 14: Comparison between the actual vertical displacement curves measured by using MS 19 and MS 20 monuments and the simulated numerical model curves (source: BVP, 2019a)

According to this analysis, the actual facility behavior, as per synthetic vertical and horizontal displacement ratios along the embankment/foundation interface downstream the dam axis (Table 1), fits the facility/foundation deformation mechanism, in which foundation is 2-2.5 times more flexible than the embankment, due to self-weight settlement.

Highlight of the discussion

Despite the presence of a highly compressible layer in the foundation as compared to the embankment stiffness, the ratio of horizontal to vertical displacements has shown full compatibility concerning the shape of the function captured in the Theoretical Reference Model in which the foundation was repeatedly stiffer than landfill in all cases modeled by the authors. This similarity suggests the dam would have experienced just gravitational settlement as the single deformational mechanism.

Conclusion

Typical horizontal and vertical displacement behavior evolution, as the downstream raise of the analyzed dam developed, has shown a similar pattern to that of the theoretical reference model of Clough and Woodward (1967), with various relative embankment/foundation stiffness ratios being considered. In the

actual case, as in the model, the horizontal displacements measured near the dam axis tend to be minimal or cancel out where vertical displacements reach their peak value, whatever the relative embankment/foundation stiffness may be. At about one-third of the distance from dam toe to crest, the horizontal displacements are more significant and decrease both upstream and downstream. Itabiruçu Dam measurements replicate with excellent adherence the idealized model pattern of deformations induced by gravitational settlement.

The curve shape of normalized displacements along the embankment/foundation interface underneath the downstream shell in the actual case is compatible with the normalized curve pattern of the theoretical self-weight settlement model, and is even coherently located on the opposite side to the theoretical curves, since the typical Itabiruçu Dam foundation stiffness turned out to be around 2 to 2.5 times lower than that of the embankment.

The main value of this finding is that the origin of the dam cracks is confirmed by differential settlement given its occurrence as pockets of most compressible soil unit (SAC), with the lowest SPT blow counts of the program, usually less than 10. To date, there have been no unequivocal findings of horizontal displacements in inclinometer logging, regardless of the depth below the facility/foundation interface, nor occurrence of cracks in drainage channel concrete downstream of the dam. Horizontal displacements recorded by the instrumentation have been proven to correspond to settlement components of SAC deformation, mainly. Over almost four years of continuous monitoring, low-angle shear bands in the facility foundation embankment have been ruled out. The most important aspect in analyses of this nature is the actual facility/foundation behavior, over the long period of instrumentation monitoring, which points to gradual and consistent settlement stabilization over time, mainly due to the dissipation of excess construction pore pressures induced in the SAC unit.

As for horizontal displacements, no behavior was recorded during the period of continuous measurements for almost four years, which could raise suspicions of a second facility movement mechanism, possibly associated with strain softening of the foundation under large deformations, as a result of potential mobilizations of foundation strength in the post-peak regime. The observations of the entire set of monitoring instruments on the dam scale show convergence with the mechanical stress-strain response in dozens of undrained and drained triaxial tests, carried out both in the SAC and in the SSG unit, which showed maximum losses of peak strength of only 10% in some tests, despite the development of positive pore pressures in the SAC up to close to the maximum deviator strength.

Finally, settlement recurrence along the reference section as raise works resumed was at lower magnitudes than those recorded immediately after work was halted, due to a maximum height loading of 17 meters in the 2022 stage, compared to a 40-meter loading between 2018 and 2019. On the other hand,

the decreasing settlement rates from the recent construction completion are similar to those of the previous long period, in our opinion caused by gravitational settlement.

Enhancing Pseudo 3D Seepage Modeling with Topographic Integration for Heap Leach Facilities

I.J. Vega, SRK Consulting, Argentina
A.G. Terlisky, SRK Consulting, Argentina
M. Noël, SRK Consulting, Canada

Abstract

The management of heap leach facilities (HLFs) is a critical aspect of sustainable mining operations. Seepage control is key in optimizing the production of mineral extraction and drainage systems, and it is also a crucial component in ensuring environmental protection and structural stability. Building upon our previously developed automated modeling tool (Noël et al., 2023), which facilitated time-dependent pseudo-3D seepage analysis using Hydrus-1D, Python, and Autodesk® Dynamo®, we introduce a significant enhancement that incorporates topographic features into the seepage modeling process. This advancement allows for a more realistic representation of the HLF environment by intersecting heap leach pads volumes with the surrounding topography.

The novel feature extends the capabilities of the existing tool by enabling the simulation of seepage through the heap leach pads as it interacts with the natural landscape. This interaction is critical for understanding how topography influences the distribution and flow of seepage, which in turn affects the design and optimization of HLF drainage systems and the assessment of potential environmental impacts. The methodology involves:

i) integrating detailed topographic data into the discretization process of the HLF shape in both space and time;

ii) analyzing the interaction between the heap leach pads and the topography to assess changes in seepage patterns; and

iii) computing the modified time-dependent total seepage over the entire base of the HLF and the variation of the water entrained by the heaps, considering the topographic constraints.

The application of this improved modeling approach is exemplified through a theoretical case study, where a simplified analysis was previously conducted. Utilizing our enhanced tool, we will intersect the topography with the HLF to validate and analyze the results. This case study not only validates the tool but also illustrates the practical implications of incorporating topographic data into seepage modeling. The tool

also supports the evaluation of seepage in various types of waste containment facilities, including waste rock dumps (WRD), tailings storage facilities (TSF), and co-disposal sites.

Introduction

Seepage modeling for various mine waste containment facilities, such as heap leach facilities (HLFs), tailings storage facilities (TSFs), "dry" stacks, waste rock dumps (WRDs), and co-disposal sites, is typically performed in 1D and 2D to predict seepage into the groundwater system. Due to the complexity and computational load, 3D simulations are rarely performed.

The modeling presented relies on Hydrus-1D, an industry-standard code for simulating water and solute transport in variably saturated porous media. The modeling tool discretizes the deposition of mine waste in time and space, enabling 1D modeling for individual blocks and stacking material as the facility is constructed. Autodesk® Dynamo® discretizes the variable 3D geometry of the TSF into independent columns at different time steps, which are then assembled into stacks representing the gradual construction of the waste facility. Python reads the inputs, runs the Hydrus simulations for each block and stack, and processes the results.

A significant enhancement to this modeling tool incorporates topographic features into the seepage modeling process. This advancement allows for a more realistic representation of the facility environment by intersecting heap leach pads volumes with the surrounding topography.

1D model considerations

The modeling was performed using Hydrus-1D software. The water transport is based on Richards' equation for the saturated/unsaturated water flow with the van Genuchten model (van Genuchten, 1980). The automatic stacking modeling was done as presented in (Noël et al., 2023). As an instance the sequence of modeling is illustrated in Figure 1 for one column.

The model was configured to extract results at the bottom surface of the heap leach and to quantify the water entrained by the heaps. Each column's seepage was modeled separately, and the total seepage and entrained water were obtained by integrating all the discretized blocks over the entire heap leach domain.

The bottom boundary was set to model a drain, representing a drainage system open to atmospheric pressure, and did not allow any water uptake in the event of negative pressures (suction). The top boundary condition was set for two conditions: irrigation of the heap and a no-flux condition when the heap was being drained. For the sake of simplicity, climatic conditions were not modeled in this study. However, future work can incorporate these factors to enhance the model's accuracy.

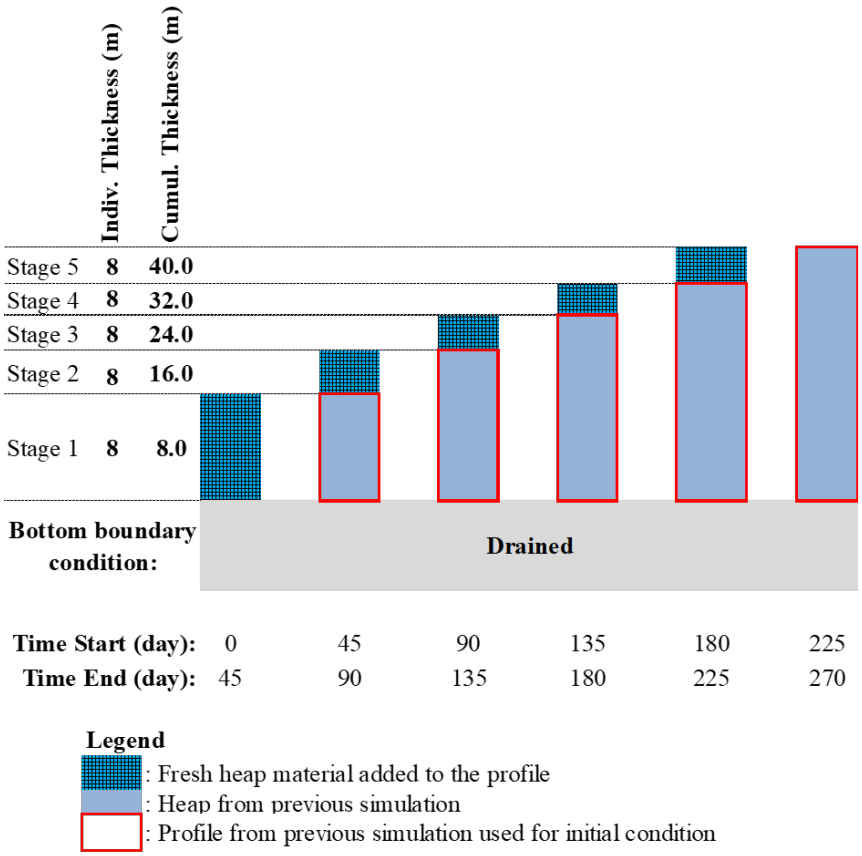

Figure 1: Discretization and the stacking sequence assembled by the Python code and modeled by Hydrus – evolution of a given column over six time stages

The initial condition for the first simulation involved specifying the volumetric water content corresponding to the degree of saturation observed in the field. Subsequent simulations used the model output as the initial condition for the already placed material. Newly placed material was assigned a volumetric water content matching the field-observed degree of saturation. This process was repeated for all simulations as the heap thickness increased.

Pseudo 3D model and sequential columns discretization

To enable Hydrus-1D to solve seepage for complex 3D geometries, a discretization into vertical columns is necessary. The volume of the heap leach pad and the topographic surface was first assembled in Autodesk® Dynamo®. The entire geometry is then automatically discretized into a grid of vertical columns covering the full heap leach footprint. Each vertical column intersects the topographic surface and the heap leach volume at different elevations.

The 3D representation of the HLF is vertically discretized into typical lift thicknesses, starting from the deepest point. Each lift's surface is further subdivided based on the surface area of the irrigation cells,

with a corresponding irrigation duration. This results in a specific number of irrigation cells for each lift. It is assumed that the first lift is completed before adding the subsequent lift. The irrigation duration is then used to establish the sequential timing for the start and end of irrigation for each cell.

Finally, the results obtained are elevation vs. time curves for each column, which are used as input for the Hydrus-1D simulations. It is important to note that each column has its own unique growth curve depending on its position in the grid and the timing. No lateral flow is considered in this model.

All these processes are automated using Python coding enabling changes such as topographic surface, grid spacing, and lift thickness to be made automatically. This makes sensitivity analysis very straightforward to perform.

Theoretical case study

A theoretical case study utilizing the tools discussed in the previous sections of this paper is presented.

Figure 2 illustrates the heap leach volume (in blue) and the topographic surface (in silver) imported into the Autodesk Dynamo® environment.

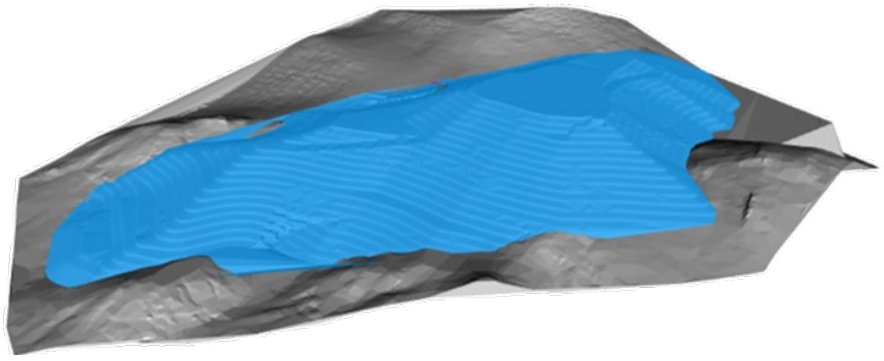

Figure 2: Heap Leach 3D volume and topographic surface

Figure 3 displays the 1D columns resulting from the discretization of the 3D heap leach volume, accounting for the intersection of the heap leach with the topographic surface.

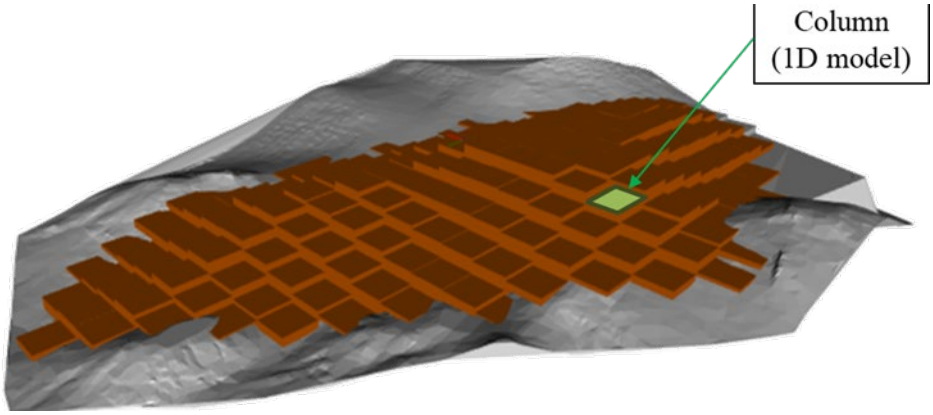

Figure 3: Grid of 1D columns discretization of the heap leach

Subsequently, the position and elevation of each column's starting and ending points are extracted as X, Y, and Z coordinates for data processing, enabling the construction of coupled space and time Hydrus 1D simulations for each 1D column.

Figure 4 illustrates the thickness of each point in the heap leach at the end of construction, depicted on the left colormap plot, which is based on the Z coordinates of each 1D column's starting and ending points. The right plot displays the 163 columns with their corresponding indexing, resulting from the grid spacing of 80 m × 80 m.

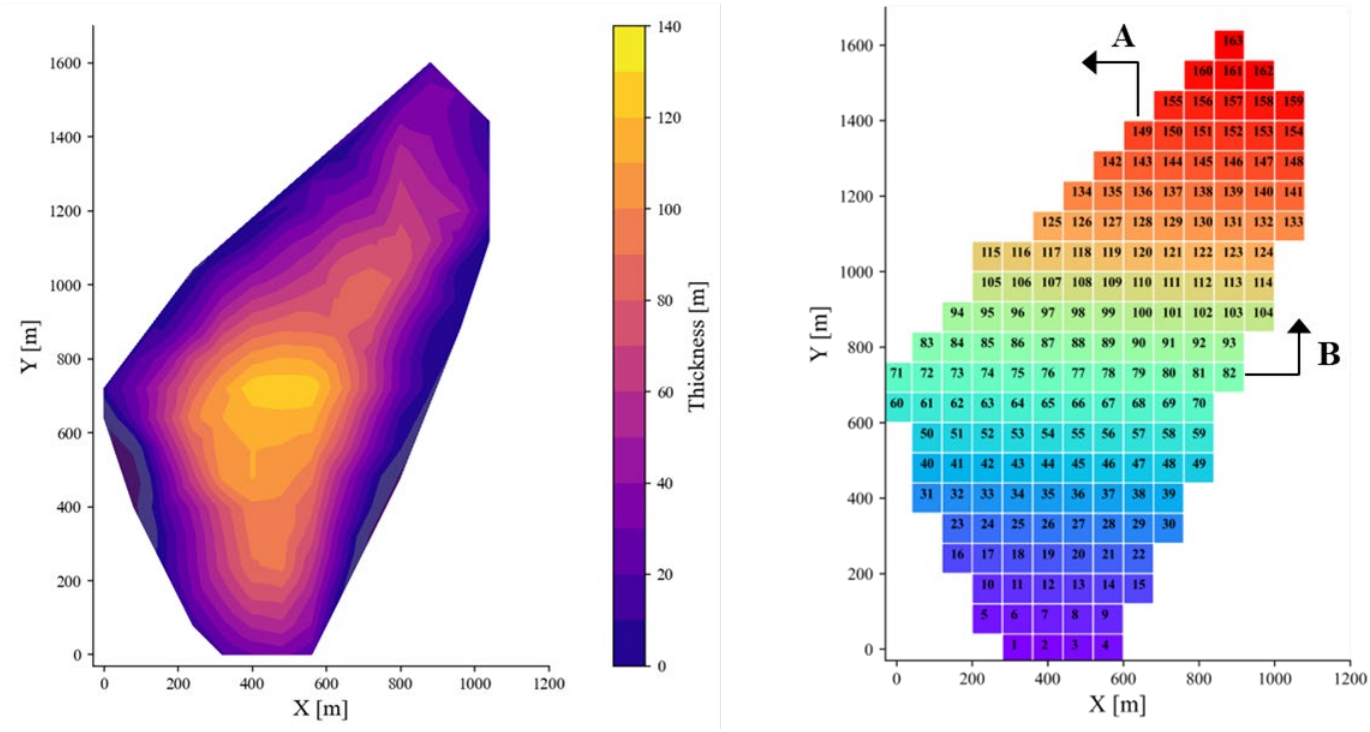

Figure 4: Heap leach 1D columns discretization: total thickness and indexing.

For a better understanding of the topography on the construction sequence, sections A and B are shown in Figure 5. The horizontal gray lines represent the typical 8-meter-thick lifts.

Examining Section A, it is observed that column 143 is the first to emerge in time, as it has the lowest intersection with the topography and will emerge at lift number 5 (i.e., 40 m). In contrast, column 15 is the last to commence, as it intersects the topography at a higher elevation.

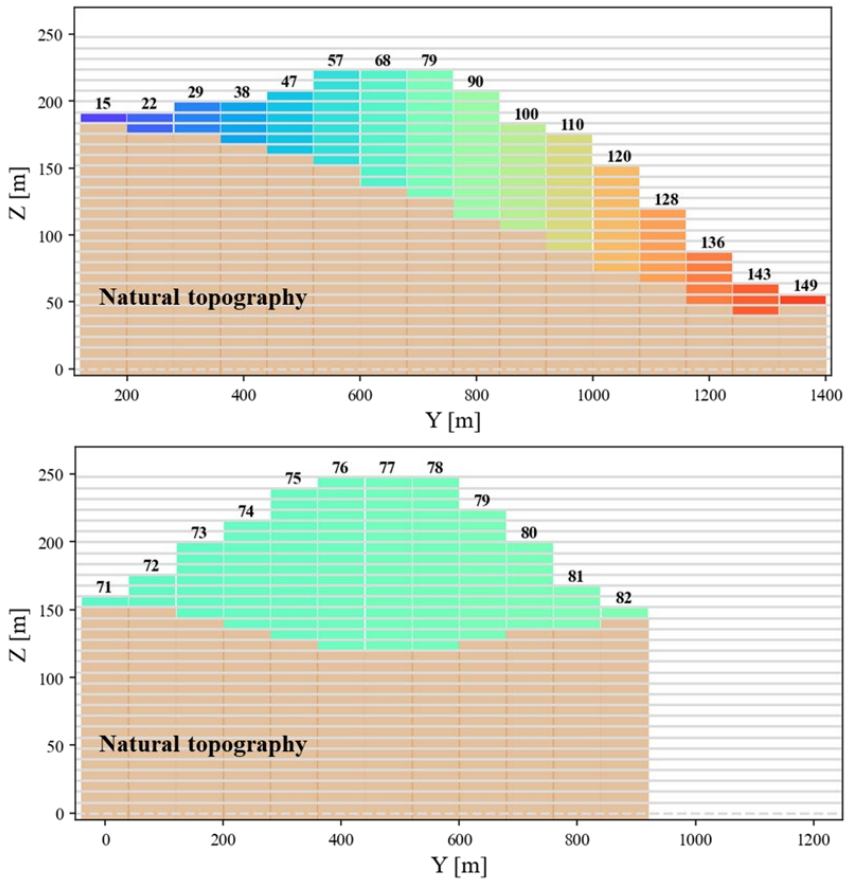

Figure 5: Section A (upper panel) and Section B (lower panel), referred to Figure 4

The surface of each lift was then discretized according to the surface of the irrigation cells, which was set to 90,000 m² with an irrigation duration of 45 days. An irrigation rate of 6 liters per hour per m² was used to model the heap when being irrigated. A quantity of irrigation cells was therefore obtained for each lift. Given that each column covers an area of 6,400 m², if a single lift encompasses more than approximately 14 columns, the lift is divided into multiple cells. It was assumed that the first lift would be completed before adding the subsequent lift. The irrigation duration was then used to establish the sequential time at which each irrigation cell would start and end irrigation.

As an initial instance, the first three lifts are illustrated in the plan view of Figure 6. Adjacent to each column footprint, a number indicates the total height of each column for a given lift. If the number is colored, it signifies that the column is increasing in height during that lift. Conversely, if the number is black, it indicates that the column has reached its final height.

In the bottom left corner of each plot, the cell surface area is displayed. As shown in Figure 6, the first three lifts do not exceed one cell, as the total area of the columns is significantly less than 90,000 m².

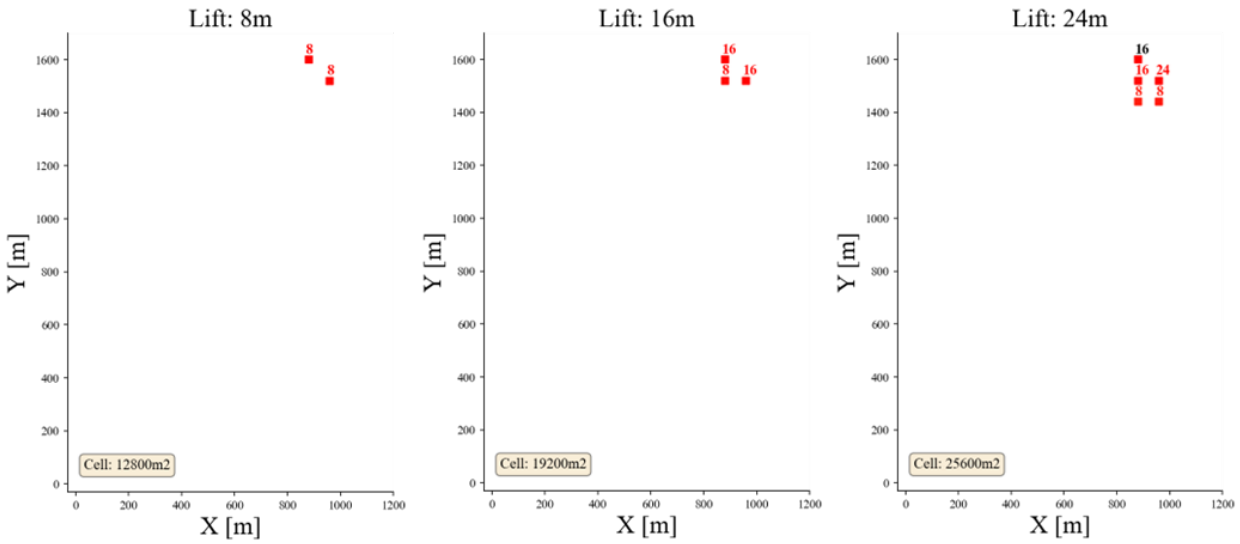

Figure 6: Construction sequence – first 3 lifts

Figure 7 depicts the lifts at 88 m and 96 m. Since the 96 m lift exceeds 90,000 m², it is divided into two irrigation cells. In addition to the previously explained color representation, if the height number is gray, it indicates that the column is part of a cell that is not being irrigated at that specific time step. Each lift corresponds to a particular time step, and if a lift has more than one cell, those cells are irrigated at different times.

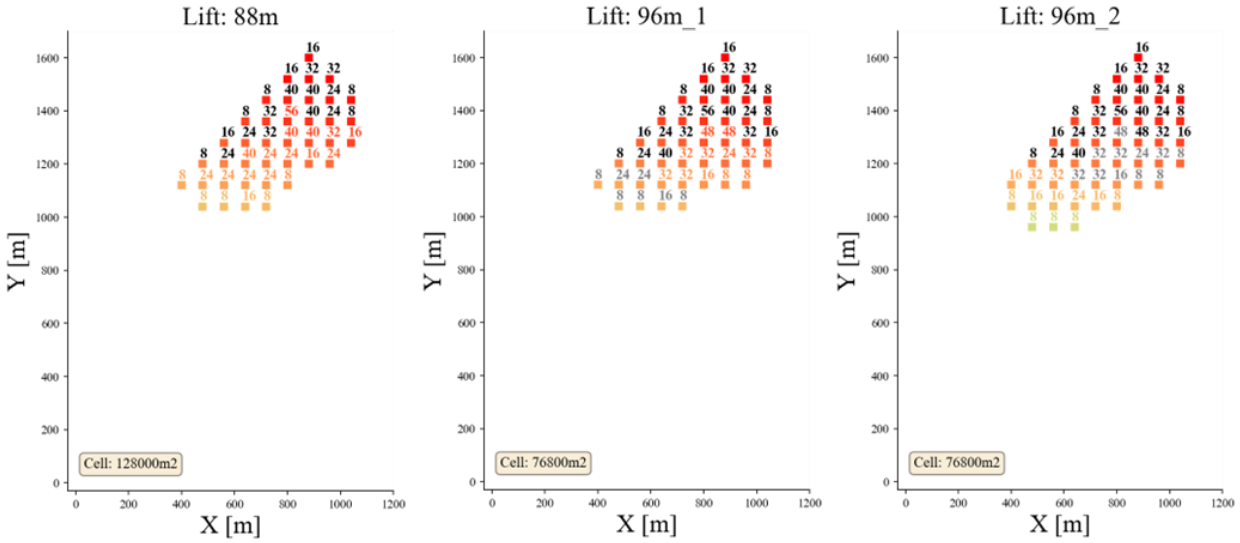

Figure 7: Construction sequence – 88 m and 96 m lifts

The final lift, corresponding to 248 m, is shown in Figure 8. The height numbers indicate the final height of each column.

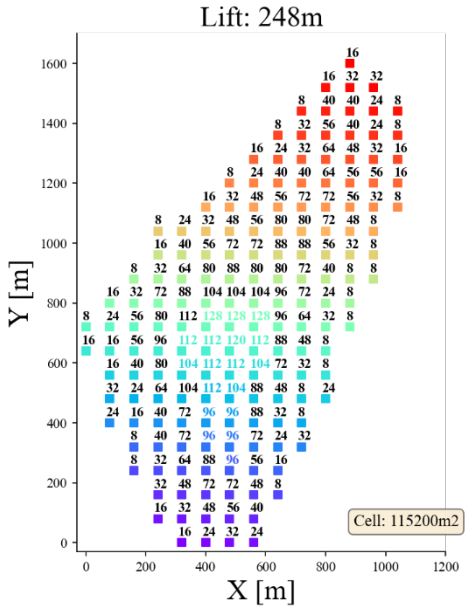

Figure 8: Construction sequence – 248 m lift

Finally, the total accumulative bottom flux volume BF_{Total} and the total entrained water EW_{Total} are calculated by adding up all the columns as shown in Equation 1 and 2, results are shown in Figure 9. Hydraulic properties of the heap leach material used to run the simulations are shown in Table 1. Additionally, the infiltration rate is shown in Figure 10.

$$(1)\ \boldsymbol{BF_{Total}(t) = \sum_{n=1}^{163} BF_{Col_n}(t)}$$

$$(2)\ \boldsymbol{EW_{Total}(t) = \sum_{n=1}^{163} EW_{Col_n}(t)}$$

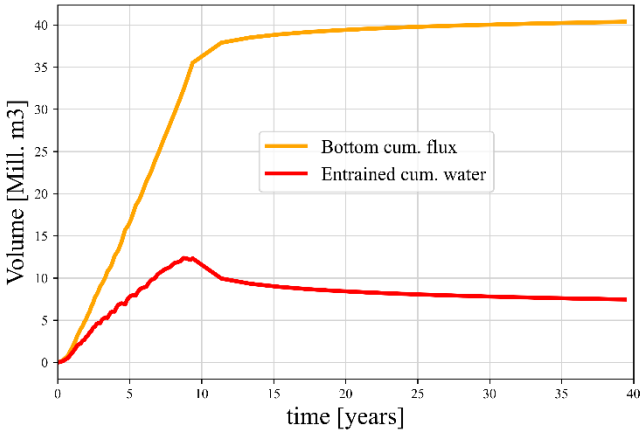

Figure 9: Total drain down – total entrained water

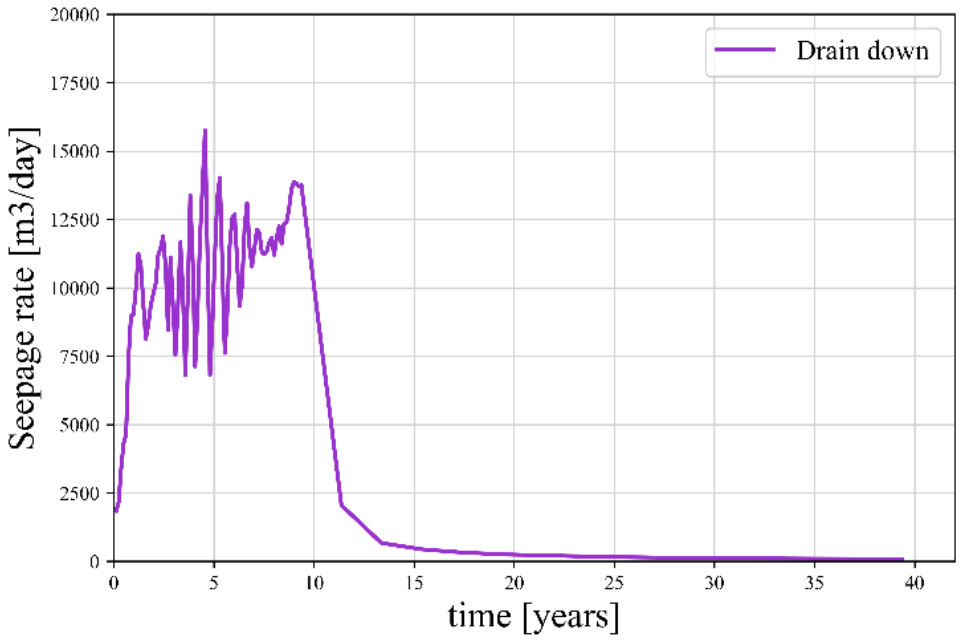

Figure 10: Total drain down rate as function of time

Table 1: Hydraulic properties of the heap leach material

Parameter	Value
θ_r	0.04 m³/m³
θ_s	0.38 m³/m³
$\theta_{initial}$	0.08 m³/m³
α	40 1/m
n	1.5
l	0.5
K_s	1.00e-5 m/sec

To analyze how topography influences the distribution and flow of seepage, colormaps of cumulative bottom flux at six different times during the construction of the heap leach are presented in Figure 10. Understanding the distribution of flow through the heap leach is crucial for the design and optimization of drainage systems.

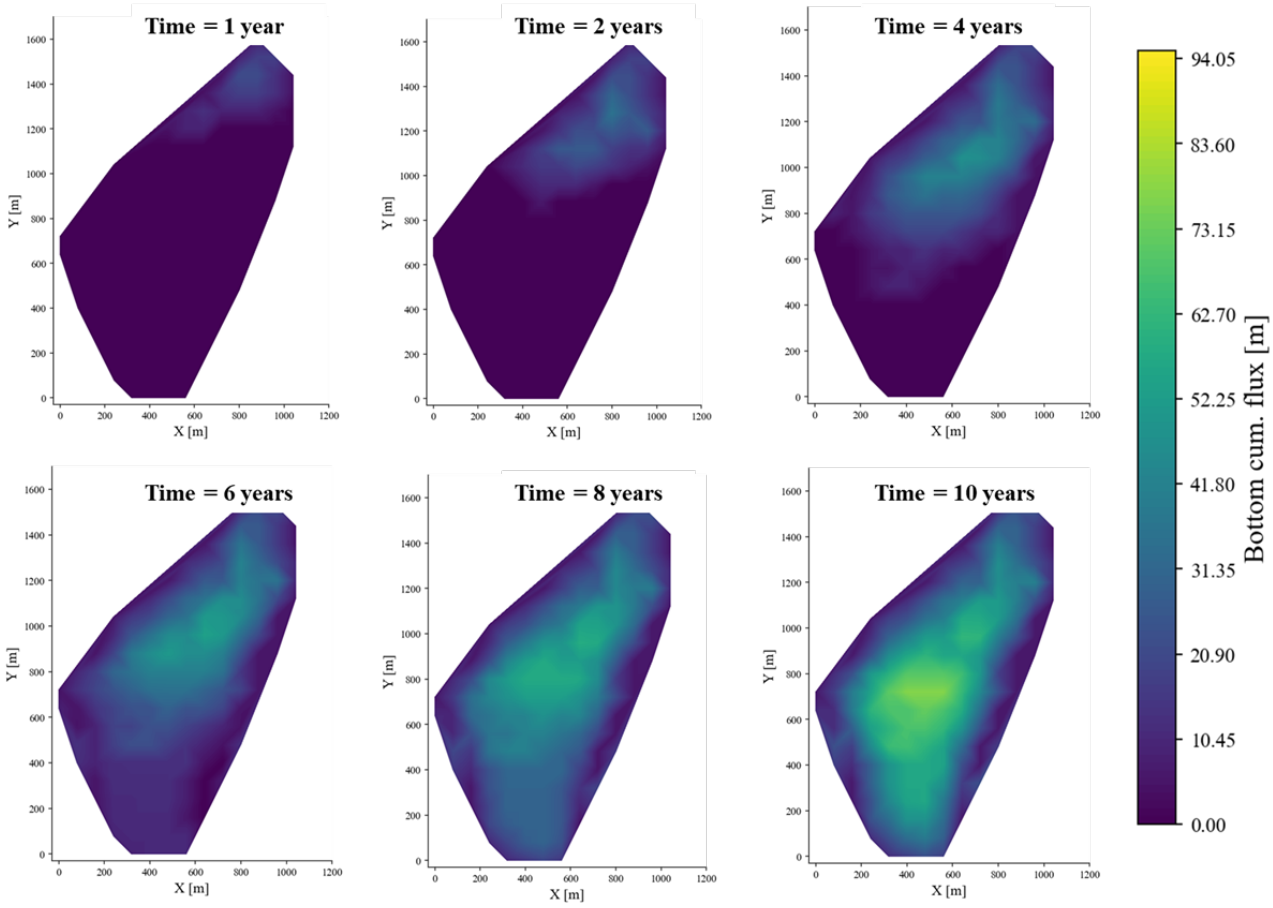

Figure 11: Bottom cumulative flux distribution as function of time during construction of the heap leach

Discussion

The pseudo-3D model presented in this study offers a valuable tool for simulating water flow in HLFs by integrating topographic features into the seepage modeling process presented in Noël et al. (2023). However, it is important to acknowledge the inherent limitations of the 1D column approach used in this model.

The main limitation is the omission of the horizontal flow component. This approach is acceptable in facilities where deposition occurs in horizontal layers and for facilities that have a geometry with a high ratio of horizontal to vertical dimensions. However, in more complex situations this simplification can become inaccurate.

Additionally, the consolidation and void ratio variation (and implicitly the saturated hydraulic conductivity) of the materials are not coupled into the analysis given the limitation of Hydrus-1D. This limitation would, however, be limited to filtered tailings, and even less for waste rock and heap leach

materials. Future research could build upon the methodologies presented by Fredlund et al. (2015) to enhance the accuracy of seepage modeling by integrating the effects of consolidation.

To address the horizontal flow limitation, it is planned to validate the model with either 3D or 2D models. This additional step will allow for the evaluation of the magnitude of horizontal flow and its impact on the distribution and flow of seepage in the HLF. It is crucial to mention these limitations in the present work to acknowledge the potential constraints of the 1D column models.

In summary, while the pseudo-3D model with topographic integration represents a significant advancement in seepage simulation in HLFs, it is essential to consider the limitations associated with the omission of horizontal flow and the uncoupled consolidation and void ratio variation.

Conclusion

The integration of topographic features marks a significant advancement in pseudo-3D seepage modeling for waste containment facilities. This study demonstrates that incorporating topographic data enhances the realism of seepage simulations, allowing for more accurate predictions of seepage distribution, which is crucial for optimizing drainage systems and assessing environmental impacts.

The enhanced tool was validated through a theoretical case study applied to an HLF, demonstrating its utility in such facilities, and incorporating irrigation sequences into the modeling. The tool can also be applied to various mine waste facilities, including waste rock dumps, tailings storage facilities, and co-disposal sites. Automation using Python facilitates easy adjustments and sensitivity analysis, enabling the evaluation of different scenarios and their impact on seepage patterns.

Additionally, the tool allows for the analysis of various deposition methods, optimizing the process to the maximum extent. It enables changes in irrigation areas, irrigation duration, irrigation quantity, and maximum heights for drain placement, considering the height of the HLF and the inclusion of impermeable layers within the heap.

Furthermore, future work will incorporate climatic conditions into the model. This will allow for the analysis of HLF performance under different climatic scenarios (humid or arid), assessing the influence of climate on water entrainment and flow. This capability will enable the evaluation of HLF functionality for any location by changing climatic conditions.

In summary, integrating topographic features into pseudo-3D seepage modeling enhances the accuracy and realism of seepage predictions and provides a robust tool for optimizing HLF drainage systems. Future improvements should focus on addressing the identified limitations and incorporating climatic conditions to further enhance the model's applicability.

Comparative Analysis of Vane Shear and Fall Cone Tests for Characterizing Oil Sands Tailings in the Sandy-fine Category

Peter Kaheshi, University of Alberta, Canada
G. Ward Wilson, University of Alberta, Canada
Heather Kaminsky, Northern Alberta Institute of Technology (NAIT), Canada

Abstract

Some tailings deposits encountered in oil sands mine sites today fall into the sandy-fine category, characterized by fines content and sand-fines ratio ranging from 25% to 50% and 1 to 3, respectively. These include composite tailings and thickened tailings deposits; more can be expected to come from coarse sand and centrifuged fluid fine tailing mixtures resulting from the emerging co-deposition approach. Tailings in this category may be too fine to behave as cohesionless or too sandy to behave as cohesive, depending on the amount and properties of fines included.

Although Fall Cone tests (FCT) and Vane Shear tests (VST) are common, less complex and cheaper techniques for measuring undrained strength can certainly be used to measure strength for these materials (i.e.: Triaxial and Direct Shear tests); however, their applicability in sandy-fine oil sand tailings has not been explored. This paper compares experimental shear strength data obtained from FCT and VST to determine their applicability and repeatability in measuring strengths for sandy-fine tailings with different fines content and stress levels. Five mixtures of coarse sand and mature fines tailing (MFT) were made to obtain samples mimicking deposits within the sandy-fine category. Samples were characterized for particle size distribution and Atterberg limits before their shear strength was measured using both FCT and VST at their different stresses. Experimental data have shown a strong correlation between FCT and VST data up to 60 kPa strength. Also, a good agreement is seen between measured strength data up to 60 kPa and estimated values using the liquidity index for each sample.

Both FCT and VST are deemed suitable for sandy-fines deposits' shear strength measurements up to 60 kPa; beyond 60 kPa to 100 kPa VST gives a better estimate than FCT.

Introduction

Canada has about 167 billion barrels of oil that is viable for economic extraction with current economic conditions and technology. This ranks Canada as the fourth largest oil producer in the world, and about 97% of these reserves are in oil sands (Natural Resources Canada, 2023). Surface mining is used to extract 20% of these oil reserves as they are deposited less than 75 m below the surface. Trucks and shovels are used to load and transport the oil sand to a plant where bitumen is separated from sand by hot water extraction and froth treatment (AER, 2023; Natural Resources Canada, 2023). Byproducts known as tailings are left after the bitumen-recovering process. These contain water, silt, remnant bitumen, and clay, and traces of metals, salts, and other hydrocarbons. Since FFTs are fines-dominated, constituting mainly illite but also kaolinite and illite-smectite layers (Chalaturnyk et al., 2002), they take exceedingly long to consolidate and gain the required strength for trafficability and reclamation due to their high dispersion. This has led to the accumulation of fluid tailings (FT) in the Athabasca oil sands to about 1,392 Mm^3 in 2022 (AER, 2023).

As an initiative to manage these volumes, Directive 85 has set out the requirements for oil sands mining projects, including identifying any fluid waste coming from bitumen extraction with more than 5% solids and undrained shear strength less than 5 kPa as FT (AER, 2022). Undrained shear strength is one of the key performance indicators of oil sands tailings deposits; thus, it requires appropriate techniques to measure.

Some of the tailings deposits encountered in oil sands mine sites today have fines contents falling into the transition zone between fines and sand zones (COSIA, 2014); these include composite tailings (CT), some thickened tailings (TT) (Imperial, 2022; Oil Sands Tailings Consortium, 2012), and non-segregating tailings (NST) resulting from co-deposition of sand and FT to avoid segregation and fasten consolidation (CNRL, 2020; COSIA, 2012; Oil Sands Tailings Consortium, 2012). Shear strength measured in FT will be undrained because, with the highest composition being fines, pore pressure dissipation is not likely during measuring. It remains unknown, due to limited research on transitional oil sands tailings, whether the strength measured will be undrained or drained depending on the fine fractions and their properties, because they may be too fine to behave as cohesionless or too sandy to behave as cohesive. This research therefore intends to correlate undrained shear strength estimated from index properties to the one measured using both Vane Shear and Fall Cone tests.

Both Vane Shear and Fall Cone tests have been commonly used to measure undrained shear strength for soft cohesive soils. Das (2009) has identified Vane Shear as a tool for reliable undrained shear measurement results for medium to very soft and cohesive soils. ASTM D4648/D4648M-24 (2024) has clearly stated that vane shear test for strength does not apply to non-plastic silts and sandy soils; it has also been noted by the same standard that the use of vane shear in predominately silty soils can cause deviation from the cylindrical surface assumed, thus leading to errors in estimated strength.

The Vane Shear test involves penetrating a four-bladed vane in a sample followed by rotating it at a constant rate to determine the torque required for the vane to cause a cylindrical shear surface. This torque is then converted to a unit shearing resistance of the cylindrical surface area. Undrained shear strength by Vane Shear test is calculated using Equation 1 and Equation 2

$$\tau_v = \frac{T}{K} \quad \text{(Equation 1)}$$

$$\text{where } K = \frac{\pi D^2 H}{2} X \left(1 + \frac{D}{3H}\right) \quad \text{(Equation 2)}$$

where T is the maximum torque applied to cause failure, which is determined by the spring constant and angle of rotation, K is a constant accounting for shape and dimension of vane used, H is the height of the vane and D is the vane width. The ASTM (D4648/D4648M-24, 2024) for laboratory Vane Shear test has clearly stated that these tests are suitable for soils with undrained shear strength less than 100 kPa.

The Fall Cone test is a simple testing procedure in which a cone with known mass just touching the surface of soil specimen is released and allowed to penetrate through by its own weight; the penetration depth h is recorded. Like the Vane Shear test, the Fall Cone test is also applicable only for cohesive soils (Canelas et al., 2018; Hansbo, 1957; Koumoto and Houlsby, 2001). Equation 3 by Hansbo (1957) has been used to estimate undrained shear strength for cohesive soil; it relates cone penetration depth *h* to the shear strength of soils τ_f

$$\tau_f = \frac{KQ}{h^2} \quad \text{(Equation 3)}$$

where Q is the weight of the cone and K is a factor accounting for the cone angle. Values of K were initially estimated by Hansbo (1957) by relating cone penetration depths to field Vane Shear tests, out of which 1 and 0.3 were concluded as K values for 30º and 60º cones, respectively. Later, Wood (1985) did experimental measurements for K values and arrived at 0.85, 0.49, 0.29 and 0.19 as average cone factors for 30º, 45º, 60º and 75º cones, respectively. Recent theoretical estimation of K values by Koumoto and G. Houlsby (2001) showed a good agreement with both Hansbo (1957) and Wood (1985).

Claveau-Mallet et al. (2012) and Lu and Bryant (1997) have shown that a minimum penetration between 4 mm and 5 mm can give consistent Fall Cone test results. Working on stiff clay, Hansbo (1957) showed that the Fall Cone test can give a good strength estimation value up to 20 t/m^2, which is approximately 200 kPa while using a 400 g and 30º cone.

For decades now, undrained shear strength has been predicted by using index properties, mainly liquidity index (I_L) (Skempton, 1954, 1957). From experimental tests by Wroth and Wood (1978) on four different clays, a great correlation between liquidity index and strength was found; it was proposed that

there is a fixed approximate value of strength for liquid and plastic limit and that these values correspond to the ratio of 1:100. From this study they developed Equation 4:

$$C_u = 170e^{-4.6I_L} = 1.7 * 10^{2(1-I_L)} \text{ (kPa)} \quad \text{(Equation 4)}$$

Leroueil et al. (1983) proposed an alternative equation, Equation 5, which fits well for materials with a liquidity index ranging between 0.5 and 2.5. This is not appropriate when the I_L value is less than that range as it will result in infinite strength when 0.21 is the liquidity index.

$$C_u = \frac{1}{(I_L-0.21)^2} \text{ (kPa) for } 0.5<I_L<2.5 \quad \text{(Equation 5)}$$

For a higher liquidity index, Locat and Demers (1988) developed a correlation between undrained shear strength and liquidity index ranging from 1.5 to 6.0, as shown in Equation 6:

$$C_u = \left(\frac{1.167}{I_l}\right)^{2.44} \text{ (kPa) } 1.5<I_L<6.0 \quad \text{(Equation 6)}$$

Materials

Materials used in this study were designed to have fines contents that fall within the transitional zone of oil sand tailings (25% to 50% fines content and sand-fines ratio of 1 to 3). These samples were made by mixing coarse sand tailings (CST) and mature fluid tailings (MFT) in predetermined ratios. Because tailings from different sites could have different properties and compositions as they come from different ores with different nature and/or different froth processes were employed (Romanova et al., 2006), Sand and MFT used in this study were received from different oil sand mines' operators to cover a wider spectrum of mineral and chemical composition encountered in sites. Four resulting mixtures have been named in the format SMXX-X.X where SM stands for sand and MFT mixture, and XX and X.X stand for fines content (in percentage) and MBI value respectively for each sample. One sample was designed to include Kaolinite to assess the effect of clay mineralogy, this is named SMKXX-X.X with SMK standing for sand, MFT and Kaolinite mixture, while XX-X.X has the same meaning.

Methodology

Materials characterization

Each sample was characterized to determine PSD; sieve analysis was used to determine PSD for soil particles greater than 45 μm; whereas laser diffraction was used to analyze particles with less than 45 μm size.

Atterberg limits were measured by ASTM D4318 – 17 (ASTM International, 2017), a modified air-dried sample preparation procedure was used, and both bitumen and >425 μm particles were not removed from the sample before testing.

A Methylene Blue Index (MBI) test involved dispersing the sample for homogeneity, acidifying to remove iron oxide-hydroxide effects to titration, and finally titrating the sample with methylene blue to determine the endpoint, which is shown by a blue halo.

Fall Cone and Vane Shear strength test

Samples were allowed to drain water to reach different moisture contents by using Tempe cells. They were subjected to different suctions that were known to be below the Air Entry Value of the respective sample. At the end of water release each sample was tested for undrained shear strength using both the Vane Shear test and Fall Cone test, before getting them in the oven to measure moisture content. At least five measurements of FCT and VST were taken to determine shear strength values for each sample at a given moisture content; this made it possible to check the repeatability of measurements and omissions of outliers.

To measure undrained strength using the Fall Cone test, a metal cone was released to fall under gravity and penetrate the sample. Archived penetration depth was then measured using the gauge attached to a device. Depending on the strength of the material being tested either a 100 g or 400 g cone with 30 degrees aperture angle was used to archive a penetration depth of not less than 5 mm. The Hansbo (1957) equation (Equation 3) was then used with a constant K value of 0.85 to correlate penetration depth to undrained shear strength.

Compliance with ASTM D4648/D4648M-24 (2024) was done to measure shear strength using the Vane Shear test. In this test an electric motor-driven vane shear test equipment was used. The test involved the insertion of a 1/2" by 1/2" four-bladed vane within the sample and rotating at a constant rate of 60º/min until failure occurred. The spring deflection angle (Δ) was recorded at failure, to be used with the spring constant to determine torque (T).

Results and discussion

Materials characterization

The particle size distribution curves for the five designed mixtures are shown in Figure 1 with fines, and the clay contents are summarized in Table 1. The fines content refers to <44 μm particles. In the five samples this ranged from 27.5% to 43%, and the sand-to-fines ratio (SFR) was between 1.3 and 2.6. Sample SMK43-1.6 had the highest clay fraction (38%) because the mixture was composed of sand and kaolinite, which is almost entirely clay-sized. In contrast, other mixtures consisted of sand and mature fine tailings (MFTs) where MFT has particle sizes both below and above clay particle size (<2 μm); thus, they had lower clay

size contents in their resulting mixtures.

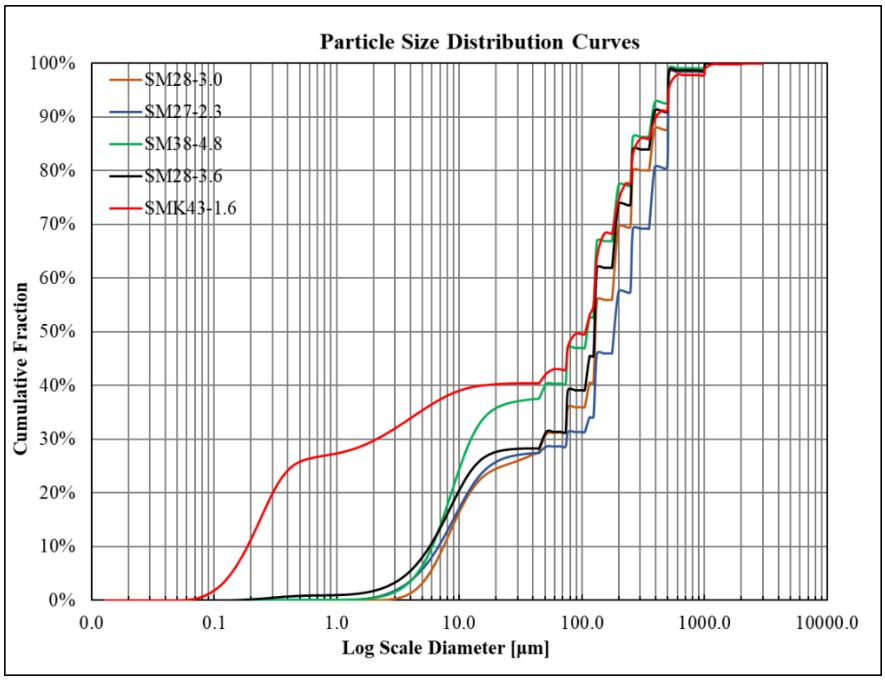

Figure 1: Particle size distribution data for the sample used in the study

Table 1 presents the Atterberg limits and clay properties for each sample. The liquid limit of the samples ranged from 21% to 29%, and the plasticity index varied between 9% and 19%. Despite sample SMK43-1.6 having the highest fines and clay contents, its methylene blue index (MBI) values were significantly lower compared to the other samples. Also, the sample did not show a significant difference in consistency limits when compared to other samples with less fines and clay contents. This discrepancy is due to SMK43-1.6 containing kaolinite, which is less active than the illite typically found in fluid tailings (FT).

Table 1: Summarized index properties for tested samples

ID	Fines (-44m)	Clay (-2µm)	MBI	Liquid Limit %	Plastic Limit %	PI (%)
SM28-3.0	28%	12%	3.0	23%	11%	13%
SM27-2.3	27%	13%	2.3	22%	9%	13%
SM38-4.8	38%	18%	4.8	29%	10%	18%
SM28-3.6	28%	16%	3.6	21%	12%	9%
SMK43-1.6	43%	38%	1.6	24%	12%	11%

FCT and VST data comparison

Figure 2 is a scatter plot for average values from both the FCT and VST data of each of the five samples. Samples SM28-3.0, SM27-2.3, SM38-4.8 and SM28-3.6 show a strong correlation between shear strength

values obtained from FCT and those obtained from VST up to 60 kPa. Beyond this point, the correlation keeps decreasing as strength increases. Also, past 60 kPa the shear strength values measured by FCT are higher than those measured by VST. This can be explained by the crust forming on the surface, thus inhibiting the penetration of the Fall Cone, which will result in an overestimation of the sample's strength, as opposed to the VST, which is inserted to measure strength at the middle portion of the sample. A very weak correlation between FCT and VST was observed for sample SMK43-1.6's data; the trend shows that the VST overestimates strength values below 80 kPa while underestimating values above that. This is the sample that constituted mainly sand and kaolinite. While the comparison is not as good as for other samples, it is still reasonable.

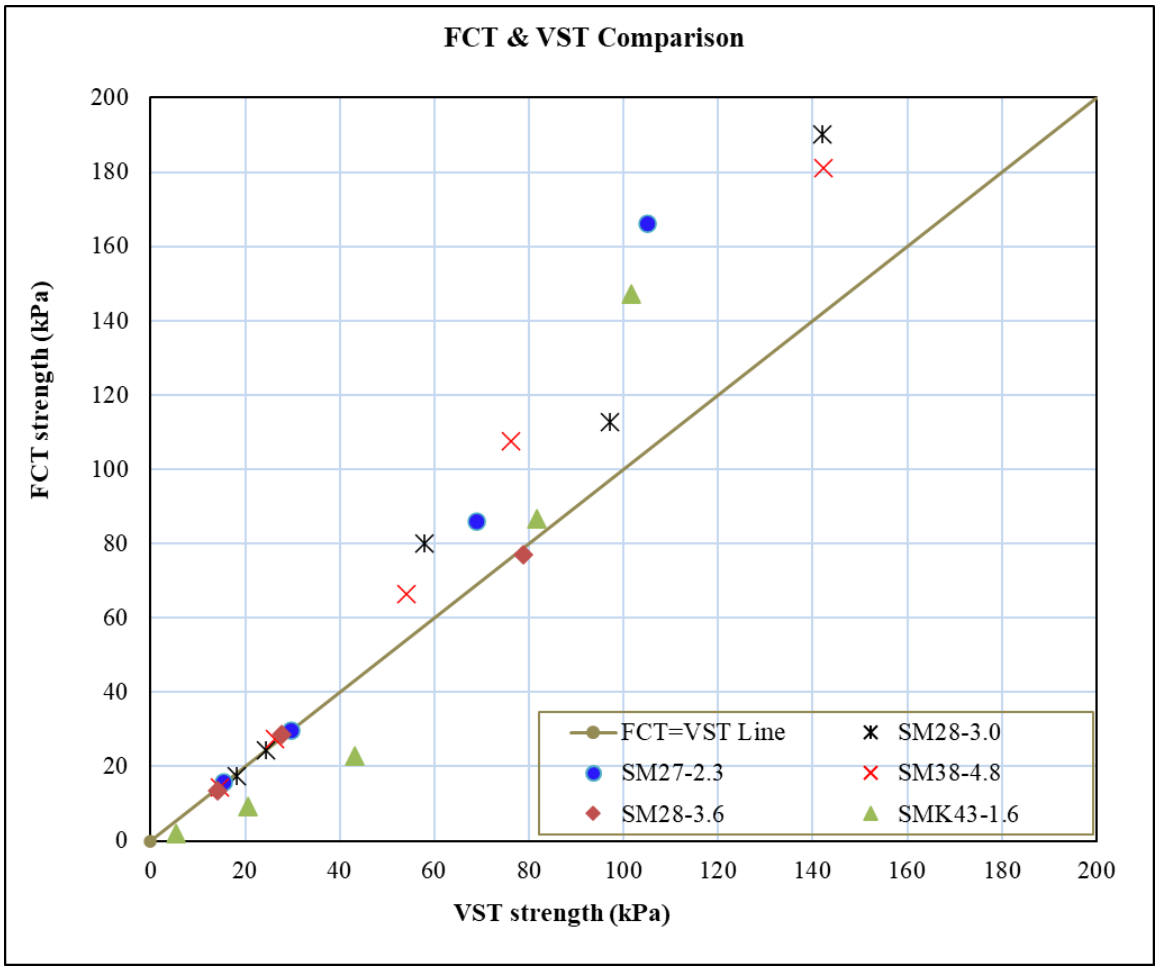

Figure 2: Data comparison between FCT and VST in transitional oil sands tailings

Figure 3 and Figure 4 show very good correlation for strength data, from both the FCT and the VST, for samples SM28-3.0, SM27-2.3, SM38-4.8, SM28-3.6 and SMK43-1.6 to undrained shear strength estimated by Leroueil et al.'s (1983) Equation 5 and Locat and Demers' (1988) Equation 6 respectively, especially in their intended range of liquidity index (greater than 0.5).

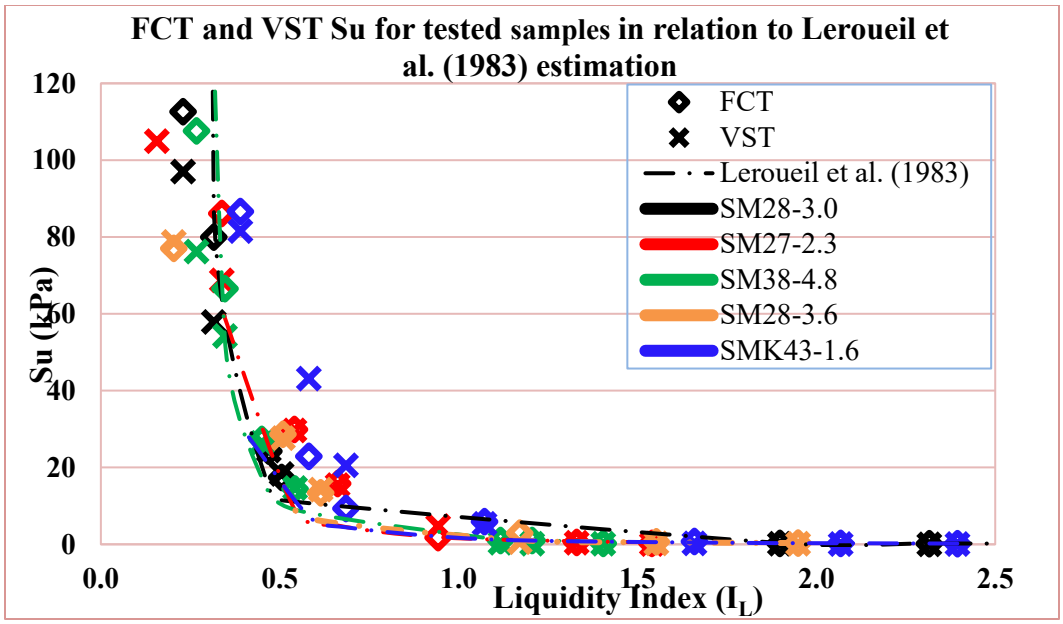

Figure 3: Shear strength correlation between the FCT experimental data, the VST experimental data and strength estimates using the Leroueil et al. (1983) approach

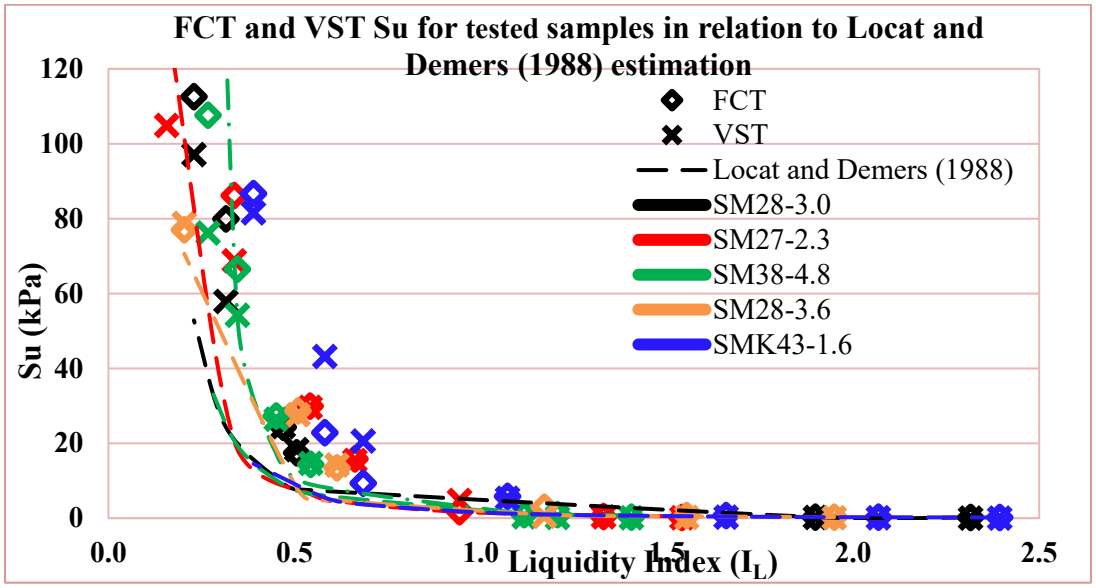

Figure 4: Shear strength correlation between the FCT experimental data, the VST experimental data and strength estimations using the Locat and Demers (1988) approach

All samples show an exponential increase in shear strength with a decrease in their water content and liquidity index, which agrees with the trend observed by Boger (2006) through experiments on various tailings samples. At first, strength increases slowly with liquidity index/water content decrease, and a quick increase is observed at the point where these materials get to a liquidity index of about 0.5. For samples

SM28-3.0, SM27-2.3, SM38-4.8, and SM28-3.6, a great correlation between measured values and estimated values by Leroueil et al. (1983) is evidenced up to 60 kPa strength. The Locat and Demers (1988) estimated values in Figure 4 show a better agreement with higher measured strengths when samples have reached less than 0.5 liquidity index values. The agreement between laboratory tests data and estimates by Leroueil et al. (1983) and Locat and Demers (1988) models that were developed based on cohesive materials provides confidence that both FCT and VST can be used in estimating undrained strength for oil sands tailings in sandy-fines category.

The correlation of FCT and VST measured strength values with both the Leroueil et al. (1983) and the Locat and Demers (1988) estimates keeps diminishing as strength values increase, especially beyond 100 kPa. A diminishing correlation can be explained by the suitability of VST and FCT to measure only up to 100 kPa and 200 kPa respectively, which means measurements are unreliable beyond and close to those limits, and also by the fact that both Leroueil et al. (1983) and Locat and Demers (1988) are designed for undrained strengths of samples with higher than 0.5 liquidity index values. Another significant factor affecting FCT measurements could be the crust forming on the top layer of the samples during their preparation in Tempe Cells, leading to a strength overestimate for the strength of the inner part of the sample. Both FCT and VST experimental data for sample SMK43-1.6 are poorly correlated to either of the two estimation approaches, even at a higher liquidity index where all other samples have shown a good correlation. From the sample characterization study, the sample SMK43-1.6 has the least activity with an MBI value of 1.6, even though it has the highest fines and clay contents. With these properties, this sample likely exhibited drained shear strength, whereas FCT and VST are meant to measure undrained shear strength, and hence the incorrect strength values.

Conclusion

Experimental data have shown a great correlation with estimated data using Atterberg properties of the samples. From this study it can be concluded that either the Vane Shear or Fall Cone test can be used to measure the shear strength of oil sands tailings in sandy-fines category for shear strength up to 60 kPa with great accuracy and repeatability. For measurements of higher strengths of these materials, it would be better to consider the use of other shear strength measurement counterparts, i.e., direct shear and triaxial tests.

If there is a need to measure strength between 60 kPa and 100 kPa while understanding the inaccuracy and reliability of the data, then VST should be used as it gives values closer to the estimated values of strength, with no effects caused by the crust forming on the surface.

Selection of the Seismic Coefficient in Pseudostatic Slope Stability Analyses of Tailings Dams

Jonathan Bray, University of California Berkeley, USA
Jorge Macedo, Georgia Institute of Technology, USA

Abstract

The seismic coefficient used in pseudostatic slope stability analysis of tailings dams is often based on precedence without consideration of what constitutes satisfactory performance. The potential for a material to lose significant shear strength due to earthquake ground shaking should be evaluated first. A flow slide is possible if the post-liquefaction slope stability factor of safety is less than one. The seismic coefficient used in the analysis should be compatible with the allowable amount of seismic slope displacement. The seismic coefficient can be selected to achieve an assessment consistent with the amount of seismic slope displacement that would have been calculated with a seismic slope displacement procedure. The seismic slope displacement procedure employed captures the dynamic response characteristics of the slope with its fundamental period and the seismic demand with the 5% damped elastic design spectral acceleration at the degraded period of the potential sliding mass and the moment magnitude of the governing earthquake. The uncertainty in the estimates of these parameters can be captured using different percentile estimates of these values. By using a *displacement-compatible* seismic coefficient in the pseudostatic slope stability analysis, the engineer considers the amount of seismic displacement judged to be allowable and the seismic hazard at the site in the selection of the seismic coefficient.

Introduction

Pseudostatic slope stability procedures are often used in engineering practice to evaluate the seismic performance of tailings dams. These procedures have the advantage of being straightforward to use in preliminary seismic slope stability assessments. However, the parameters utilized in the analysis should reflect the potential seismic demand at the site and its impact on the seismic performance of the tailings dam to provide a reliable assessment of the potential seismic performance of the tailings dam. The seismic coefficient should be selected in a rational manner because its value determines the reasonableness of the results of a pseudostatic slope stability analysis. As seismic slope displacement provides an index of the anticipated seismic performance of the slope, the seismic coefficient used in the analysis should be

compatible with the allowable amount of seismic slope displacement of the tailings dam and the characteristics of the governing seismic hazard.

After discussing the pseudostatic slope stability procedure, a procedure is recommended that takes advantage of recent work on performance-based earthquake engineering (PBEE) seismic slope displacement procedures. This procedure calculates a seismic coefficient that is a function of the allowable seismic slope displacement, the seismic demand at the tailings dam site, and the sliding mass's properties. The way this approach can be used in engineering practice is also discussed.

Pseudostatic slope stability procedure

The pseudostatic slope stability analysis calculates a factor of safety (*FS*) using a static limit equilibrium method in which a horizontal inertial force is applied to the potential sliding mass to represent the destabilizing effects of the earthquake shaking. The horizontal inertial force is expressed as the product of a seismic coefficient (*k*) and the weight (*W*) of the potential sliding mass (see Figure 1). The pseudostatic analysis also requires the use of appropriate material dynamic strengths (*s*). The static limit equilibrium method should satisfy all three conditions of equilibrium to ensure that a reliable *FS* is calculated (Duncan et al. 2014). The seismic performance of a tailings dam is judged to be acceptable if the calculated *FS* is above a specified minimum value (which is often assumed to be 1.0, 1.1, or 1.2). The seismic coefficient, shear strength, and acceptable minimum factor of safety are often based on precedence. The basis for the selected *s, k,* and *FS* values used in a pseudostatic slope stability analysis is often unclear. The rationale for the selected values is often questionable. Justifiable values of *s*, *k*, and *FS* are required if a pseudostatic slope stability procedure is to be used reliably to assess the seismic performance of a tailings dam.

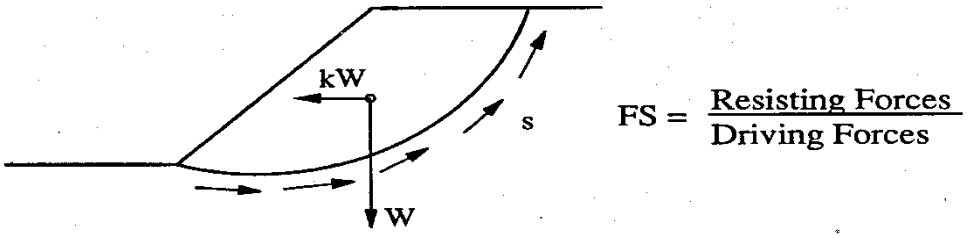

Figure 1: Pseudostatic slope stability analysis

Severe strength loss evaluation

In the evaluation of the seismic performance of a tailings dam, the engineer must first assess if there are materials in the tailings dam or in its foundation that can lose significant strength because of cyclic loading. Soil liquefaction is a primary concern, especially if flow liquefaction can occur. The pseudostatic slope stability procedure can provide misleading results if the cyclic strength of the tailings and earth materials

is not evaluated appropriately. The calculated *FS* is meaningless if pre-seismic static strength values are utilized in the analysis and these materials lose significant strength due to earthquake shaking. The potential for significant strength loss either due to liquefaction of sandy or silty materials or cyclic softening of sensitive clayey soils must be evaluated first. If it is likely that these materials will undergo severe strength loss, their post-shaking reduced shear strength values should be employed in the seismic stability evaluation. If the post-seismic slope stability *FS* approaches or falls below unity, a potentially catastrophic flow slide is possible. Therefore, the assessment of the strength loss potential of the materials in and below the tailings dam should be the initial focus of the evaluation.

Several soil liquefaction triggering procedures are available (e.g., Robertson, 2009; Boulanger and Idriss, 2016). The Chinese criteria should no longer be used to assess the liquefaction susceptibility of fine-grained soil. Updated criteria such as those developed by Bray and Sancio (2006), which are based on soil plasticity ($PI \leq 12$) and sensitivity ($w_c/LL \geq 0.85$), should be used. Additionally, soils with $PI > 12$ should be evaluated carefully, as sensitive clay flow slides have occurred, such as those in Anchorage during the 1964 Alaskan earthquake (e.g., Idriss 1985). The potential for flow slides resulting from severe strength loss due to liquefaction or post-peak strength reduction in sensitive clays should be evaluated carefully before employing a limit equilibrium stability procedure that assumes a rigid-perfectly plastic material response during shear (e.g., Bray and Macedo, 2023).

Framework for the selection of the pseudostatic coefficient

The pseudostatic slope stability method can provide reasonable results for a tailings dam if the combination of *k*, *s*, and *FS* used provides a performance assessment that is consistent with that expected from advanced analysis and field case histories. A properly calibrated pseudostatic slope stability procedure requires a compatible selection of the seismic coefficient, dynamic material strengths, and an acceptable factor of safety. All three of these critical design parameters must be specified and shown to provide reliable results in terms of the anticipated amount of seismic displacement of the tailings dam.

The horizontal force *kW* in the pseudostatic slope stability analysis represents the dynamic effects of the design earthquake. However, unlike the earthquake's actual dynamic effects, this pseudostatic force acts as a constant force in only one direction. In limit equilibrium analysis, $FS = 1.00$ occurs when the activating forces (or moments) equal the resisting forces (or moments). Hence, only the condition of incipient motion is considered. With dynamically applied earthquake-induced loads, the force may act in one direction for only a few tenths of one second before its direction is reversed. The results of these transient forces will be a series of displacement pulses (Newmark, 1965). Satisfactory performance is judged by whether the accumulated seismically induced permanent displacement is tolerable. Selecting a seismic coefficient that is a fraction of the maximum seismic demand is reasonable because exceeding the

maximum seismic resistance during a few instances will only lead to small seismic slope displacement. Thus, the results of a pseudostatic slope displacement procedure should be tied to the likely shear-induced seismic slope displacement (D_S) of the tailings dam.

A Newmark sliding block model can capture that part of the seismically induced permanent displacement attributed to shear deformation. Ground movement due to volumetric compression of the soil is not captured explicitly by a Newmark model. The top of a tailings dam can displace downward due to shear and volumetric-induced deformation. Shear-induced and volumetric-induced displacement should be estimated separately using procedures based on the sliding block model to estimate shear-induced displacement and other procedures to estimate volumetric-induced displacement (e.g., Tokimatsu and Seed, 1987 or Bray and Olaya, 2023). The sum of the shear-induced and volumetric-induced dam displacement components should be considered.

The yield coefficient (k_y) used in a Newmark-type calculation is the k value that results in a $FS = 1.00$ in the pseudostatic slope stability analysis; it represents the dam's dynamic resistance. Recognizing that k_y for a sliding mass depends exclusively on the slope characteristics is important. Although a pseudostatic slope stability analysis is performed to find k_y, one should remember the problem is inherently dynamic, so several potential slip surfaces should be considered to find the sliding mass that produces the largest D_S, which is the critical sliding surface. The most important parameter in a rigid or decoupled flexible sliding block analysis is $k_y/k_{max,}$ where k_{max} is the maximum seismic demand. The sliding mass with the lowest k_y/k_{max} value will produce the largest D_S.

The Seed (1979) pseudostatic slope stability method was developed for earth dams with materials that do not undergo severe strength loss and dam crest accelerations less than 0.75 *g*. Seismic performance is judged to be acceptable by this method using $k = 0.15$ with appropriate dynamic strength if $FS \geq 1.15$. This approach involves several simplifying assumptions and is calibrated for evaluating earth dams wherein D_S = 1 m implies satisfactory seismic performance. Another significant limitation of this method is that earthquake shaking is represented by a single seismic coefficient value ($k = 0.15$) for all cases. Instead, k should depend on the source-to-site distance (R), site conditions (V_{s30}), and the moment magnitude (M) of the design earthquake event. Additionally, the use of a minimum acceptable FS other than 1.00 leads to inconsistencies. Using $FS \geq 1.15$ ensures k_y will be greater than 0.15 by an unknown amount. The expected seismic performance is unclear because the level of conservatism resulting from $FS \geq 1.15$ is unknown.

The Hynes-Griffin and Franklin (1984) pseudostatic screening procedure is based on a conservative interpretation of the dynamic response of an earth dam to an older set of shallow crustal earthquake ground motions. They too assumed materials are not susceptible to severe strength loss, and D_S = 1 m implies satisfactory seismic performance. Their procedure applies $k = 50\%$ of the peak ground acceleration on rock (PGA_R) at the site, $s = 80\%$ of the static shear strength of the materials, and $FS \geq 1.00$. If these criteria are

met, the dam is judged to be safe as defined by D_S = 1 m being tolerable. Tying k to 50% PGA_R enables the pseudostatic slope stability analysis to consider the different seismic hazard hazards at sites worldwide, but PGA is not an optimal seismic intensity parameter for estimating D_S for tailings dams (Bray and Travasarou 2007). Seismically induced displacement of an earth structure is better captured by peak ground velocity (PGV) (Newmark 1965), or 5%-damped elastic spectral acceleration (S_a) (Bray and Travasarou, 2007).

A pseudostatic stability procedure developed by Saragoni (1993) based on observations of the performance of rigid retaining structures at ports in Valparaiso during the 1985 Chile earthquake has also been applied to evaluate the seismic performance of tailings dams. In it, $k = 0.30\ PGA/g$ for $PGA \leq 0.673\ g$ or $k = 0.22\ (PGA/g)^{0.333}$ for $PGA > 0.673\ g$. This procedure was not developed to capture the response of tailings dams, which are not rigid. Moreover, Saragoni (2014) later states "… *displacements are not related with maximum ground acceleration* …" Thus, this procedure should not be used to select the seismic coefficient in a pseudostatic slope stability analysis of a tailings dam.

Historically, engineering judgment and precedence guided the selection of k. There are now several studies that recommend the k value to be used in pseudostatic slope stability analysis. However, the basis of the recommended k value is often not linked explicitly to the properties of the potential sliding mass, the seismic hazard, and importantly, the likely amount of seismic slope displacement. With the adoption of modern PBEE approaches and an enhanced understanding of the seismic hazard, the use of a prescribed seismic coefficient value across a geographic region because it has been used previously is not justifiable. Instead, k should be selected based on the unique seismic hazard present at a site and the level of seismically induced permanent displacement that constitutes an acceptable level of seismic performance of the tailings dam. This paper presents a rational framework for selecting k in pseudostatic slope stability analysis.

PBEE seismic slope displacement model

The recommended procedure for selecting a *displacement-compatible* seismic coefficient is based on the work of Bray and Macedo (2019) for shallow crustal earthquakes and the work of Macedo et al. (2023) for interface and intraslab subduction zone earthquakes. These procedures utilize thousands of recorded ground motions from defined tectonic sources with a validated nonlinear coupled flexible stick-slip sliding model to estimate seismic slope displacement of earth structures, including tailings dams, and the uncertainty of the estimate of D_S. The methodology, model, and their limitations are described in Bray et al. (2018). This seismic slope displacement model allows the engineer to estimate D_S using two equations that calculate: (1) the probability of negligible ("zero") slope displacement (i.e., $D_S \leq 0.5$ cm), and (2) the likely amount of "nonzero" slope displacement. The probability of negligible slope displacement equation can be neglected in this application because it does not have a noticeable effect on k for a median seismic slope displacement value larger than 5 cm. Neglecting this first step yields conservative results for displacements less than 5 cm. Given the

simplifications of a sliding block model, it should not be used in cases when it estimates median D_S values greater than 5 m. It can be used when limited zones liquefy if post-liquefaction residual strengths are used.

For ordinary shallow crustal earthquake shaking, D_S (cm) is estimated as (Bray and Macedo, 2019):

$$ln(D_S) = a_1 - 2.482Ln(k_y) - 0.244\left(Ln(k_y)\right)^2 + 0.344Ln(k_y)Ln(Sa(1.3T_s)) + 2.649Ln(Sa(1.3T_s)) - 0.090\left(Ln(Sa(1.3T_s))\right)^2 + a_2T_s + a_3(T_s)^2 + 0.603M_w + \varepsilon \quad (1)$$

where k_y is the yield coefficient; T_s is the initial fundamental period of the sliding mass in seconds; a_1 = -5.981, a_2 = 3.223, and a_3 = -0.945 for systems with $T_s \geq 0.10$ s, and a_1 = -4.684, a_2 = -9.471, and a_3 = 0.0 for $T_s < 0.10$ s; S_a is the 5% damped elastic spectral acceleration of the ground motion acting on the material below the sliding mass at a period of $1.3T_s$ in the unit of g; M is the earthquake's moment magnitude; and ε is a normally-distributed random variable with zero mean and standard deviation (σ) of 0.72.

For subduction zone earthquakes, D_S (cm) is estimated as (Macedo et al., 2023):

$$ln(D_S) = a_0 + a_1ln(k_y) + a_2(ln(k_y))^2 + a_3ln(k_y)\ln\left(S_a(1.3T_s)\right) + a_4\ln\left(S_a(1.3T_s)\right) + a_5(\ln\left(S_a(1.3T_s)\right))^2 + a_6T_s + a_7(T_s)^2 + a_8M_w + \varepsilon \quad (2)$$

where the parameters are as defined previously, except the coefficients a_0 to a_8, and σ are defined in Table 1 for interface and intraslab sources.

Table 1: Coefficients for interface and intraslab earthquakes (Macedo et al., 2023)

Coefficient	Interface		Intraslab	
	$T_s < 0.1$ s	$T_s \geq 0.1$ s	$T_s < 0.1$ s	$T_s \geq 0.1$ s

The Newmark (1965) rigid block sliding analysis assumes a rigid block sliding on a rigid plane that is excited by an acceleration-time history. Tailings dams are not rigid blocks, so capturing the dynamic response characteristics of their flexible sliding mass is important. This can be done approximately with the decoupled approximation or more robustly with a fully coupled model (Rathje and Bray, 2000). Kramer and Smith (1997) noted: "*If permanent displacements are assumed to be restricted to the sliding interface, the most important characteristics are the stiffness and distribution of mass within the failure mass.*" The sliding mass can be

represented by a dynamic system that captures its fundamental period and mass.

Tailings dams are part of a larger dynamic system. They may be founded on rock, or they may be founded on deep alluvium. It is a simplification to characterize the fundamental period of a tailings dam without considering the flexibility of its foundation. It is a simplification to characterize a part of the tailings dam that may slide during an earthquake without considering the flexibility of the material below the sliding plane. It is equally a simplification to characterize a structural system by its fixed-based fundamental period when it is founded on a soil deposit. Yet, these simplifications are routinely made in practice because they can provide useful insights. The fundamental period of a potential sliding mass within a larger dynamic system provides an index of its flexibility and the dynamic response characteristics of the sliding mass.

The Bray et al. (2018) sliding block model assumes a flexible sliding mass that can slide atop a rigid base, which is consistent with the approach developed by Kramer and Smith (1997). The spectral acceleration value (S_a) at $1.3T_s$ represents the seismic loading on a flexible sliding mass that is not rigid (i.e., $T_s > 0$ s). As with other rigid or flexible sliding block Newmark-type models, this approach suffers from the assumption that the earth below the sliding mass is assumed to be rigid. However, $S_a(1.3T_s)$ can be used as an index of the seismic loading on a potential sliding mass by validating its use with observations from field case histories and the results of robust advanced analyses, as was done in developing the Bray and Macedo (2019) and Macedo et al. (2023) procedures. T_s can be estimated approximately in most cases, or it can be estimated reliably using the methodology proposed by Bray and Macedo (2021).

For the base sliding case and for other deep sliding cases, use of the T_s of the dam or T_s of a large sliding mass that is a large part of the dam is reasonable for estimating the seismic demand. For shallow sliding cases, the response of the material below the potential sliding mass changes the input characteristics of the ground shaking, which can be estimated using nonlinear 1D seismic site response methods. Additionally, the estimated $S_a(1.3T_s)$ value, which approaches *PGA* as $1.3T_s$ approaches 0, should be adjusted for topographic effects (e.g., amplifying the PGA by a factor of 1.3 for moderate slopes (Rathje and Bray, 2001) or using the dam crest PGA relationship of Park and Kishida, 2019). A simplified sliding block analysis cannot capture all the aspects of the problem that can be captured by a nonlinear dynamic finite difference analysis with a robust, validated, calibrated constitutive model. However, a nonlinear, coupled flexible sliding block model that has been validated with field case history data can provide an index of the likely seismic performance of a tailings dam.

Selection of the seismic coefficient

The Bray and Macedo (2019) procedure and Macedo et al. (2023) procedure have been adapted to provide a rational basis for selecting k that is based on the expected seismic demand at the project site and the desired level of seismic performance of the tailings dam in terms of its allowable seismic displacement. Instead of calculating D_S as a function of k_y, T_s, S_a, and M, Equations (1) and (2) can be revised to solve for a

displacement-compatible k as a function of the allowable seismic displacement (D_S), T_s, S_a, and M. If this value of k is used in a pseudostatic slope stability analysis and the calculated $FS \geq 1.00$, then the selected percentile estimate of D_S will be less than or equal to D_{Sa}. Specifically, the calculated shear-induced seismic slope displacement will be less than D_{Sa} if one performs a seismic slope displacement calculation using the Bray and Macedo (2019) procedure or the Macedo et al. (2023) procedure.

The *displacement-compatible k* applied in pseudostatic stability analyses is not the yield coefficient (k_y). However, k can be linked to k_y in a pseudostatic slope stability analysis to get the same result as if one had performed a seismic slope displacement calculation. This is the approach proposed by Whitman (1990) to select k in a pseudostatic analysis of a rigid retaining wall with the value of k linked to k_y, so the analysis achieved results consistent with those of a seismic displacement analysis. If k is selected to be k_{max} and $FS \geq 1.00$ for a rigid or decoupled flexible sliding block case, $D_S = 0$ because the seismic demand never exceeds k_y (i.e., $k_y/k_{max} \geq 1.00$). If k is selected to be less than k_{max} and $FS = 1.00$ for a rigid or decoupled flexible sliding block case, D_S will be calculated to be greater than 0, because the seismic demand exceeds k_y (i.e., $k_y/k_{max} < 1.00$). As the selected k decreases for these cases when $FS = 1.00$, k_y/k_{max} also decreases, and thus D_S increases. Thus, the value of k selected in a pseudostatic slope stability analysis is tied to D_S. Although the sliding mass has a unique k_y value, an engineer can choose the value of k to use in a pseudostatic slope stability analysis, and their choice of k leads to more or less D_S being calculated in a corresponding seismic slope displacement analysis. The inversion of Equation (1) or (2) provides a value of k consistent with a Newmark-type seismic slope displacement calculation that gives the desired range of seismic slope displacement. These equations can also be used to cast the estimation of k in a fully probabilistic framework (Macedo and Candia, 2020), but in this case, the estimation of k needs the estimation of D_S hazard curves.

The Bray and Macedo (2019) site-dependent and allowable displacement-dependent value of k is:

$$k = exp\left[\frac{-a+\sqrt{b}}{0.49}\right] \geq 0.03 \quad (3a)$$

where

$$a = 2.491 - 0.344Ln(S_a(1.3T_s)) \quad (3b)$$

$$b = a^2 - 0.98(Ln(D_{Sa}) - a_1 - 2.703Ln(S_a(1.3T_s)) + 0.089Ln(S_a(1.3T_s))^2 - a_2T_s - a_3(T_s)^2 - 0.6070M - \varepsilon) \quad (3c)$$

where the model parameters and coefficients are defined previously in Equation (1). A similar manipulation of Equation (2) can be done to estimate k for interface and intraslab subduction zone earthquakes as functions of the seismic hazard and D_{Sa}, as presented in Macedo et al. (2023). The minimum design value of k is set to 0.03 regardless of what is calculated to establish a reasonable threshold. The basis of this threshold value of k are the simplifications involved in the pseudostatic slope stability analysis, the uncertainty of the seismic slope displacement procedure increases as k decreases, and the requirement to

have an adequate static factor of safety in a relatively gentle infinite slope.

The steps required to perform the pseudostatic slope stability analysis with a seismic hazard-dependent and project performance-dependent *displacement-compatible* seismic coefficient are:

1. Evaluate if there are materials that could lose severe strength during earthquake shaking (e.g., liquefaction). Use post-shaking reduced strengths for these materials and use best-estimate dynamic shear strengths for materials that do not lose significant strength (Bray and Macedo, 2023). Calculate the post-liquefaction slope stability FS. If $FS \leq 1.0$, a flow slide may develop, and the seismic displacement can be large. Evaluate and implement mitigation measures or consider using advanced analysis to assess the seismic performance of the tailings dam. If $FS > 1.1$, the pseudostatic slope stability method may be used. A pseudostatic slope stability analysis is most appropriate for evaluating a tailings dam and foundation that are composed of materials that do not lose significant strength loss due to earthquake shaking. For example, a well-compacted downstream dam built on a competent foundation (i.e., dilative materials) can be evaluated with the pseudostatic slope stability method. For this case, best-estimate strain-compatible dynamic shear strengths can be used for the dam and its foundation, but the liquefied residual shear strength should be used for the impounded saturated contractive tailings as they will likely liquefy near the start of ground shaking. Cases with limited zones of liquefied material in the dam and its foundation can also be evaluated assuming these materials reach their liquefied residual shear strength at the start of earthquake shaking. The pseudostatic slope stability method should not be used to evaluate the seismic performance of an extreme consequence upstream dam built atop liquefiable contractive tailings with a brittle response.
2. Establish the total allowable seismic displacement (D_a in cm) of the tailings dam through consultation with the owner while considering the consequences of unsatisfactory performance at displacement levels greater than this threshold. The total allowable seismic displacement is the summation of the shear-induced seismic slope displacement D_{Sa} (cm) and the allowable seismic volumetric-induced displacement D_{Va} (cm); D_a should not exceed about 300 cm, given the limitations of the pseudostatic slope stability method and volumetric-induced displacement methods. The volumetric component D_{Va} is typically relatively small in cases in which the shear component D_{Sa} is significant, so one can assume $D_{Sa} = 0.8\ D_a$. The percent exceedance of the D_{Sa} displacement threshold is typically set at the 16% exceedance level (i.e., set $\varepsilon = \sigma$ in Equation 3) considering the consequences of unsatisfactory performance of a tailings dam.
3. The seismic demand is defined in terms of the design spectral acceleration for outcropping site conditions below the sliding mass (which may include topographic amplification) at the degraded

period of the sliding mass (i.e., $S_a(1.3T_s)$) and the moment magnitude (M) of the controlling earthquake event. The ground motion hazard level should be established based on the uncertainty in the seismic hazard characterization, the criticality of the project, and the consequences of unsatisfactory performance.

4. Calculate the *displacement-compatible k* (e.g., using Eq. 3 for shallow crustal earthquakes) and apply this k in a pseudostatic slope stability analysis that satisfies all three conditions of equilibrium. If the resulting $FS \geq 1.00$, the selected percentile estimate of D_S will be less than D_{Sa} if one had performed a seismic slope displacement calculation. The preferred minimum value of the acceptable FS is 1.00 because this method has been calibrated to provide an assessment consistent with the seismic slope displacement calculated with a sliding block analysis. A spreadsheet is available on the authors' websites to simplify the calculation of the design seismic coefficient (e.g., Bray and Macedo, 2024).

Figure 2 illustrates the general relationships between k and D_S and the seismic hazard (i.e., $S_a(1.3T_s)$ and M) for a selected T_s for several seismic source mechanisms. Allowable shear-induced seismic slope displacement values of 30 cm and 1 m at the 16% exceedance level were used to illustrate the dependence of k on the selected level of allowable displacement. Results are also provided for the 1 m displacement level for two earthquake magnitude scenarios. For a selected allowable shear-induced seismic slope displacement target, the seismic coefficient increases with increasing ground motion intensity, as one would expect. It also increases as the magnitude (i.e., duration) of the earthquake event increases. Importantly, the seismic coefficient decreases significantly as the allowable displacement level increases. The seismic coefficient is shown to vary systematically as the allowable shear-induced seismic displacement threshold and design ground shaking level vary.

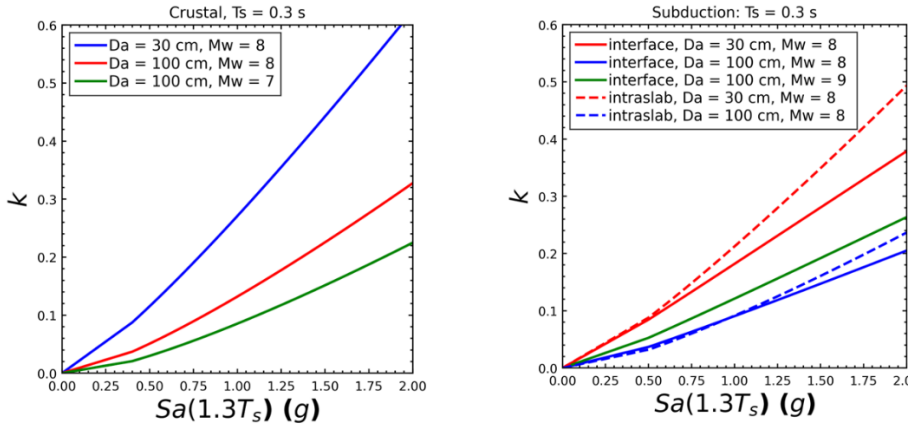

Figure 2: Variation of the seismic coefficient as a function of allowable shear-induced seismic displacement set at 30 cm and 100 cm at the 16% exceedance level and the specified seismic hazard for several cases (k < 0.03 values displayed to show trends)

The seismic coefficient also depends on the potential sliding mass's fundamental period. Relatively stiff slopes with short fundamental periods (i.e., 0.1 s < T_s < 0.3 s) tend to displace more because of resonance with the earthquake ground shaking. More flexible slopes (i.e., T_s > 0.5 s) have relatively less potential for seismic displacement. This effect can be seen by examining representative earthquake scenarios specified in Figure 3 (i.e., soft rock site at R = 20 km from a shallow crustal strike-slip M = 8 earthquake and at R = 50 km from a subduction M = 8 earthquake). After the peak k value is reached, it decreases progressively as the slope's fundamental period increases. The seismic coefficient required to limit a specified allowable seismic displacement threshold is larger for shallow stiff sliding masses than for deep flexible sliding masses (e.g., Rathje and Bray, 2000). The differing effects of interface and intraslab subduction zone earthquake sources are illustrated in Figure 3b.

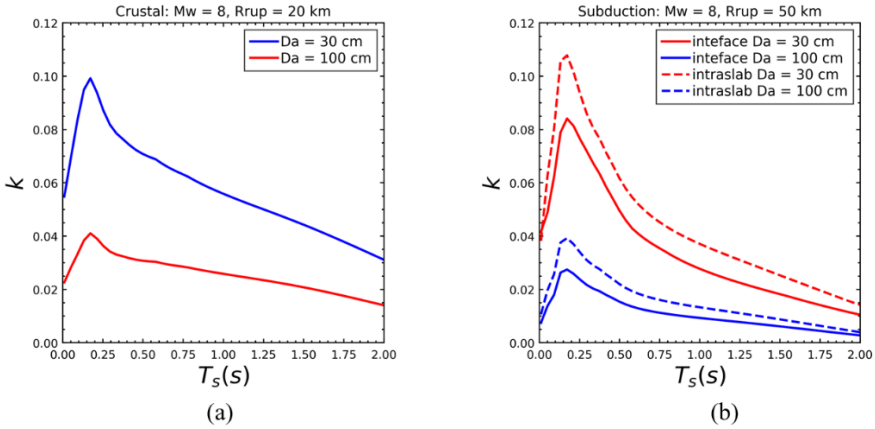

Figure 3: Dependence of the seismic coefficient on the fundamental period of the potential sliding mass for a scenario earthquake with seismic slope displacement set at 30 cm and 100 cm at the 16% exceedance level (k < 0.03 values displayed to show trends)

Example of the selection of the *displacement-compatible* seismic coefficient

The steps presented previously to perform a pseudostatic slope stability analysis with a *displacement-compatible* seismic coefficient are applied to a tailings dam shaken by the 2010 M8.8 Maule, Chile earthquake. Information on the Las Tortolas main tailings dam is provided in Valenzuela (2015) and Valenzuela et al. (2020). It is a downstream-constructed sand dam. Its cross-section, which shows the sliding mass analyzed in this example, is shown in Figure 4.

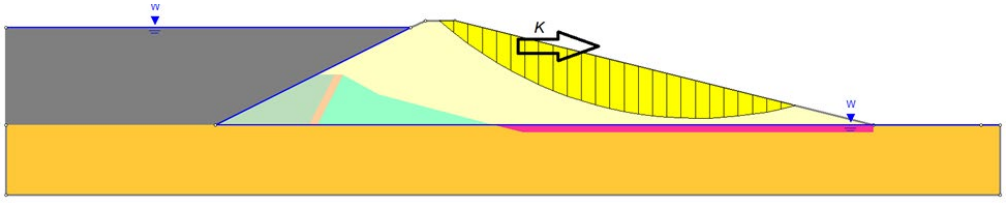

Figure 4: Idealized cross-section of the Las Tortolas main dam (from Valenzuela, 2015) with the potential sliding mass analyzed in this example shown

The selection of the *displacement-compatible* seismic coefficient for the tailings dam for the seismic demand produced by the 2010 Maule earthquake proceeds as follows:

1. No materials lose severe strength at the 2010 Maule earthquake level of shaking. Best-estimate dynamic shear strengths of the dam materials are based on the information provided by Valenzuela (2015) and Valenzuela et al. (2020). The calculated post-seismic slope stability *FS* exceeds 1.1, so the pseudostatic slope stability method can be used.
2. No significant deformation was observed at the Las Tortolas main dam after the 2010 Maule earthquake (Valenzuela, 2015). In this back-analysis of a tailings dam in which no significant deformation was observed, seismic displacement value of D_a is assumed to be negligible (i.e., less than 5 cm). The low value of D_a in this back-analysis should not be confused with the design D_a which is selected at higher level (i.e., often 1 m or more) to judge satisfactory dam performance for the design earthquake, which has a higher seismic demand. The shear-induced seismic slope displacement (D_{Sa}) is assumed to be 80% of D_a, so D_{Sa} = 4 cm. The percent exceedance of the D_{Sa} displacement threshold is set at the 16% exceedance level considering the consequences of unsatisfactory performance of a tailings dam.
3. The initial fundamental period of potential sliding mass (T_s) shown in Figure 4 is estimated as 0.52 s using $T_s = 2.6\ H/V_s$, where H = 70 m and V_s = 350 m/s based on information in Valenzuela (2015). The estimated spectral acceleration for outcropping site conditions below the sliding mass at the degraded period of the sliding mass (i.e., $S_a(1.3T_s)$) is estimated as 0.18 *g* based on $S_a(1.3T_s)$ being about equal to the outcropping *PGA* at the site reported in Valenzuela et al. (2020). The 2010 Maule earthquake is M = 8.8.
4. The *displacement-compatible k* is estimated using the Bray and Macedo (2024) spreadsheet for a subduction zone interface event, which is the tectonic setting of the Maule earthquake. With D_{Sa} = 4 cm, T_s = 0.52 s, $S_a(1.3T_s)$ = 0.18 *g*, *PGV* set to -1 to use the scalar model, M = 8.8, mechanism set to 0 for an interface event, and epsilon = 0.75 to set D_{Sa} at the 16% probability of exceedance level, k = 0.12. The value of k = 0.12 is applied in a slope stability analysis program using the Spencer (1967) method to calculate FS = 1.8 which exceeds 1.0. The result of the pseudostatic slope stability analysis indicates the earthquake-induced displacement of the Las Tortolas tailings dam during the 2010 Maule earthquake should be less than 5 cm, which is consistent with the observed performance reported by Valenzuela (2015). In a forward design analysis of the dam, the seismic demand (i.e., $S_a(1.3T_s)$ and M) would be higher and the allowable seismic displacement (D_a) would be higher, which would produce a different value of k as it is selected to be compatible with the allowable design displacement and consistent with the design seismic hazard.

Conclusion

The seismic coefficient used in a pseudostatic slope stability analysis should be selected in a rational manner. It is not rational to select an arbitrary value of k without considering the site-specific seismic hazard and determining the threshold of allowable seismic displacement that constitutes satisfactory seismic performance of the tailings dam. A rational PBEE procedure is presented that estimates k based on the consequences of different seismic displacement values and different seismic hazards. The engineer should consider the project performance criteria and the seismic hazard when selecting a *displacement-compatible* k value to apply in a pseudostatic slope stability analysis.

This approach requires the engineer to establish a project-specific allowable level of seismic displacement of the tailings dam in consultation with the owner. This is an important dialogue and is project specific. The robustness of the tailings dam and its appurtenance structures should be assessed, and the consequences of unsatisfactory performance should be considered. The site-dependent seismic demand is characterized by the 5% damped elastic design spectral acceleration at the degraded period of the potential sliding mass, either through a probabilistic or deterministic seismic hazard assessment (PSHA or DSHA). The uncertainty in the seismic demand estimate can be addressed using different fractiles in the PSHA or different percentiles of the deterministic estimate of the design spectral acceleration in the DSHA. The uncertainty of the seismic displacement estimate is handled using the 16% exceedance level of the estimated seismic displacement that is judged to be allowable.

The potential for severe strength loss of the materials within and below the tailings dam due to earthquake shaking must be evaluated before employing the pseudostatic slope stability procedure. It is critically important to assess the strength loss potential of the tailings dam and its foundation. A flow slide is possible if the post-liquefaction slope stability FS $\leq$ 1.0. Best-estimate strain-compatible dynamic shear strengths should be used for materials that do not lose significant strength, and liquefied residual shear strengths should be used for saturated contractive materials that are likely to liquefy. Additionally, it is important to remember that seismic slope performance is evaluated in terms of the potential range of seismically induced permanent displacement, even when a pseudostatic slope stability procedure is employed. The estimated seismic displacement of a tailings dam is an index of seismic performance. Thus, an appropriate level of engineering judgment should be exercised.

Acknowledgments

The Faculty Chair in Earthquake Engineering Excellence at UC Berkeley provided financial support to perform this research, which was supplemented by Georgia Tech. The PEER Center provided access to the NGA-West2 and NGA-Sub ground motion intensity measures.

The Critical State Line Parameters of Iron Ore Tailings from Basic Laboratory Tests: Updated Insights with Additional Data

José Ccotohuanca, Klohn Crippen Berger Consultoria Ltda, Brazil
Daniel Klassen, Klohn Crippen Berger Ltd, Canada

Abstract

Characterizing iron ore tailings using the critical state soil mechanics (CSSM) framework has become standard practice in Brazil to support the static liquefaction assessments of tailings storage facilities (TSF) undergoing decommissioning processes and the design of filtered tailings stacks. This has resulted in a substantial published database of iron ore critical state (CS) parameters, as most iron ore TSF projects are situated within the Iron Quadrangle (Minas Gerais) in Brazil, an area renowned for hosting one of the world's largest reserves of iron ore.

In early 2024, the authors presented a database containing CS parameters derived from laboratory testing of 26 iron ore sources. Based on newly published data, this database has been expanded. This article compiles CS parameters from an updated database that includes 40 iron ore tailings from various sites in Brazil and worldwide. These parameters are then compared to basic laboratory data including specific gravity (G_s), fines content (FC), mean particle size (D_{50}), coefficient of uniformity (C_u), Atterberg limits represented by the plasticity index (PI) and liquid limit (LL), minimum (e_{min}) and maximum (e_{max}) void ratios as well as the iron oxide content. The aim is to establish correlations between basic iron ore tailings data and CS parameters, providing a screening approach to determine whether laboratory results fall within expected ranges, or if more detailed tests are necessary when assessing static liquefaction for iron ore TSFs.

Introduction

Static liquefaction is defined as sudden strength loss in a (near) saturated (typically granular) soil, accompanied by rapid generation of excess pore-water pressure. This could develop into a liquefaction flow failure if the soil strength drops below the applied shear stress (Lade and Yamamuro, 1997). Recent incidents, such as the failures at Fundão (Morgenstern et al., 2016) and Brumadinho (Robertson et al., 2019), have identified static liquefaction as a primary failure mechanism. These Brazilian tailings storage facility (TSF) failures have resulted in unprecedented and devastating consequences for the environment,

infrastructure damage and human losses. In response, new regulations have been enacted in Brazil, introducing the concept of "TSF decharacterization." This involves transitioning from an existing upstream-constructed tailings dam to a structure that no longer primarily serves as a tailing containment facility, thereby functionally reintegrating the facility into the environment. The failures also spurred increased interest in alternative dewatered tailings technologies (e.g., filtered tailings), due to their lower risk compared to conventional hydraulically deposited tailings.

In the Brazilian context, where decharacterization and filtered tailings projects were not commonly practiced, comprehensive geotechnical investigations were required to understand the behavior of the tailings material to support static liquefaction assessment, generally following the critical state soil mechanics (CSSM) framework. Consequently, a database of critical state (CS) parameters was developed and published. This was primarily on iron ore tailings, given the predominant location of TSFs within the Iron Quadrangle in Brazil – one of the world's largest reserves of iron ore.

While it is widely recognized that soil index properties impact critical state locus (CSL) parameters (Jefferies and Been, 2015), research linking tailings index properties to CSL parameters remains limited. Smith et. al. (2019), Torrez-Cruz and Santamarina (2020), Macedo and Vergaray (2022) and Hussien and Sgaoula (2023) are among the few related studies. Recently, an investigation targeting a unique commodity (iron ore) has been elaborated by the authors (Ccotohuanca et al., 2024).

This article aims to provide trends between CS parameters and iron ore tailings index properties (e.g., FC, D_{50}, C_u, G_s, etc.). An expanded database was compiled, including 40 iron ore tailings materials from Brazil and various global mining sites. This database, along with the correlations found, offers a valuable screening approach to discern whether laboratory results are within expected ranges, or if more detailed tests are required when assessing static liquefaction for iron ore TSFs.

Expanded iron ore tailings database

The expanded iron ore tailings database ("the IOD") consists of 40 iron ore tailings sources from several mines located throughout Brazil, Mexico, Australia, and China; 9 of them as part of this study and the rest from published literature as detailed in Table 1.

The IOD includes index properties along with CSL parameters, including: the slope on a natural logarithm base ($\lambda_e = \lambda_{10}/2.3$) and the altitude at 1 kPa (Γ), when the CSL is represented by a linear function using a semi-log idealization, $e_{cs} = \Gamma - \lambda_e \cdot \ln(p')$; and the a, b, and c coefficients, for a curved CSL represented by a power law function, $e_{cs} = a - b(p'/p_{atm})^c$. The IOD also includes the stress ratio at critical state (M_{tc}).

Table 1: Index properties and CS parameters of the expanded IOD

ID #	Index properties									Critical state parameters		Source

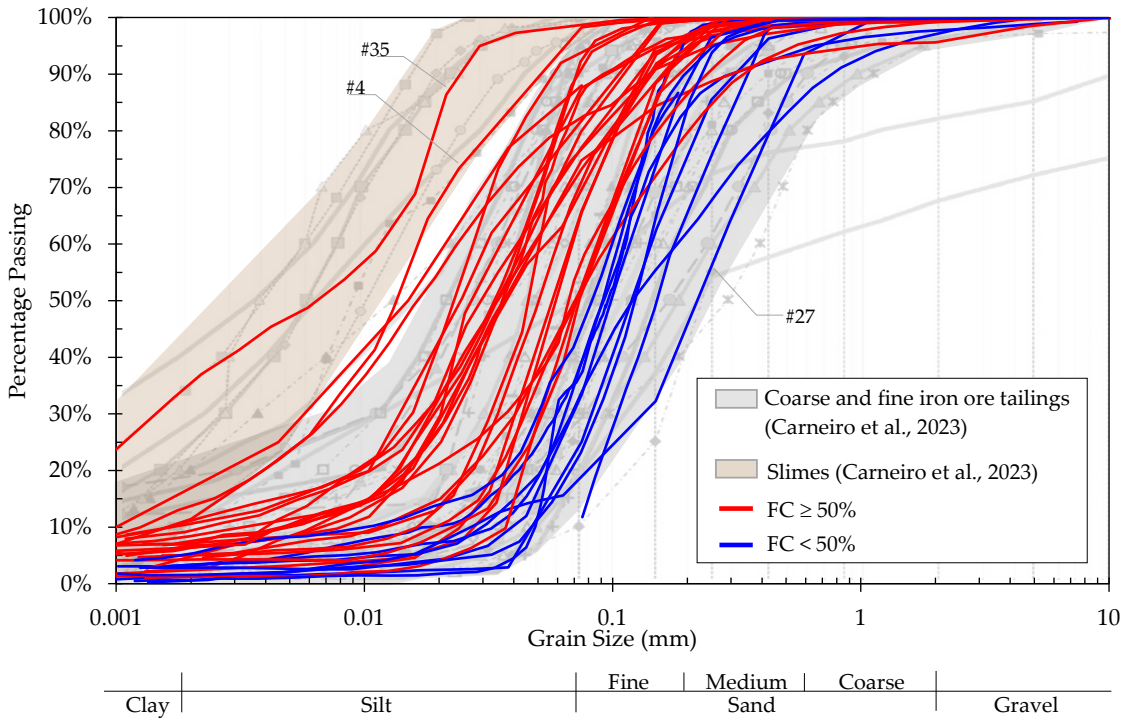
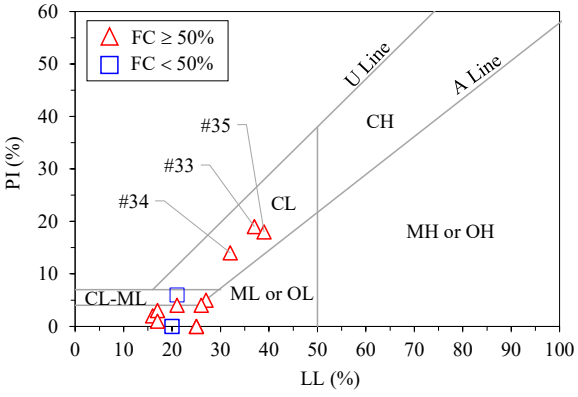
Notes:
1) NA: data not available, NP: Non-plastic, FC: Fines content, C_u: Coefficient of uniformity, D_{50}: Mean particle size, LL: Liquid limit, PI: Plasticity index, G_s: Specific gravity, Fe: Iron oxide content, e_{min}, e_{max}: minimum and maximum void ratio, A: Angular, SA: Subangular, M_{tc}: Stress ratio at critical state.
2) Tailings 10 to 13 represent results from the Fundão and Brumadinho tailings failures.
3) Tailings 14 to 17 and 36 to 39 are results from filtered tailings samples.
4) $a, b,$ and c parameters are reported in cases where CSL fits a curve, while Γ and λ_e are reported for the conventional linear approach.
5) Tailings 35 exhibited two CSL values depending on the sample preparation method (slurry deposition and moist tamping). The results obtained through moist tamping were selected for inclusion in the database.

Figure 1a illustrates the particle size distribution (PSD) of the IOD database, categorized based on their FC (% passing the #200 sieve) into two groups: those with FC higher ("fine tailings") and lower ("coarse tailings") than 50%. A comparison is drawn with the PSDs of iron ore tailings from the Iron Quadrangle (in Brazil), as compiled by Carneiro et al. (2023). The PSDs of the IOD fall within the "coarse and fine" range (grey area) of the referenced study, with two samples (#4 and #35) falling within the "slimes" range (brown area). Overall, the IOD exhibits a wide range of fine content (FC = 11.8 – 98.7%) and particle diameter (D_{50} = 6.5 – 231.7 μm).



While the majority of IOD samples are typically classified as non-plastic, the iron ore tailings exhibiting plasticity were plotted in the Casagrande plasticity chart (Figure 1b). Samples #33, #34, and #35 demonstrated the highest plasticity, while the remainder exhibited a PI of less than 6%.

Given the distinctive characteristics of iron ore tailings, notably the high G_s values, a dataset comprising the percentage of iron oxide (% hematite) alongside their corresponding G_s values, which ranges from 2.78 to 5.01, was assembled. These data are visualized in Figure 1c, revealing a strong correlation, even when incorporating literature data from Espósito (2000) and Lopes (2000).



The particle shape was assessed using Scanning Electron Microscopy (SEM) images. Most of the IOD tailings exhibit an angular-subangular (A-SA) shape, regardless of the FC. Examples of typical SEM images for different FC are depicted in Figure 1d.

Figure 2a shows the distribution of the CSLs for the expanded IOD plotted over the tailings database by Macedo and Vergaray (2022) (in grey). Overall, the CSLs from the IOD align with those observed in the referenced study. The CSLs cover a broad spectrum in the e versus p' plane, the difference in e for a given p' is on the order of 0.4. Half of the CSLs follow a linear relationship (in a semi-log plot). The CSLs from samples #4 and #14 / #40 form the upper and lower boundaries for the IOD.

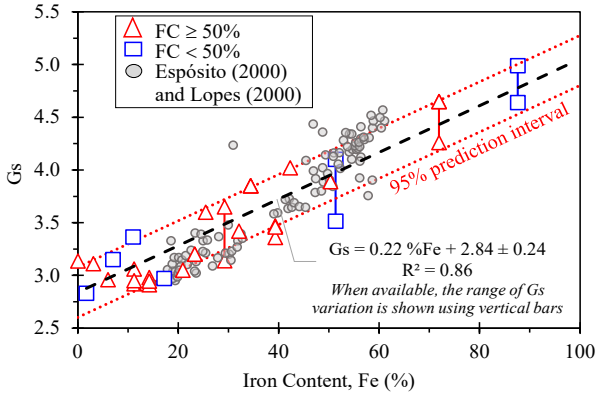


Figure 2b shows a histogram of the M_tc values for sands (from Jefferies and Been, 2015), various types of tailings (from Macedo and Vergaray, 2022), and those pertaining to the IOD. The M_tc values for mine tailings, including those of the IOD, are generally higher compared to sands. For the IOD, this parameter spans from 1.10 to 1.49, with a mean value of 1.36.

Evaluation of trends and discussion of the results

A review of trends and correlations between CS parameters (Γ, λ_e and M_{tc}) and index properties was conducted. To investigate the influence of the PSD, three key material characteristics (D_{50}, FC and C_u) were evaluated. Plasticity was assessed via Atterberg limits (PI and LL), material state through void ratio (e_{min} and e_{max}), and mineralogy by considering the iron oxide (%Fe) content.

For the "curved" CSLs with minimal curvature, a void ratio deviation of less than 0.02 over the stress range of p' = 30 – 900kPa, which typically encompasses the range of interest for most geotechnical TSF projects, a common semi-logarithmic representation was adopted for comparison purposes.

Figure 3 displays a series of charts illustrating acceptable trends observed in the comparison between CSL and soil index parameters. When available, data from the literature on other tailings and/or natural soils have also been incorporated into these figures for comparison.

(a) (b) (c)

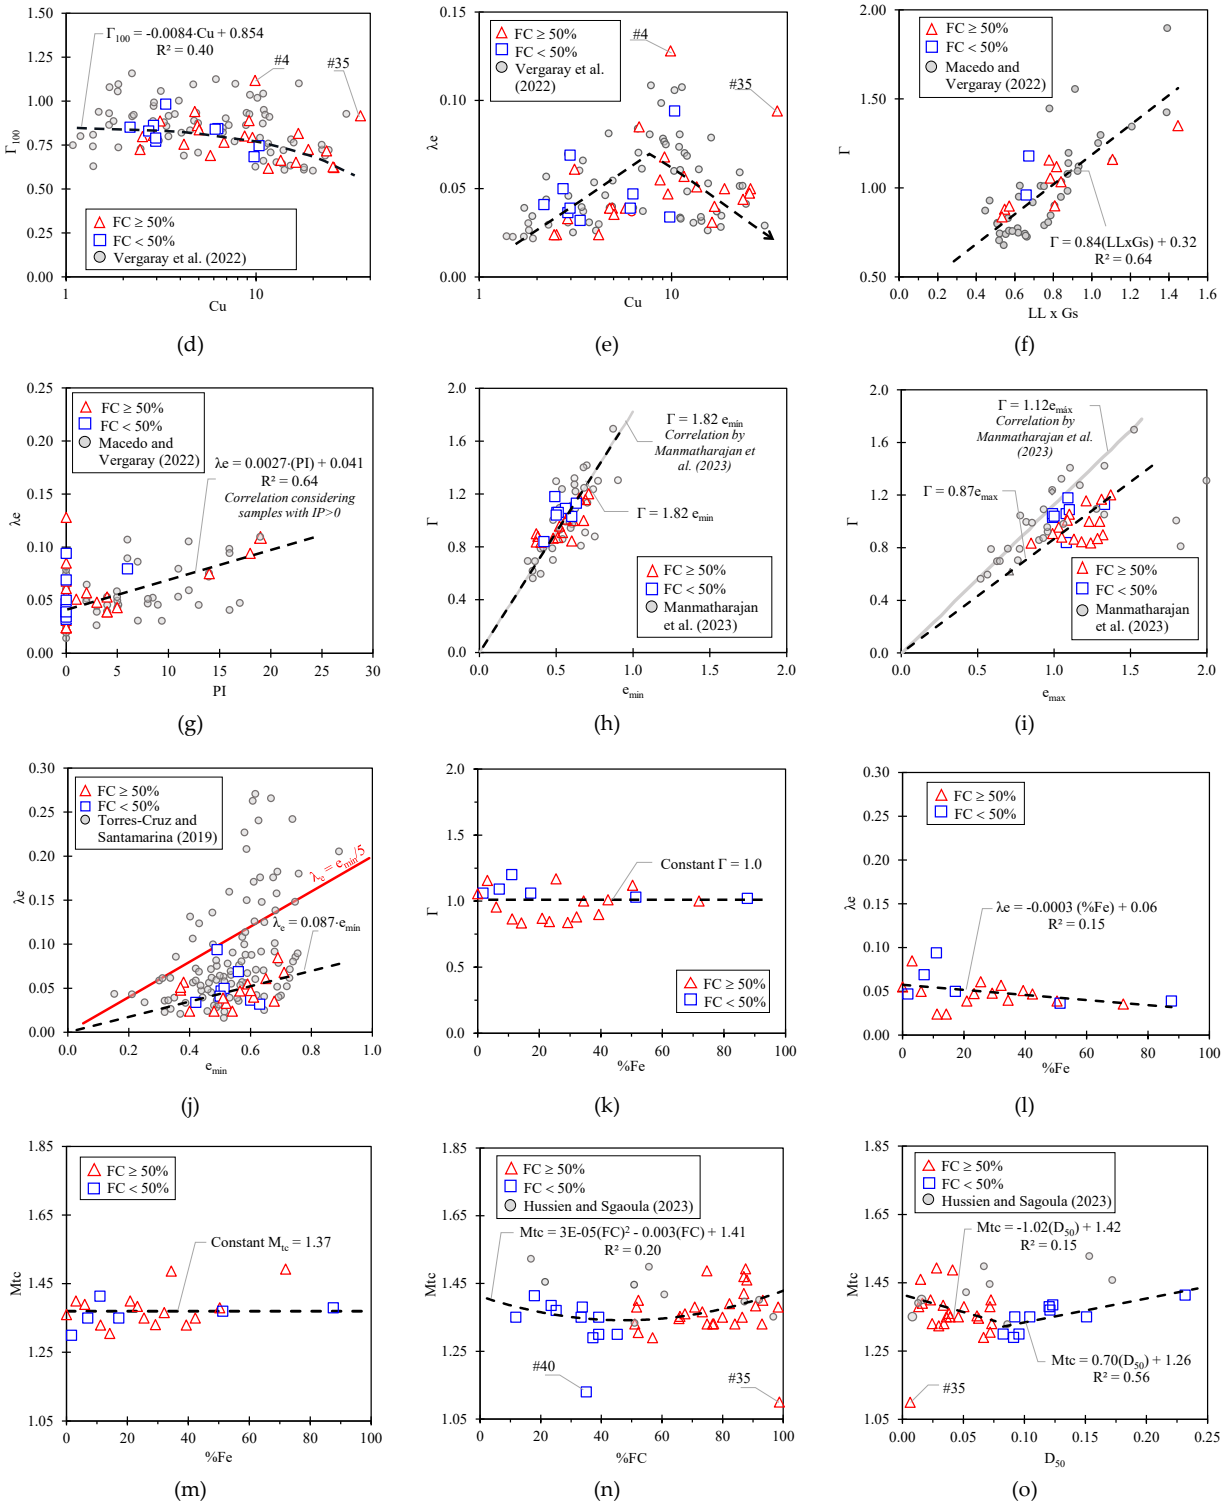

Figure 3: Evaluation of trends and correlations for the expanded IOD

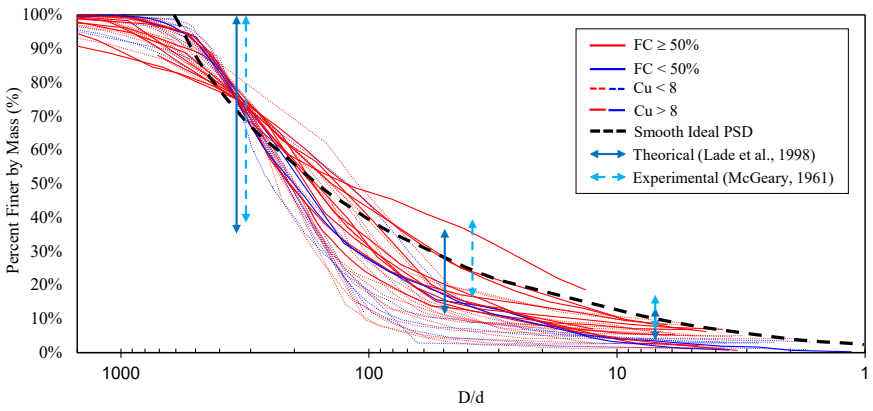

Figure 4: Normalized PSD of the IOD to evaluate particle packing according to the theories of Lade et al. (1998) and McGeary (1961)

Based on the figures, the following can be highlighted:

- Both Γ and λ_e exhibit a low to moderate correlation with FC (Figures 3a, 3b), with Γ decreasing as FC increases until it reaches approximately 50% of FC, after which this trend reverses. This pattern is consistent with findings from published studies, such as Thevanayagam et al. (2002), Carrera et al. (2011), Smith et al. (2019), Macedo and Vergaray (2022) (also represented in the figures), and Manmatharajan et al. (2023). The U-shaped trend can be attributed to the behavior of finer particles filling the voids: below 50% FC, the tailings are dominated by a sand skeleton, while above 50%, contacts are primarily influenced by silt and clay-sized particles. At around 50% FC, the finer fraction filling the voids contributes to the load-carrying skeleton, resulting in a less compressible material (i.e., lower λ_e).
- D_{50} exhibits a moderate relationship with λ_{10} (Figure 3c) and Γ (not depicted here). The trend follows a V-shaped curvature, with λ_{10} sharply decreasing as D_{50} increases until reaching approximately 0.075 mm. Beyond this point, the trend reverses, showing a smooth positive linear relationship. The results are compatible with Hussien and Sgaoula (2023), also plotted in Figure 3c.
- Figure 3d depicts the impact of material grading (using C_u as a proxy) on Γ, presented in an alternative form as Γ_{100} (i.e., the altitude of the CSL at 100kPa) as proposed by Torrez-Cruz and Santamarina (2019). The observed linear trend suggests a decrease in Γ as C_u increases. The IOD values fall within the range of results from other tests on different types of tailings and sands with lower roundness (as compiled by Macedo and Vergaray, 2022) (plotted in grey), typically characterizing the tailings of the IOD (see Figure 1d).
- Figure 3e shows λ_e in terms of C_u. It is noted that λ_e tends to increase with C_u up to values on the order of 6-8 and then decreases as C_u keeps increasing following a similar trend as showed in Macedo and Vergaray (2022). This observation suggests an enhanced particle packing with high C_u,

consistent with classical criteria for classification of "well-graded" sand by the Unified Soil Classification System (USCS), which states that a more densely packed arrangement of particles can be achieved when C_u is greater than 6 and C_c (coefficient of curvature) is between 1 and 3.

- The trends observed in Figure 3d and 3e can also be interpreted considering the ranges for PSD curves that promote optimal packing, as proposed by Lade et al. (1998) and McGeary (1961) and shown in Figure 4. When examining normalized PSD curves (normalized by D_{75}, the size at which 75% of particles are finer) for the IOD, it is evident that the PSD curves with $C_u > 8$ match the ranges of optimal particle packing indicated by the aforementioned authors. This supports the potential use of C_u as an acceptable proxy for interpreting and understanding the CSL position. Of note, a similar result was observed in a database for several tailings presented by Vergaray et al. (2022).
- While the available data on iron ore tailings with Atterberg limits are limited, the available results suggest a good linear correlation between Γ and LL when normalized by specific gravity $LL{\times}Gs$ (see Figure 3f), a trend also observed by Macedo and Vergaray (2022) and Smith et al. (2019). This correlation aligns with concepts from the CSSM framework, as outlined by Schofield and Wroth (1968). Similarly, a strong linear correlation was observed between PI and λ_e (see Figure 3g). This outcome is expected, given that both parameters serve as proxies for compressibility, in line with CSSM-based concepts. Furthermore, this is consistent with using PI (as an indicator for compressibility) in fine-grained plastic soils for analyzing liquefaction susceptibility, as proposed in the methodology of Bray and Sancio (2006).
- The spatial variability of e_{min} within a tailings deposit anticipates spatial variability of Γ, given the good correlation between these parameters (see Figure 3h). This correlation extends to other datasets of natural soils and various types of tailings (from Manmatharajan et al., 2023), as also depicted in grey in Figure 3h. Similarly, a good linear trend was observed between e_{max} and Γ (see Figure 3i). However, the slope of the linear regression for iron ore tailings is lower compared to tailings from other commodities or natural soil. It appears that iron ore tailings tend to exhibit lower Γ values than other materials for a given e_{max}.
- The range of possible λ_e values increase with e_{min} (see Figure 3j). Overall, the expected λ_e values are lower than $e_{min}/5$. The data from IOD falls within the range of most of other quartz-rich tailings (plotted in grey) based on the Torrez-Cruz and Santamarina (2020) database.
- Figures 3k, 3l and 3m suggest that the iron oxide content (% hematite) does not exert a significant influence on λ_e, Γ or M_{tc}, with only a weak linear trend observed for λ_e.
- Broader investigations by Torres-Cruz and Santamarina (2020), encompassing soils beyond tailings, suggest that the primary factor influencing M_{tc} is neither mineralogy nor particle size, but particle

shape. While this study finds no significant variation in particle shape among the examined iron ore tailings (mainly angular to subangular), a wide range of M_{tc} values was observed within the IOD. Upon examining M_{tc} values alongside index properties, it was observed that, despite weak to moderate correlations, there may be a potential influence of FC (Figure 3n) and D_{50} (Figure 3o). These trends exhibit similar U-shaped patterns as seen in Figures 3a to 3c.

- Caution is advised when analyzing very fine iron ore tailings (slimes) (refer to Figure 1a). In certain instances, such as with samples #4 and #35 in Figures 3d, 3e, the results for these samples are outliers when compared to other "Fine and Coarse" iron ore tailings.

Conclusion

In this article, we compared CSL parameters inferred from laboratory testing of iron ore mine tailings gathered from mine sites in Brazil and globally with their laboratory index properties. Our aim was to establish correlations between basic iron ore tailings data and CSL parameters. A database, expanded from an initial 26 sources to a total of 40 iron ore tailings sources, was collected.

Upon analyzing the results, we confirmed previously observed conclusions with a smaller IOD dataset. First, the trends observed using an extended iron ore tailings database did not show significantly different behavior from other types of tailings. This is evident when examining correlations with index properties such as FC, D_{50}, C_u, plasticity, and void ratio, which displayed a greater potential to influence CSL parameters compared to correlations with iron oxide ($\%Fe$) content. This suggests that inferences about tailings behavior made from other types of tailings can be reasonably adopted. Second, when particle shape remains consistent (angular to subangular particles in this study), as observed for the expanded IOD, certain index parameters such as FC and D_{50} may exert a slight influence on M_{tc} values.

Enhancing Tailings Dam Foundation Assessment: a SHANSEP Approach for a Brazilian Alluvium Soil

Carlos Besso, Worley Consulting, Australia
Sergio Capellão, Geocoba Projetos de Engenharia, Brazil

Rodrigo Marinaro, Vale, Brazil

Abstract

This paper outlines the rational methodology applied to validate the undrained parameters for the foundation alluvium layer of an existing tailings dam, providing adequate input for slope stability analysis. A comprehensive in-situ and laboratory investigation survey revealed high coarse fraction content, partial drainage effects, slight over-consolidation, and a non-linear trend in the undrained strength ratio plot, leading to the need to define a linear intercept to properly design the undrained shear strength envelope. It is concluded that the continued use of advanced testing methodologies and SHANSEP principles is crucial for accurately assessing the slope stability of tailings dam foundations under similar geological contexts in Brazil, rather than relying on empirical correlations through standard penetration tests (SPTs).

Introduction

To comply with the new Brazilian national legislation ANM 2022, the geotechnical stability of an existing tailings dam was reassessed under undrained loading conditions for long-term scenarios. The dam's foundation comprises a clayey alluvium stratum among other layers, prompting a comprehensive site and laboratory investigations to enhance the understanding of the alluvium geomechanical behavior, especially regarding its physical properties, undrained shear strength, stress history, and drainage conditions for dissipating excess pore-water pressures.

The survey encompassed boreholes (including new SPT, rotary drilling, and undisturbed Shelby sampling), vane shear tests, piezocone tests, characterization tests, consolidation tests, and triaxial tests. The results revealed four main aspects: a high degree of coarse fraction content; a marked partial drainage effect; a slightly over-consolidated behavior; and a non-linear trend in the undrained strength ratio plot. These findings led to the usage of a linear-intercept approach to obtain more realistic undrained parameters.

This paper outlines the rational methodology applied to validate the undrained parameters for the foundation alluvium layer of an existing tailings dam, providing adequate input for slope stability analysis. It is noteworthy that, even by applying the undrained envelope with a linear intercept, the factors of safety for undrained loadings remained lower than those for drained loadings, which aligns with good engineering practice as recommended by international guidelines (e.g., ANCOLD 2019).

Characterization tests

The index properties of the material are presented in Figure 1 and Table 1. The particle size distribution results indicate that the coarse fraction content varies from 24 to 62% (including a significant gravel content), and the fine fraction content ranges from 28 to 76%. This finding suggests a high degree of heterogeneity in the alluvium material, leading to coefficients of consolidation and shear strengths that are not representative of a typical soft clay deposit, as discussed in the following sections.

Furthermore, the material exhibits medium plasticity, with a mean plasticity index (PI) of 11%, and a colloidal inactivity ($A_c < 0.75$), indicating that true cohesion is not expected, as discussed by Skempton (1953). Specific gravity values close to and above 3.0 were observed, suggesting that the mineralogy may contain oxides that could contribute to a certain degree of cementation, which could also lead to true cohesion (Leroueil and Vaughan, 1990). However, this was discounted as manual handling of the material demonstrated friable behavior.

Finally, the USCS classification (ASTM 2017) encompasses silt (ML), elastic silt (MH), clayey sand (SC), silty sand (SM), and lean clay (CL), reflecting the material's heterogeneity.

Table 1: Index properties

Sample	Gs	Atterberg Limits (%)			Granulometry (%)				A_c	USCS

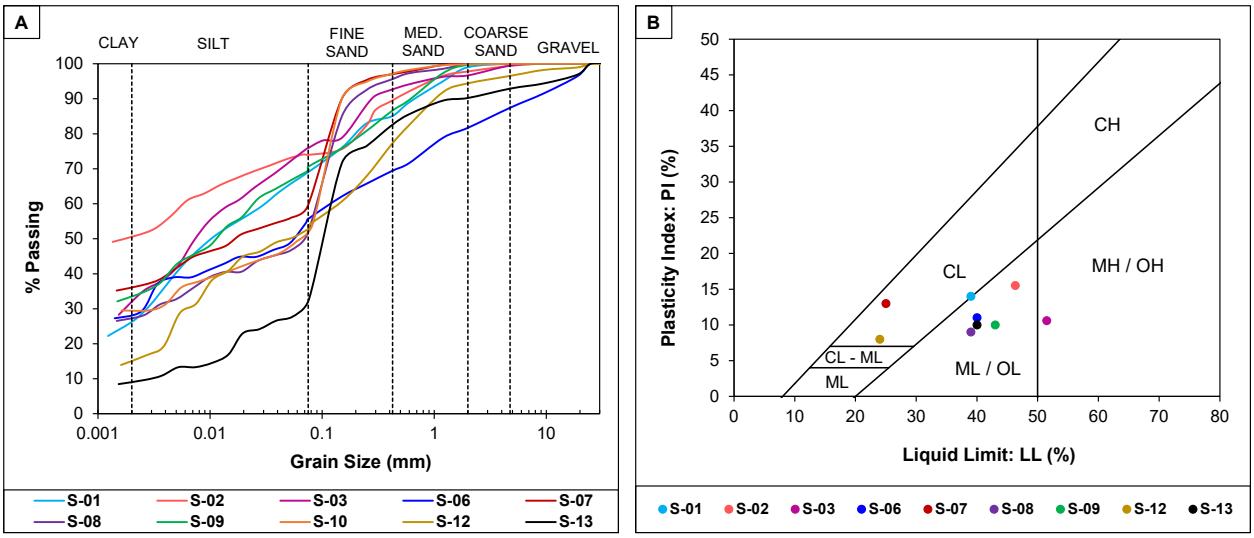

Figure 1: (A) Particle size distribution; (B) plasticity chart

Standard penetration tests (SPT)

A total of 14 SPT were conducted in the alluvium layer throughout the dam's life period. Figure 2 presents the N_{SPT} frequency histogram and profile, indicating that the values range primarily from 0 to 8 blows, with a mean value of 4, stating a low SPT resistance for the material.

This finding suggests that the alluvium may comprise a typical soft clay deposit, as the low N_{SPT} blows reflect the values obtained from Brazilian marine sedimentary deposits of soft clays (Massad, 2009). However, as discussed in the following sections, typical undrained strength parameters estimated based on SPT correlations provide overly conservative results when compared to in-situ and laboratory shearing test.

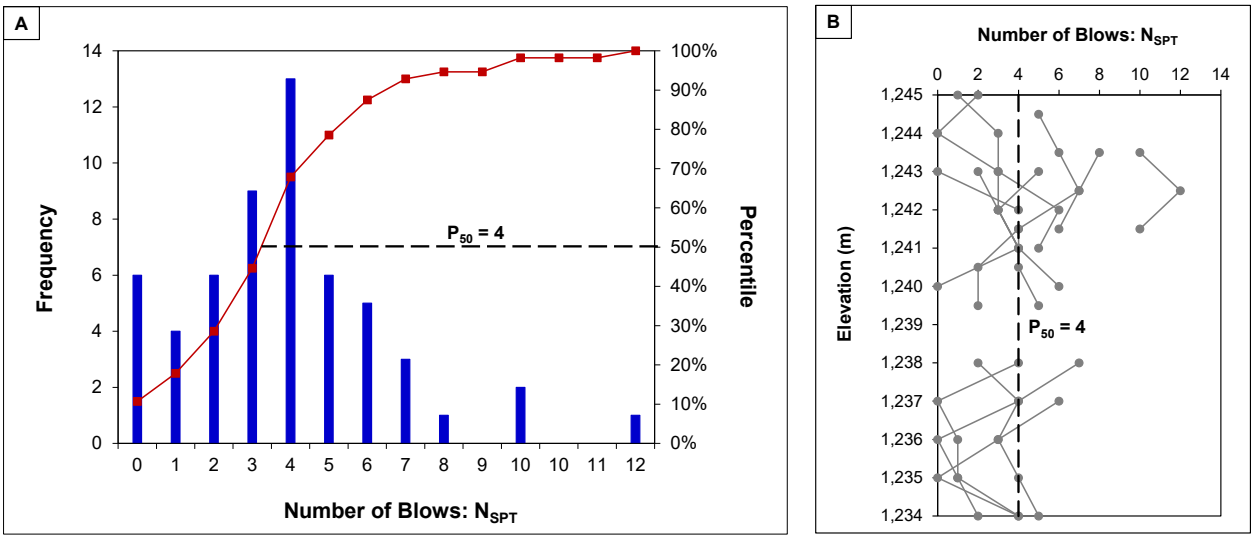

Figure 2: (A) N_{SPT} frequency histogram; (B) N_{SPT} profile

Consolidation tests

Figure 3A and Table 2 present the overall results of the oedometer consolidation tests. The coefficients of consolidation (c_v) were obtained using both Taylor (t_{50}) and Casagrande (t_{90}) methods, yielding an average value circa 10^{-2} cm²/s. Such value is found to be relatively high when compared to typical values of 10^{-4} cm²/s for traditional Brazilian marine sedimentary deposits of soft clays (Massad, 2009), likely due to the high coarse fraction content.

Similarly, the average compression index (C_c) was found to be 0.55, indicating low compressibility compared to typical values of C_c exceeding 1.0 for typical Brazilian deposits of compressible soft clays (Massad, 2009). The low compressibility is also assigned as a result of the high coarse fraction content.

Over-consolidation stresses, determined using the Pacheco Silva method, revealed over-consolidation ratios (OCR) ranging from 1.0 to 1.6, suggesting the presence of slightly over-consolidated regions within the alluvium layer. This finding supports the SHANSEP approach for the undrained shear strength envelope based on an over-consolidation stress of 400 kPa, as discussed in the following sections.

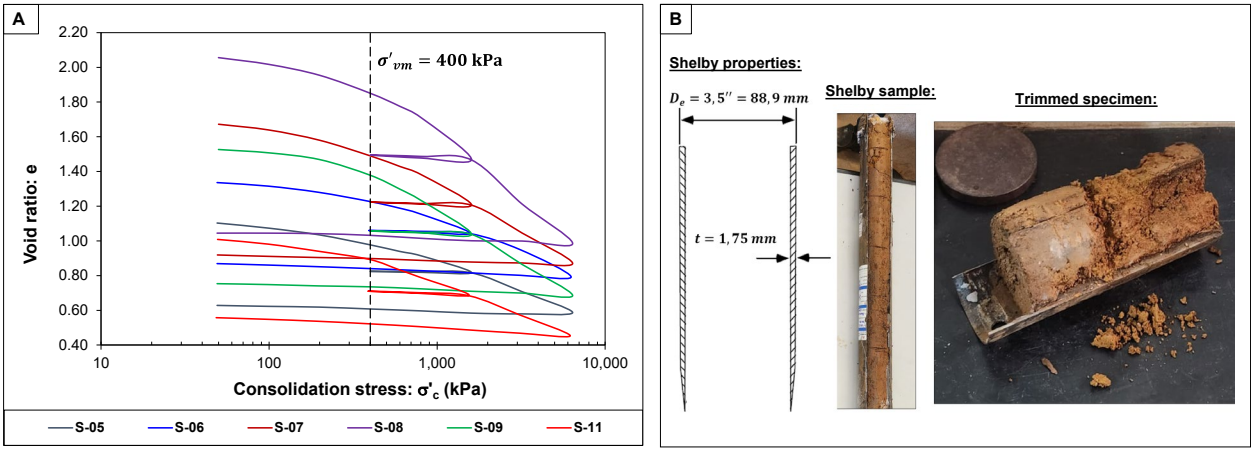

Figure 3: (A) Consolidation tests results; (B) specimen preparation

Regarding the reliability of the laboratory test results (both consolidation and triaxial), this study aimed to achieve state-of-the-art standards for obtaining undisturbed laboratory specimens. Shelby tubes with 88.9 mm (3.5 pol) diameter and 1.75 mm thickness were used for in-situ sampling, resulting in an area ratio (Ra) of 8.4%, as recommended by Clayton et al. (1998). However, the procedures outlined by Ladd and DeGroot (2004) could not be applied due to the high degree of friability during manual handling of the material, as illustrated in Figure 3B. Additionally, the gravel content obstructed cutting and trimming both the Shelby tubes and specimens with a wire saw.

Nonetheless, the obtained sample disturbance quality index ranged from good to fair, to poor according to the criteria of Lunne et al. (1997) and Coutinho et al. (1998), as presented in Table 3. Given the challenges faced during specimen preparation, the samples were ultimately considered acceptable.

Table 2: Consolidation tests results

Sample	Over-consolidation stress σ'_{vm} (kPa)	Over-consolidation ratio OCR	Coefficient of consolidation c_v (cm²/s)	Permeability k (cm/s)	Constrained modulus E_{oed} (MPa)	Compression index C_c (1/kPa)	Quality index $\Delta e/e_0$

		Very good to Excellent	Good to Fair	Poor	Very Poor
Coutinho et al. 1998	1 – 2.5	< 0.05	0.05 – 0.08	0.08 – 0.14	> 0.14
Lunne et al. 1997	1 – 2.0	< 0.04	0.04 – 0.07	0.07 – 0.14	> 0.14

Vane shear tests

A set of 4 in-situ vane shear tests (VST) were carried out in the alluvium, and the results are presented in Figure 4A. In accordance with the Brazilian national standard ABNT NBR 10905, a rotation rate of 6 degrees per minute was applied for the VST. Regarding shearing-rate corrections (Bjerrum, 1973; Morris and Williams, 1994), the medium plasticity resulted in correction factors higher than 1.0. Following a conservative approach, these corrections were not applied.

VST-01 was the sole test performed under undisturbed condition, while VST-02, VST-03 and VST-04 were conducted under remolded conditions, i.e., after 10 complete rotations of the vane. The sensitivity index (S_t) was conservatively defined by the lowest remolded strength (VST-02), resulting in a S_t value of 2.3, falling under the normal sensitivity classification according to the criteria of Skempton and Northey (1952).

Notably, partial drainage effects are suggestive when observing the drainage boundaries that indicate exceedance of 10% of porewater pressure dissipation. All the tests failed after the Blight/Chandler drainage boundary, suggesting that fully undrained strength was not mobilized. However, using the Morris and Williams drainage boundary, the undisturbed test VST-01 appears to have fully mobilized undrained

strength at failure, and thus this sole test is herein validated for peak undrained strength assessment. Further discussion on partial drainage effects will be presented in the following sections.

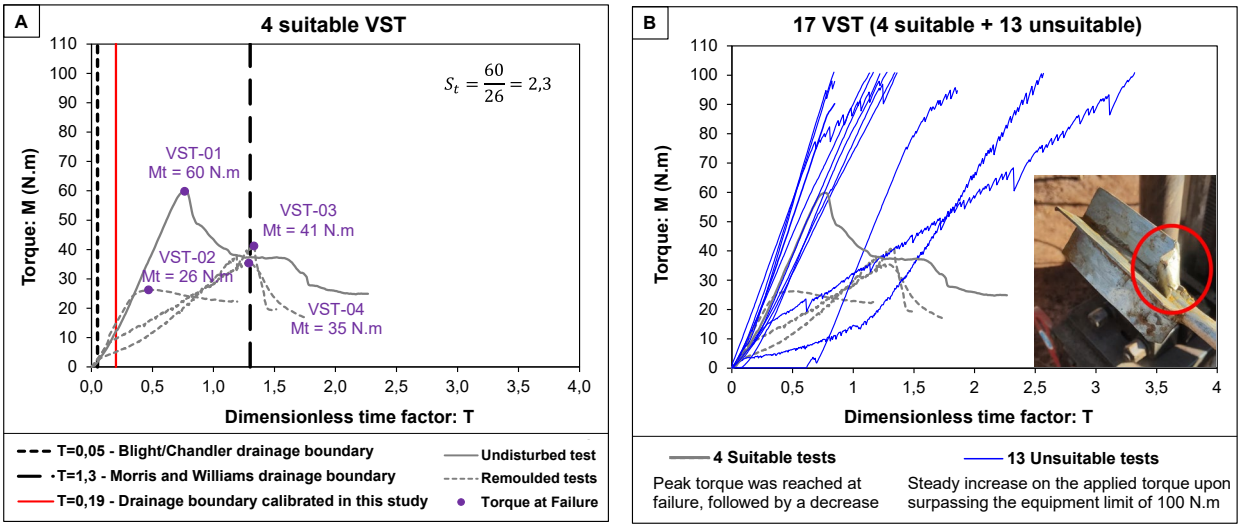

Figure 4: (A) 4 suitable vane shear tests; (B) all 17 vane shear tests

Figure 4B presents the attempts to conduct a set of 13 vane shear tests (blue contours), which were deemed unsuitable due to a steady increase in applied torque, leading to termination of the tests upon surpassing the equipment reading limit of 100 Nm. Additionally, 5 attempts to perform VST were unfeasible because torque application was impeded (possibly due to the presence of gravels, as suggested by the material's high coarse fraction content), resulting in damage to the blade, as shown in Figure 4B.

Piezocone tests

A set of 3 piezocone tests (CPTu) were carried out at 3 different locations on the dam's alluvial layer, with CPTu-01 and CPTu-02 positioned in the same section but on different embankment benches. The test results generally indicated normally consolidated (contractive) clay behavior, characterized by low tip resistances (q_t lower than 2 MPa) and high penetration pore pressures (B_q higher than 0.1). However, an exception was observed between elevations 1,242 and approximately 1,240 m, as outlined by the yellow box in Figure 5, where high tip resistances along with negative penetration pore pressures were recorded, suggesting a dilative behavior. Notably, the highest OCR values were obtained from samples S-07 and S-08, collected at elevations 1,242 and 1,241 m, respectively, near CPTu-02 borehole, corroborating the assumption of a dilative/over-consolidated region within the foundation alluvial stratum.

Results indicating contractive clay-like behavior were exclusively included in the undrained strength assessment, as shown in Figure 6B (Robertson, 2016), as high strength values within dilative zones were

disregarded. The undrained strengths were calculated using the Lunne et al. (1997) correlation, where a cone factor of N_{kt} = 14 was calibrated (Figure 6A) based on the sole vane shear test result on the undisturbed condition (VST-01), along with the net tip resistance (q_{net}) from CPTu-01 at the depth where VST-01 was conducted, as these tests were carried out at the same location with boreholes 2 m apart.

However, due to uncertainties on the drainage conditions of VST-01 and given that 13 VST surpassed the equipment reading limit, the N_{kt} was decreased to 12 to derive the S_u profile presented in Figure 5.

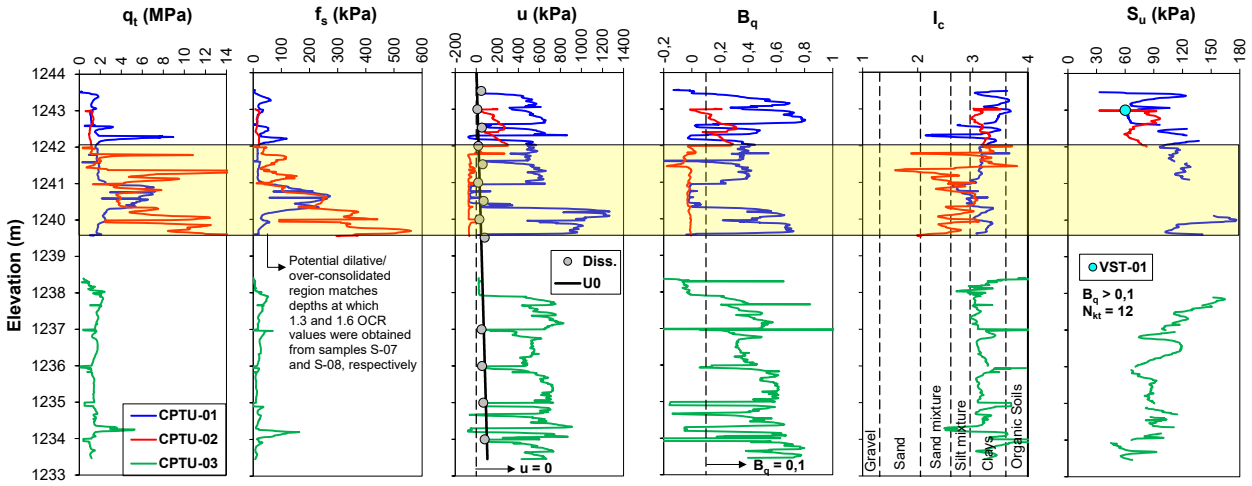

Figure 5: Piezocone tests results and interpretations

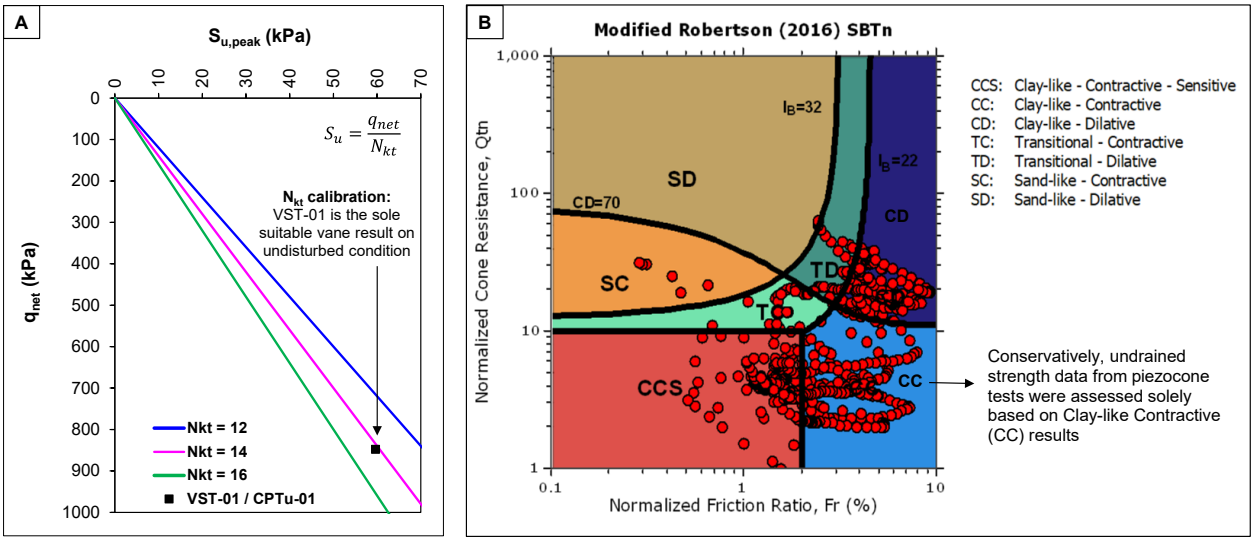

Figure 6: (A) N_{kt} calibration and sensitivity; (B) Modified soil behavior type (SBTn) chart

It is noteworthy that the hydrostatic pore-pressure profile (U0) obtained from dissipation test results was cross-verified with readings from piezometers installed near the CPTu boreholes on the same day the piezocone tests were conducted. The results showed a maximum difference of only a few dozen centimeters.

Additionally, a thorough protocol was followed to ensure the saturation of the porous stone, involving glycerin storage and subsequent rubber wrapping prior to ground penetration onset. This validation process confirmed the accuracy of the pore-pressure measurements from the piezocone tests, ensuring that the negative pore pressures observed within the dilative region were not due to cavitation effects. Finally, apparent cohesion from suction was ruled out since the material is confirmed to be saturated.

Partial drainage assessment

As shown in Figure 7A, a mean coefficient of consolidation ($c_v = 0.05$ cm^2/s) was derived from both consolidation and CPTu dissipation tests, corresponding to typical silt values (Duncan et al., 2014). Furthermore, VST results indicated partial drainage effects, as all tests fail after the Blight/Chandler drainage boundary. However, using the Morris and Williams drainage boundary, 4 VST (1 undisturbed and 3 remolded) appear to have mobilized fully undrained strength at failure, and thus these 4 tests were deemed valid for the drainage assessment. Moreover, CPTu dissipation test results indicated that 6 out of 10 tests indicate partial drainage behavior according to the DeJong and Randolph boundary, as shown in Figure 8B.

To enhance the understanding of partial drainage effects and undrained strength mobilization, further analyses were conducted. Firstly, general drainage conditions were assessed following the methodology proposed by France et al. (2015), as illustrated in Figure 7B. Considering the alluvium layer's 4-meter thickness and drainage at both the bottom and top interfaces, partial drainage is expected to occur under a rapid loading scenario applied over a hypothetical time of 1 day.

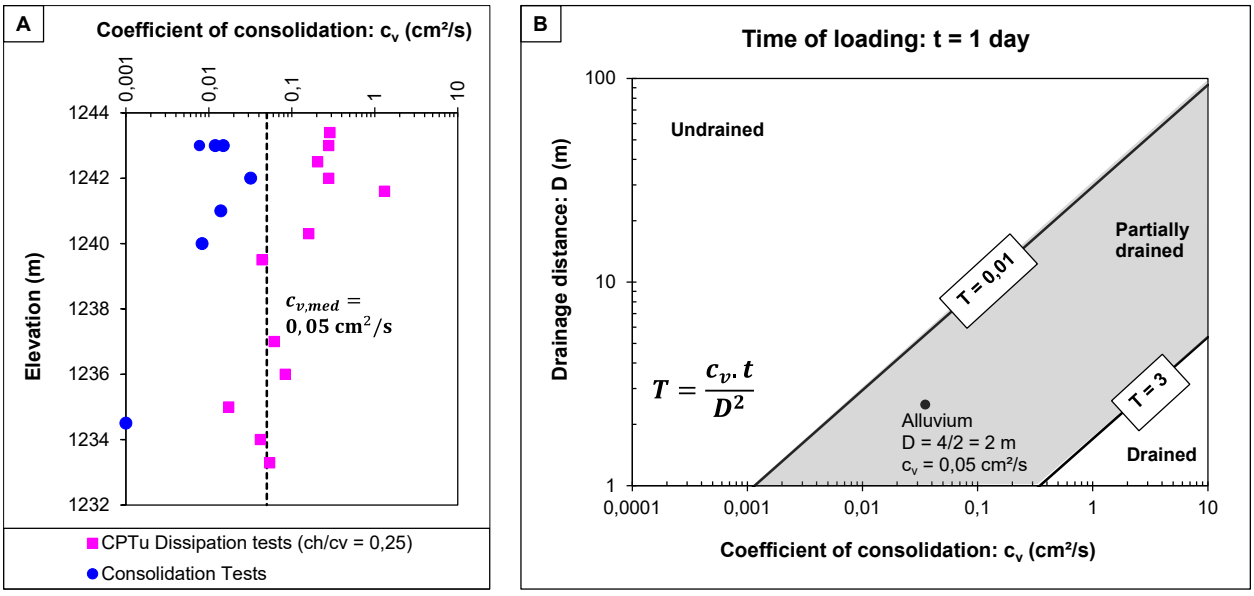

Figure 7: (A) Coefficient of consolidation mean value; (B) general drainage assessment

Further analyses encompassed calibrating the characteristic drainage curves for both vane shear and dissipation tests, as shown in Figures 8A and 8B, respectively. The theoretical curves were obtained using the methodologies of Morris and Williams (2000) for vane shear tests, and both Teh and Houlsby (1991) and DeJong and Randolph (2012) for dissipation tests. According to Morris and Williams (2000), fully undrained conditions occur until 10% of degree of drainage (U), and fully drained conditions occur after 90%. Based on this criterion, it was observed that 1 out of 14 tests (including both vane shear and dissipation tests) indicated fully undrained behavior, while the remaining 13 tests show partially drained behavior.

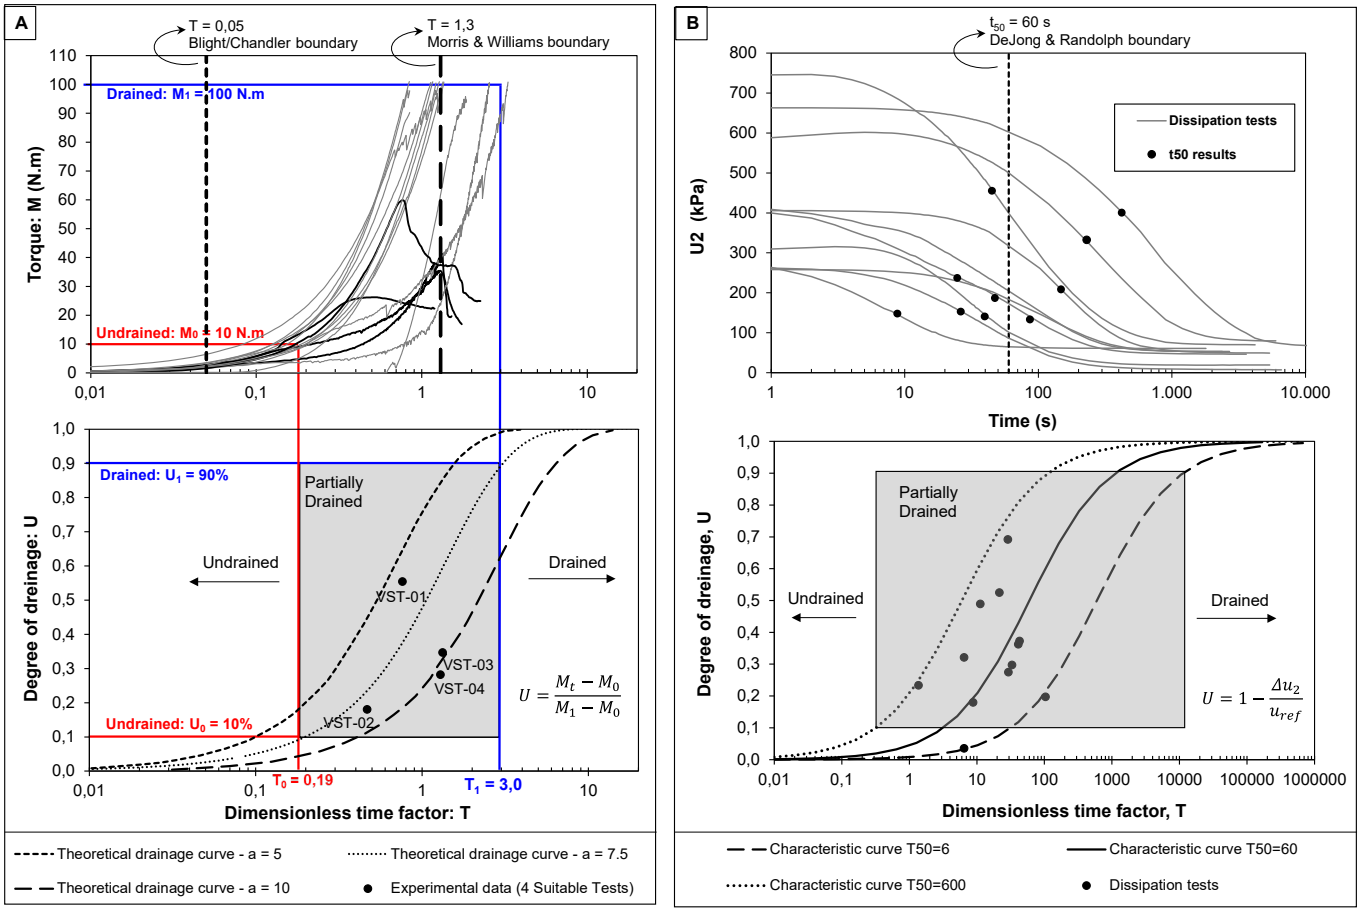

Figure 8: (A) Partial drainage in vane shear tests; (B) partial drainage in CPTu dissipation tests

Triaxial tests

A series of 11 saturated and isotopically consolidated undrained triaxial (TX-CIU) tests were carried out at confining pressures of 50, 100, 200, 400, and 600 kPa, as shown in Figure 9.

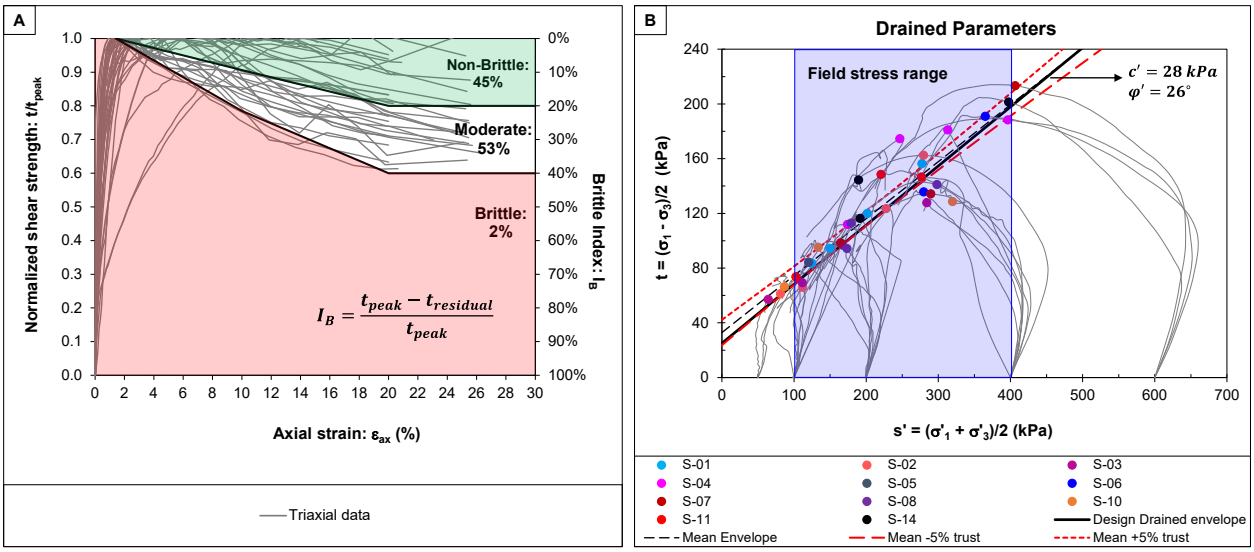

Figure 9: (A) Brittleness assessment; (B) definition of drained parameters

As illustrated in Figure 9A, the results demonstrated non to moderate brittleness, according to the criteria of Bishop (1967). Furthermore, a predominantly contractive behavior was observed, characterized by the A pore-pressure parameter ranging from 0.5 to 1.0, which classifies the material as normally consolidated clay according to the criteria of Skempton (1952). Exceptions were noted in some tests at a confining pressure of 600 kPa, where the A parameter ranged from 1.5 to 2.0, indicating a sensitive behavior per Skempton (1952). These findings highlight the need to define undrained strength parameters for the alluvium, which will be discussed in the next section.

Regarding the drained parameters, the Mohr-Coulomb criteria was assessed by the usage of maximum deviatoric stress criterion. Following the Eurocode (2007) guidelines, the drained strength envelope was designed within the field stress range, fitting the mean envelope minus 5% of the confidence interval with a t-Student value of 2.037, as illustrated in Figure 9B.

SHANSEP approach

Due to the observed dilative/over-consolidated behavior in some piezocone and consolidation tests, a SHANSEP approach was evaluated following the Ladd and Foot (1974) methodology. As shown in Figure 10A, applying an over-consolidation stress of 400 kPa revealed a non-linear trend when plotting the undrained strengths against OCR values, thereby confirming the suitability of assessing SHANSEP principles to define the alluvium undrained strength parameters, as per Gallardo (2023a, 2023b, 2022).

However, given the variation in contractive/normally consolidated and dilative/over-consolidated behaviors, it was not possible to establish an OCR profile as required for a consistent SHANSEP approach

(Duncan et al., 2014). Hence, a conservative linear envelope was defined with an intercept aimed at modelling a single relationship across all test results, as illustrated in Figure 10B.

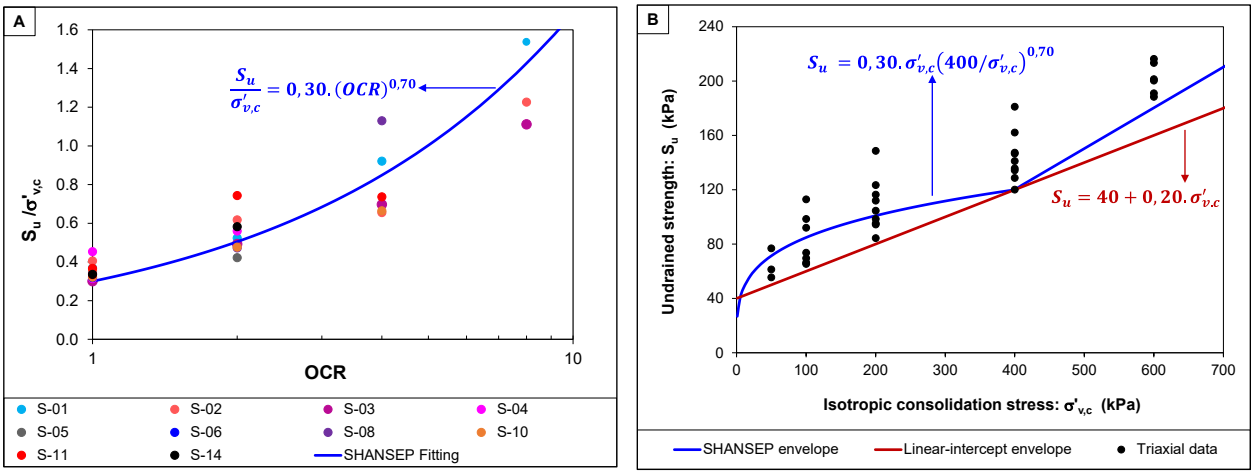

Figure 10: (A) Undrained strength ratio plot; (B) SHANSEP and linear-intercept envelopes

To define the design undrained envelope, the undrained strengths were plotted against the consolidation stresses, following Sadrekarimi and Olson (2011) and Jefferies and Been (2015). However, according to Duncan et al. (2014), undrained strengths obtained from TX-CIU tests may be unconservative due to effects of anisotropy, stress reorientation, and strain rate. The authors emphasize that such results require adjustment to be suitable for design purposes.

Therefore, a correction technique was applied to the isotropic vertical consolidation stress by introducing the anisotropic coefficient at rest (K_0), estimated using Jaky's (1944) correlation. As illustrated in Figure 11A, corrected anisotropic vertical consolidation stresses ($\sigma'_{v,0}$) 1.36 times the isotropic stresses (σ'_c) were obtained, conservatively resulting in lower slope tangent of the line. It is noteworthy that the adopted envelope was observed to fit the mean envelope minus 5% of the confidence interval with a t-Student value of 2.037 within the field stress range.

Finally, all in-situ and laboratory tests results for undrained strengths are plotted in Figure 11B, confirming that the adopted linear-intercept envelope ($S_u = 40 + 0.20\sigma'_v$) defined by triaxial tests also fairly fits the mean value of the S_u profile obtained with piezocone results based on $N_{kt} = 12$ (the CPTu-VST calibrated value of $N_{kt} = 14$ was reduced given the confirmed partial drainage observed in both tests).

Notably, Figure 11B outlines that the adopted envelope with a linear intercept of $S_u = 40$ kPa (solid contour) fits the overall results more accurately than the envelope with a cut-off of $S_{u,min} = 40$ kPa (dotted contour). In fact, the cut-off envelope, typically applied to normally consolidated material (e.g., obtained by empirical correlations through SPT results) proves to be an excessively conservative lower

boundary for the alluvium herein studied. Moreover, the upper boundary with an intercept of S_u = 80 kPa (dashed contour) states that the adopted linear intercept reflects the average trend across all tests results.

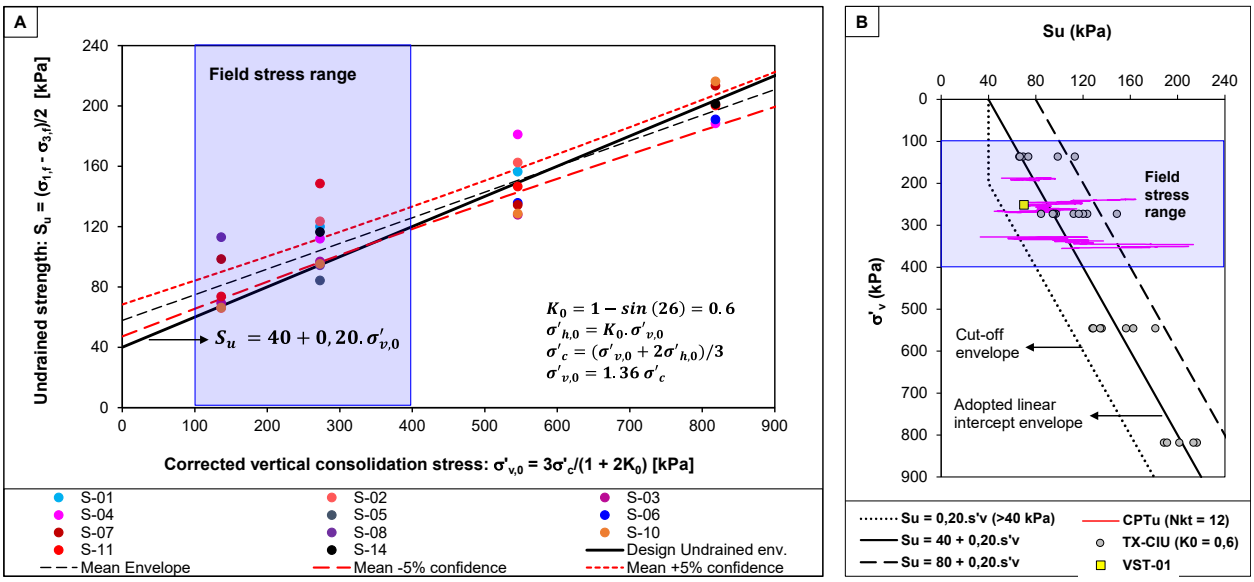

Figure 11: (A) Definition of undrained parameters; (B) in-situ and laboratory results

Conclusion

Comprehensive site and laboratory investigations on the alluvium layer of an existing tailings dam revealed significant high coarse fraction content, partial drainage effects, slightly over-consolidated behavior, and a non-linear trend in the undrained strength ratio plot. These findings led to the usage of a linear-intercept approach, resulting in more accurate undrained strength parameters and realistic factors of safety, which remained lower than those for drained conditions, aligning with established engineering guidelines.

Challenges in sampling and specimen preparation were found due to the high coarse fraction content and friability, though samples were deemed acceptable by established criteria. Vane shear and dissipation tests confirmed partial drainage behavior, suggesting that in-situ fully undrained shear strength mobilization is unlike to occur. Zones of dilative behavior in piezocone tests matched depths at which oedometer tests provided slight OCR values, indicating an over-consolidated region within the alluvial layer.

A certain degree of sensitiveness was found to the alluvium, according to sensitivity index (S_t) from vane shear test and some shear pore-pressure parameters (A) from undrained triaxial tests. Additionally, 53% of the triaxial results indicated moderate brittleness (I_B ranging from 20 to 40%), and low N_{SPT} values were observed. These findings underscore the need to define undrained strength parameters for the alluvial material, despite its in-situ partial drainage behavior and slight over-consolidated zones.

True or apparent cohesion was found to be negligible due to colloidal inactivity, friability (despite high specific gravity values suggesting potential cementation), and saturation confirmed by hydrostatic pore-pressure profile from dissipation tests and by readings from piezometers, ruling out suction effects.

A conservative linear undrained strength envelope was defined due to the inability to establish an OCR profile, given the alternation in over-consolidated/dilatant and normally consolidated/contractive behaviors. This envelope incorporates a linear intercept to model the undrained strengths obtained in all tests, ensuring consistency across the entire stratum, rather than discretizing sub-layers based on normal and over-consolidated behaviors. Additionally, a correction technique was applied to decrease the slope tangent of the obtained envelope, as TX-CIU tests typically yield unconservative undrained strength values.

The adopted linear-intercept envelope ($S_u = 40 + 0.20\sigma'_v$) exhibited greater consistency compared to the cut-off envelope ($S_u = 0.20\sigma'_v$ @ $S_u > 40$ kPa). While true cohesion is not expected for the alluvium, the high coarse fraction content, partial drainage effects, and slight over-consolidation necessitate defining a linear intercept to accurately determine the undrained strength parameters to be used in stability analysis.

Finally, it is concluded that the continued use of advanced testing methodologies and SHANSEP principles is crucial for accurately characterizing material properties to assess slope stability of tailings dam foundations under similar geological contexts in Brazil, rather than relying on empirical correlations, e.g., through SPT results.

Interpretation of Cyclic DSS Testing under Static Bias on Underflow Copper Tailings

Alfonso Cerna Diaz, AECOM, USA
Kevin Ritter, AECOM, USA
Jason Hilgers, AECOM, USA

Abstract

This paper summarizes the results of a cyclic DSS laboratory testing program that was completed to investigate the influence of static bias load reversal on the deformation mechanisms and strength loss of copper underflow tailings, using stress-controlled cyclic direct simple shear (DSS) testing.

The influence of static bias on cyclic induced permanent deformation was evaluated for a range of initial static shear stresses. For a given number of cycles, permanent deformations under static driving shear stresses were found to be dependent on the initial state parameter, the ratio between Initial Loading Stress Ratio (LSRo) and the Image Stress Ratio (ISR), which provides an index of strain potential.

Introduction

Methods to evaluate the effect of static bias on cyclic response primarily have focused on its role in liquefaction triggering in sloping ground (i.e., ground subjected to a static driving shear stress). Due to the limited number of well-documented case histories of liquefaction in sloping ground, the majority of these methods used extensive data from single element tests (e.g., cyDSS, cyTX) to extend the widely used cyclic stress approach (Idriss and Boulanger, 2008; Seed and Idriss, 1971; Whitman, 1985) that used only level-ground liquefaction case histories.

Although significant understanding was gained into the effects of static bias on the range of triggering criteria (e.g., ~3 percent shear strain), the induced post-liquefaction shear deformation processes under sloping ground conditions are still not well understood. If liquefaction is triggered in sloping ground, a post-triggering stability analysis is performed with the liquefied shear strength assigned to the liquefied soils. In addition, derived deformations pre- and post-liquefaction are best evaluated by means of nonlinear dynamic deformation analysis using effective stress-based numerical modeling. However, cyclic laboratory data for tailings under static bias to assess the applicability of such models and evaluate the seismic performance of the tailings storage facilities (TSFs) are scarce (Reid et al., 2024).

In this study, cyclic DSS testing under level ground and initial static shear stresses were performed to evaluate liquefaction triggering and post-triggering permanent deformations and use the ratio between Initial Loading Stress Ratio (LSRo) and the Image Stress Ratio (ISR), as defined by Jefferies and Been (2016), and the state parameter (Been and Jefferies, 1985) to provide an index of strain potential.

Laboratory testing program

A laboratory testing program was completed at the Norwegian Geotechnical Institute (NGI) to investigate the influence of a static bias load on underflow tailings behavior using cyclic direct simple shear (cyDSS) testing. The laboratory testing program consisted of testing samples at similar void ratios and at vertical stress and cyclic stress ratios under a varying static bias. This allowed for an evaluation of the impact of the static bias load on the cyclic and post cyclic response.

Underflow sand tailings tested here are often characterized by contractive/ductile behavior if they are saturated, based on state-based behavior characterization. The laboratory testing program used bulk samples and Shelby tube samples which were collected during various geotechnical investigations from a TSF. The underflow sand samples were reconstituted using the slurry sedimented method.

Standard index testing was performed to characterize and classify the samples used for the cyclic DSS testing with static bias. The following tests were completed as part of the index property testing: water (moisture) content, unit weight estimation, hydrometer/sieve analyses (Figure 1), and Atterberg limits.

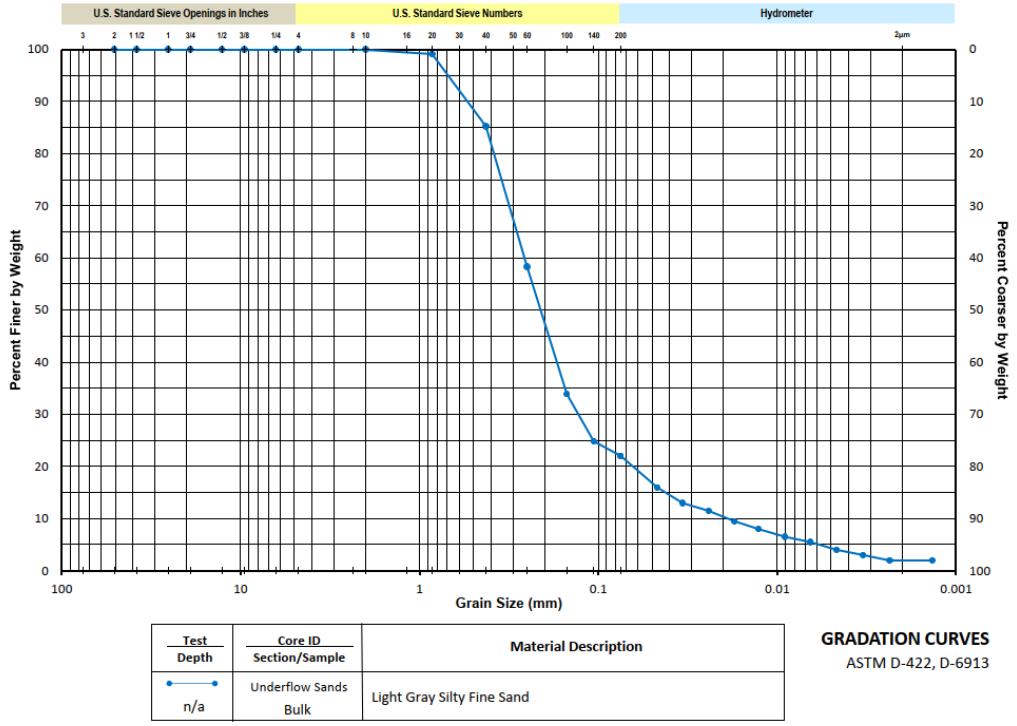

Figure 1: Typical grain size distribution of underflow sand tailings

The testing results are provided in Table 1. The results show that the underflow sand tailings are non-plastic and have a fines content of 22 percent.

Table 1: Summary of index property testing

Sample	Sample	Total unit weight (pcf)	Fines content (%)	PL	LL	PI
Underflow sands	Bulk	Various	22	NP	NP	NP

Cyclic DSS testing protocol

Cyclic DSS testing with a static shear stress bias was performed to evaluate the influence of static bias loading on the cyclic and post-cyclic behavior of the tailings material. Care was taken to vary only the static shear stress bias load. All other testing parameters, such as consolidation stress, void ratio, and cyclic stress ratio (CSR), were kept nearly constant for all samples of the same material so that the influence of the varying static bias load could be compared. From all these parameters, experimental variability in the void ratio among tests was still present. Therefore, to characterize the response of each sample, initial state parameters from all samples were estimated after consolidation.

A summary of the testing parameters is provided in Table 2.

Table 2: Summary of Cyclic DSS testing parameters

Sample	Test ID	Consolidation stress (σ'_v, psi)	Static bias ratio (bias shear stress α, psi)	Cyclic stress ratio	Initial state parameter ($\psi=e_o-e_c$)
Underflow tailings (this paper)	Base	150	0 (0)	0.17	0.07
	SB-0.2	150	0.2 (30)	0.17	0.19
	SB-0.4	150	0.4 (60)	0.17	0.04
Underflow tailings (Cerna-Diaz et al., 2022)	Various	Various	0 (0)	0.17-0.20	-0.15-0.11

The following general testing procedure was used in the completion of the cyclic DSS testing:

1. Specimen preparation: Preparation of test specimens following ASTM D6528.
2. Consolidation: One initial consolidation stress, i.e., 150 kPa, was specified for the underflow material, and all specimens were consolidated to this initial vertical effective stress.
3. Application of static bias load: for tests under static bias, the initial shear load was applied to the test specimen at a rate/increment that followed the drained stress path and did not generate excess pore pressures.

4. Cyclic loading: the cyclic stress ratio (0.17) and frequency (0.1 Hz) were specified, and all specimens were tested at this same CSR and frequency.
5. Post-cyclic loading: After cyclic loading, each specimen was sheared in a post-cyclic monotonic loading.

Cyclic DSS testing results

The results of the cyclic DSS testing at level ground (bias=0) and with static bias for the underflow tailings are summarized in the following sections.

Level ground baseline testing (no static bias)

One level ground cyclic DSS and historical test results are summarized in Figure 2. Figure 2 shows the test path (shear stress versus [vs.] vertical effective stress), shear stress vs. shear strain, excess pore pressure ratio (r_u) vs. number of cycles, and shear strain vs. number of cycles.

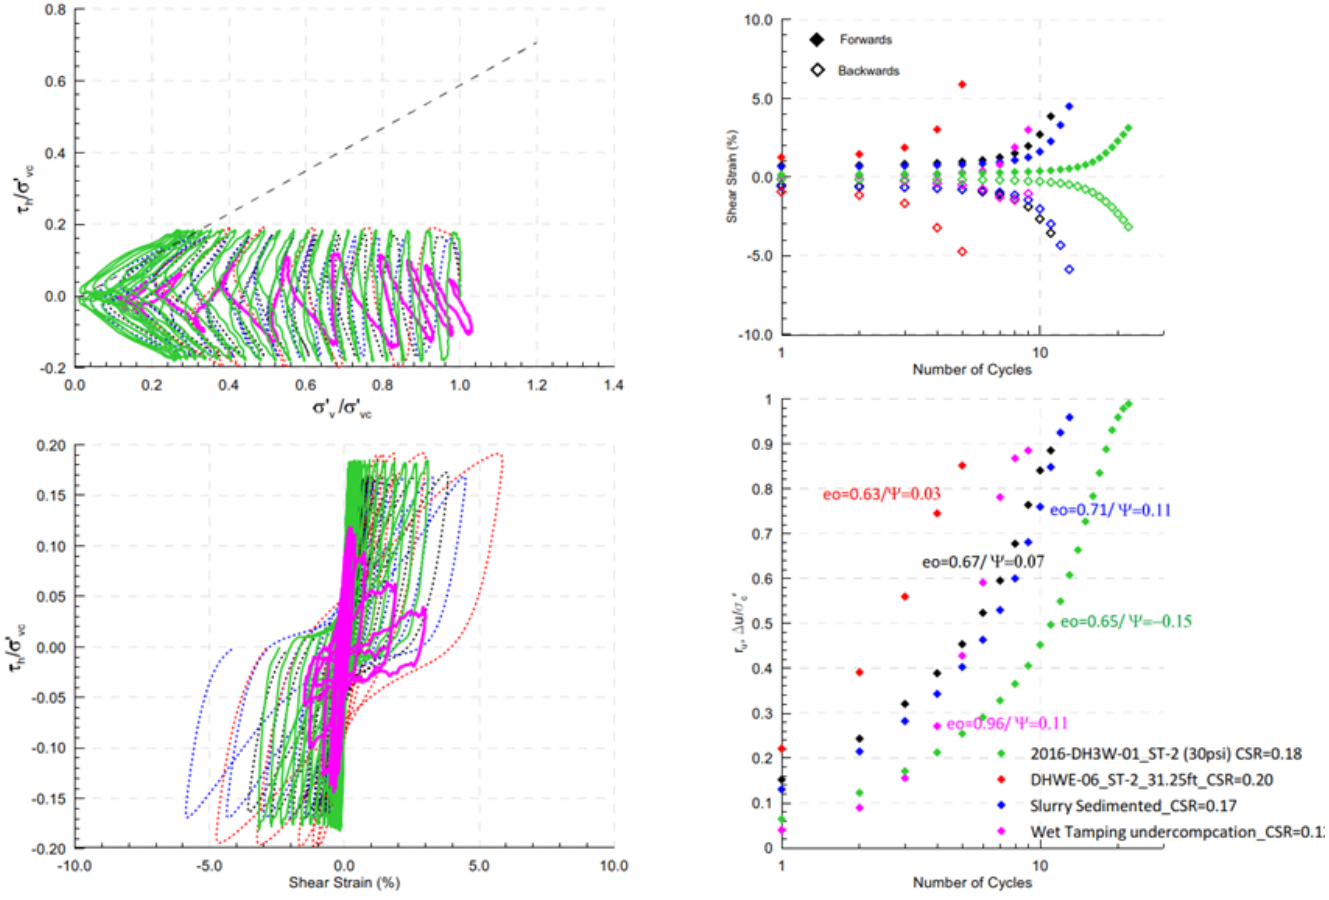

Figure 2: Cyclic level ground (no static bias) new and historical baseline DSS tests on the underflow sand tailings

Undrained cyclic loading in all level ground tests induced contractive behavior resulting in the development of positive excess pore water pressures due to the change in direction of loading, which resulted in cyclic accumulation of plastic shear strains. The accumulation of plastic shear strains and the development of excess pore pressures generally induced loss of stiffness throughout cycling; the specimens exhibited cyclic mobility type behavior with more noticeable dilatant response as the stress paths crossed the Phase Transformation Line (PTL) with subsequent cycles of softening and hardening upon proximity to the PTL at the levels of CSR imposed by the cyclic DSS tests (CSR ~ 0.17). Additionally, historical level ground cyclic DSS tests (CSR ~ 0.17-0.2). that were completed on similar underflow tailings material, as presented in Cerna-Diaz et al. (2022), are included in Figure 2.

The results of new and historical tests indicate that the level of accumulated shear strains is dependent on the initial state parameter. Samples that had a higher initial state parameter showed an increased rate of cyclically induced accumulated shear strains. The cyclic stress-strain response of the samples is governed by the void ratio and location with respect to the critical state line, as shown in Figure 3, with state parameters estimated by assuming Ko~0.6 for the DSS mean effective stresses estimates.

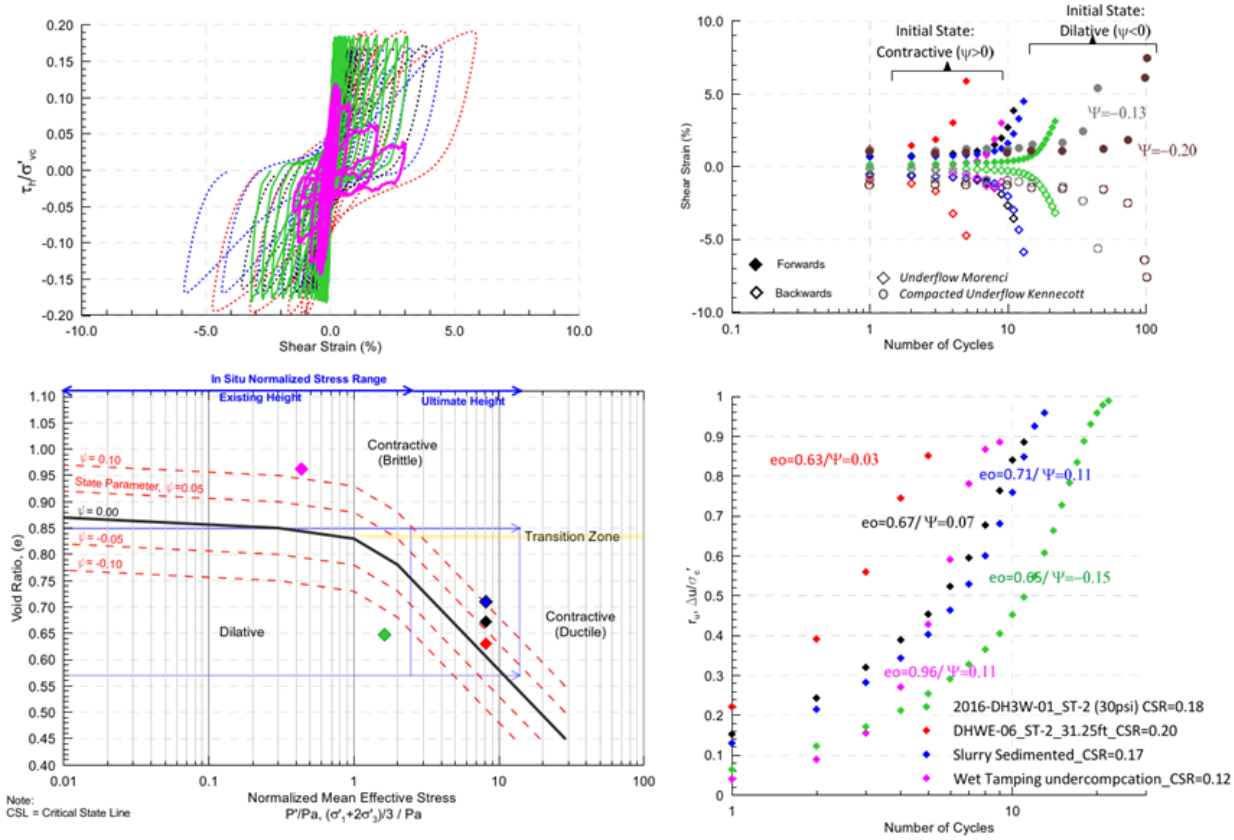

Figure 3: Cyclic level ground DSS (no static bias) baseline tests on the underflow sand tailings based on their initial state on the CSL space static bias cyclic testing results

Furthermore, a sample prepared using the wet tamping undercompaction method underwent a rapid loss of stiffness, while the pore pressures continued to increase at the fastest rate out of all of the test specimens, with the onset of triggering (e.g., the onset of strength loss) occurring at a relatively low value of r_u~0.4. This test started with an initial consolidated void ratio of 0.96 (ψ=0.11) and is in the contractive/brittle critical state line (CSL) space as defined by Robertson, 2017.

In contrast, another sample was prepared using the more realistic slurry sedimented method with an initial consolidated void ratio of 0.71. This specimen had an identical state parameter (ψ=0.11) but was tested at a higher vertical effective consolidation stress, which placed it in the contractive/ductile space. During testing, this specimen exhibited an accumulation of plastic shear strain, without a loss of strength, to levels below those induced by the cyclic CSR during cyclic loading, even upon full liquefaction of the specimen.

Static bias testing results

For the testing program completed as a part of this study, two static bias (0.2 and 0.4) cyclic DSS tests were conducted on the underflow sand tailings, and the results are plotted in Figure 4. Figure 4 shows the test path (shear stress vs. vertical effective stress), shear stress vs. shear strain, excess pore pressure ratio (r_u) vs. number of cycles, and shear strain vs. number of cycles.

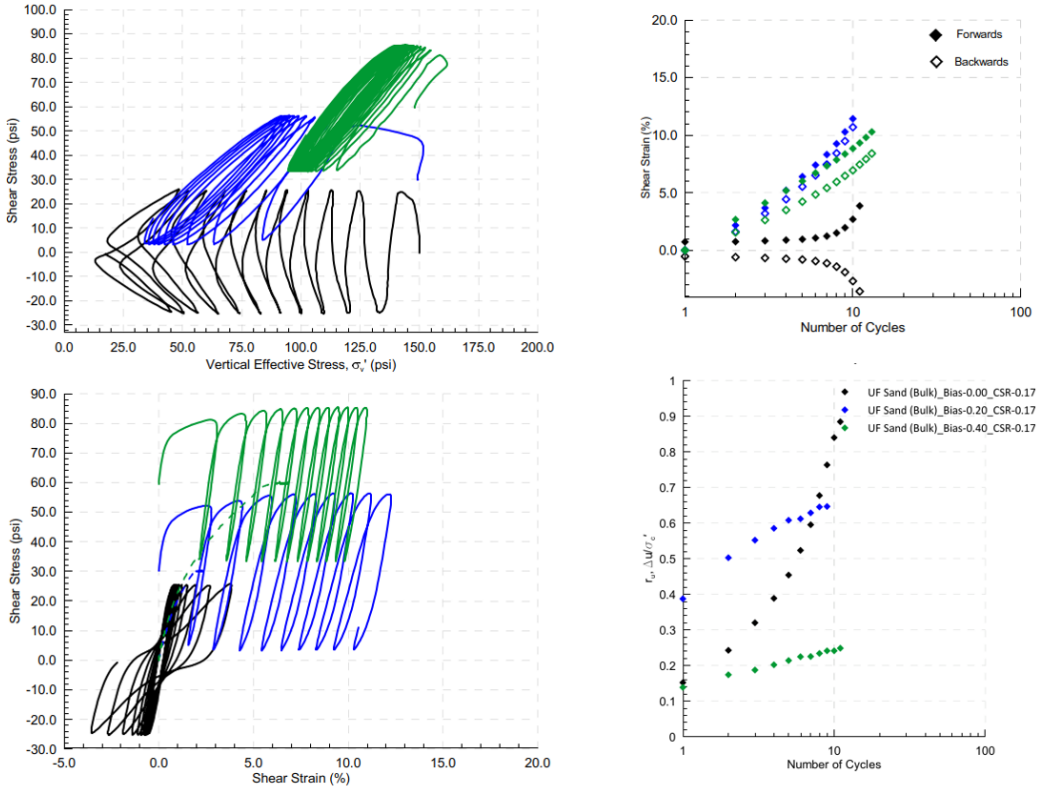

Figure 4: Cyclic DSS tests with static bias (0, 0.2. and 0.4) on the underflow sand tailings

Cyclic behavior

Similarly to level ground tests, undrained cyclic loading in all of the cyclic tests completed with static bias induced contractive behavior, resulting in the development of positive excess pore water pressures and an accumulation of shear strains, as shown in Figure 4. The testing results showed an accumulation of shear strains in the direction of the initial applied static shear stress and generation of positive excess pore pressures, which indicated a loss of stiffness with each additional cycle. The results also indicated that the samples do not exhibit loss strength to levels below those induced by the cyclic CSR as imposed by the cyclic DSS tests (CSR~0.17). This is observed as the sample continues to carry the imposed shear stress throughout the loading cycles, even after liquefaction.

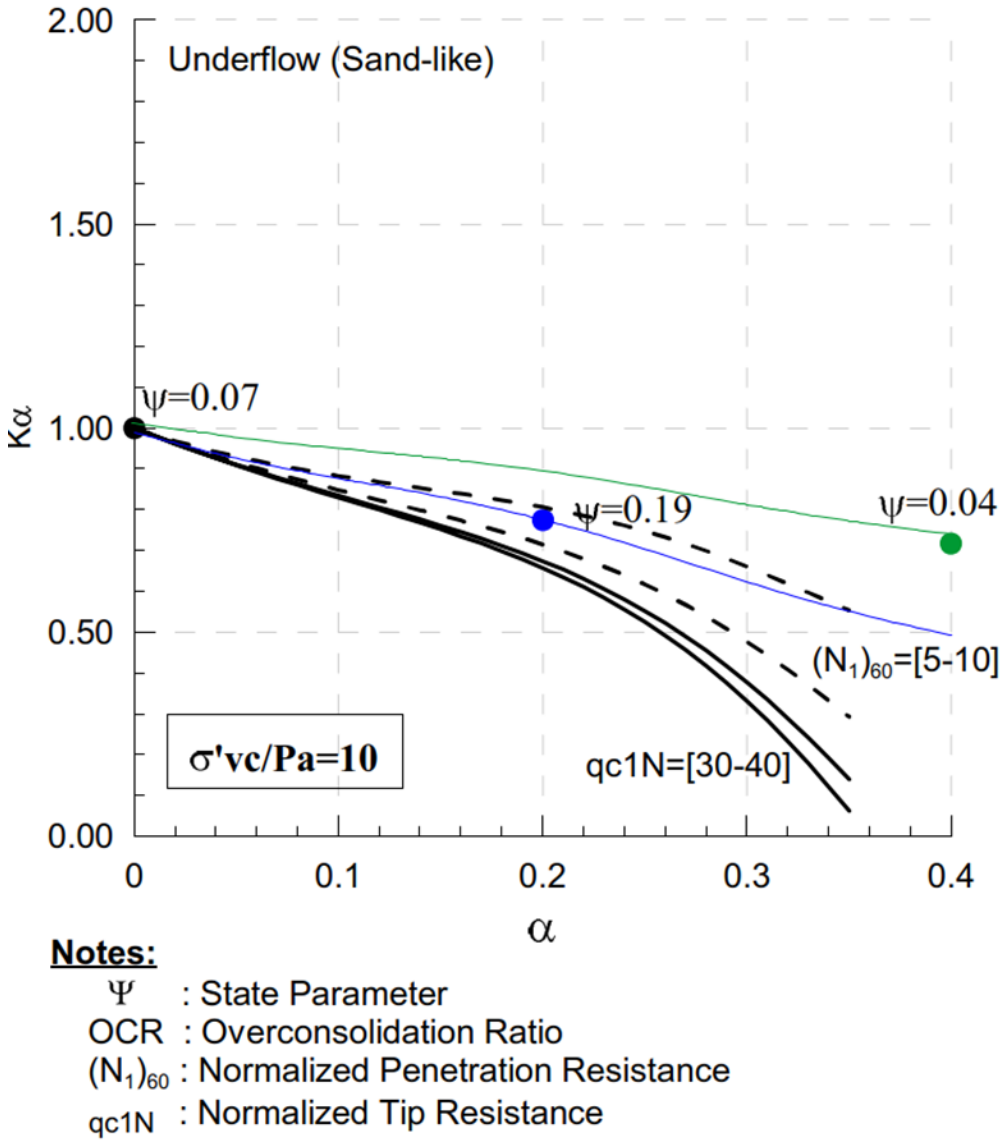

Figure 5: Sloping ground correction factor Ka from testing program vs. Boulanger (2003) relationship

In contrast to the level ground tests, the maximum induced excess pore water pressure ratio during cycling was less than 1 for each of the tests with static bias. The induced r_u ratios were the lowest for the test with the highest static bias (alpha=0.4) and the highest for the level ground level test (alpha=0.0). This is consistent with the decrease in the limiting value of the residual r_u in cyclic simple shear tests with the increase of static shear stress ratio on clean sands, as reported by Ishihara and Nagase (1980) and summarized in Idriss and Boulanger (2008). Furthermore, as shown in Figure 5, from initial screening level comparisons with Kα relationships (e.g., Boulanger, 2003) based on 3 percent single amplitude failure criteria, it appears that underflow testing suggests a lower reduction in cyclic resistance than the Boulanger (2003) correlation tailored for natural sands for similar stress and density conditions.

Initial consolidated state parameters of tested specimens, following the drained static bias phase, are plotted in the contractive ductile space of the CSL, as shown in Figure 6.

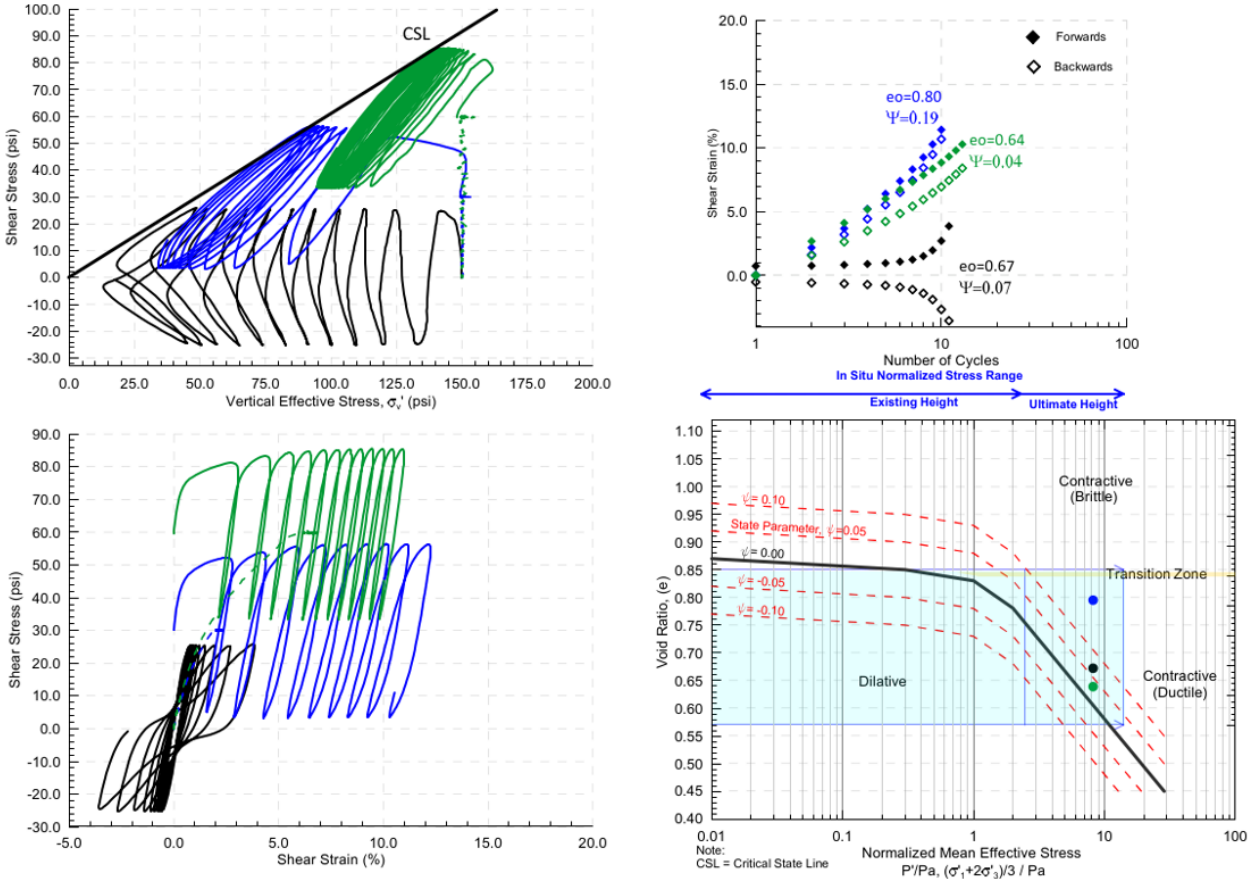

Figure 6: Cyclic DSS tests with static bias (0, 0.2. and 0.4) on the underflow sand tailings with respect to their initial state on the CSL space

The test with the largest positive state parameter (ψ=0.19) underwent the largest permanent deformation, larger than 3 percent and up to 12 percent of shear strains, for the same number of cycles, as shown in Figure 7a to Figure7e. Figure 7d also shows that although permanent strains are higher for tests

with static bias, the rate of accumulation of these deformations decreases with the number of cycles (Figure 7d) and is accompanied by a ratcheting effect showing an increase in shear stress with the number of cycles, as shown in Figure 7a and Figure 7e.

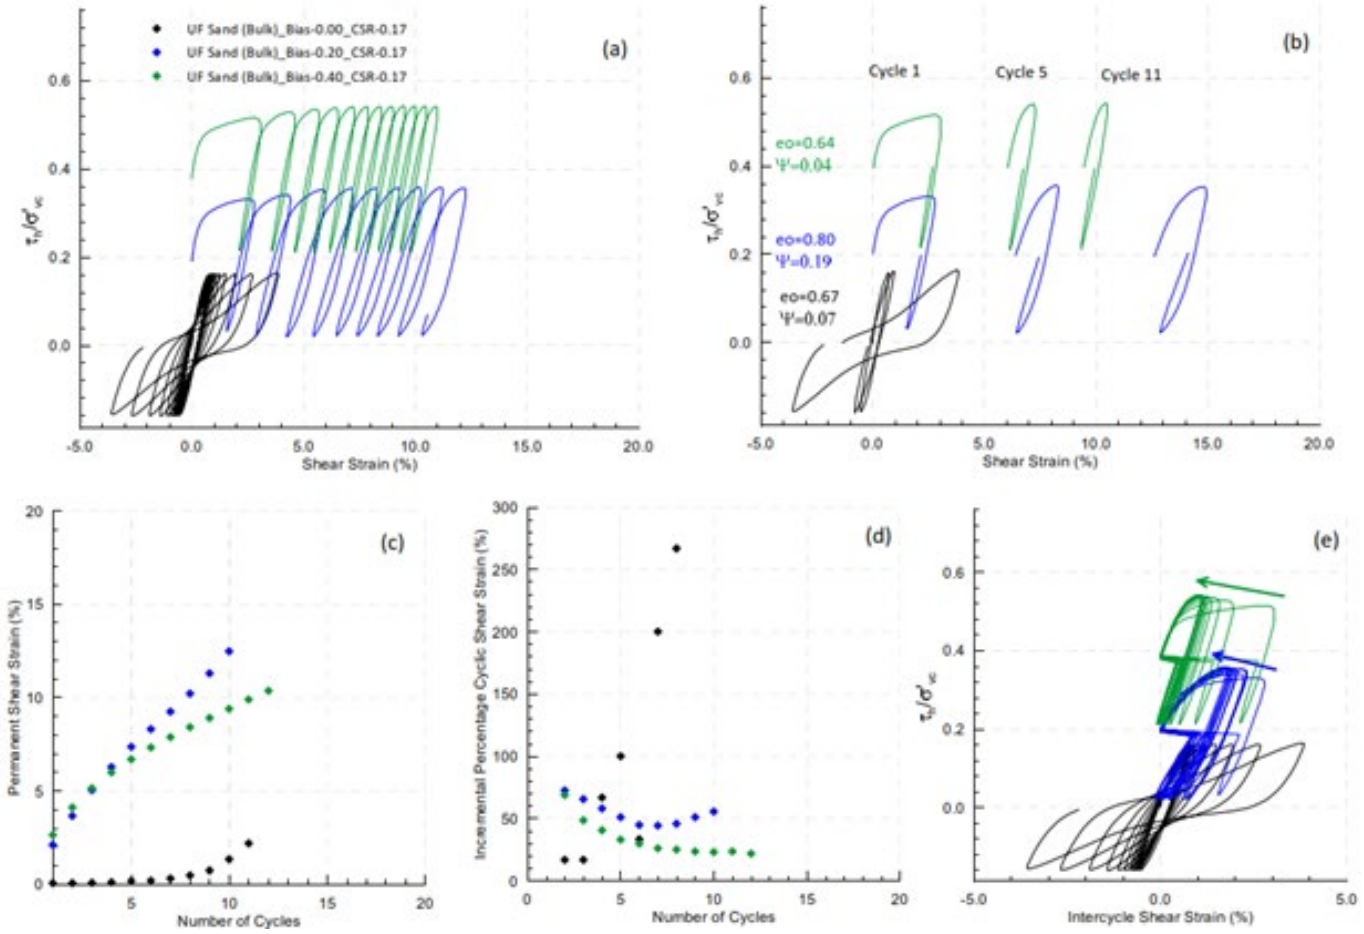

Figure 7: Cyclic DSS tests with static bias (0, 0.2, and 0.4) on the underflow sand tailings with respect to accumulation of shear strains and shear stress and initial state

The influence of static bias appears to increase the accumulation of shear strains for a given state parameter, as shown in Figure 7b, which compares the non-bias test with the test at a bias of 0.4, which is at a similar state parameter. The ISR (i.e., phase transformation line) describes the line that divides contractive and dilative behavior, and it is typically defined by monotonic tests (red lines), as observed in Figure 8. Once the stress path crosses the ISR, accumulation of strains brings the stress path close to the failure line, with a decreasing rate of permanent strain accumulation in ductile materials.

Although higher permanent deformations were recorded under static bias tests, the intercycle shear stress shear strain response indicates a slight hardening behavior for static bias tests. For instance, the sample with static bias of 0.4 (green line) starts nearly at the ISR line and begins dilating from the initial loading stage, causing a ratcheting and progressive increase in shear stress once the stress path crosses the

ISR. Analogously, the test with static bias of 0.2 (blue line) starts contracting toward the failure line, while dilation during cycles becomes more pronounced as the stress path crosses the ISR, as shown in Figure 8.

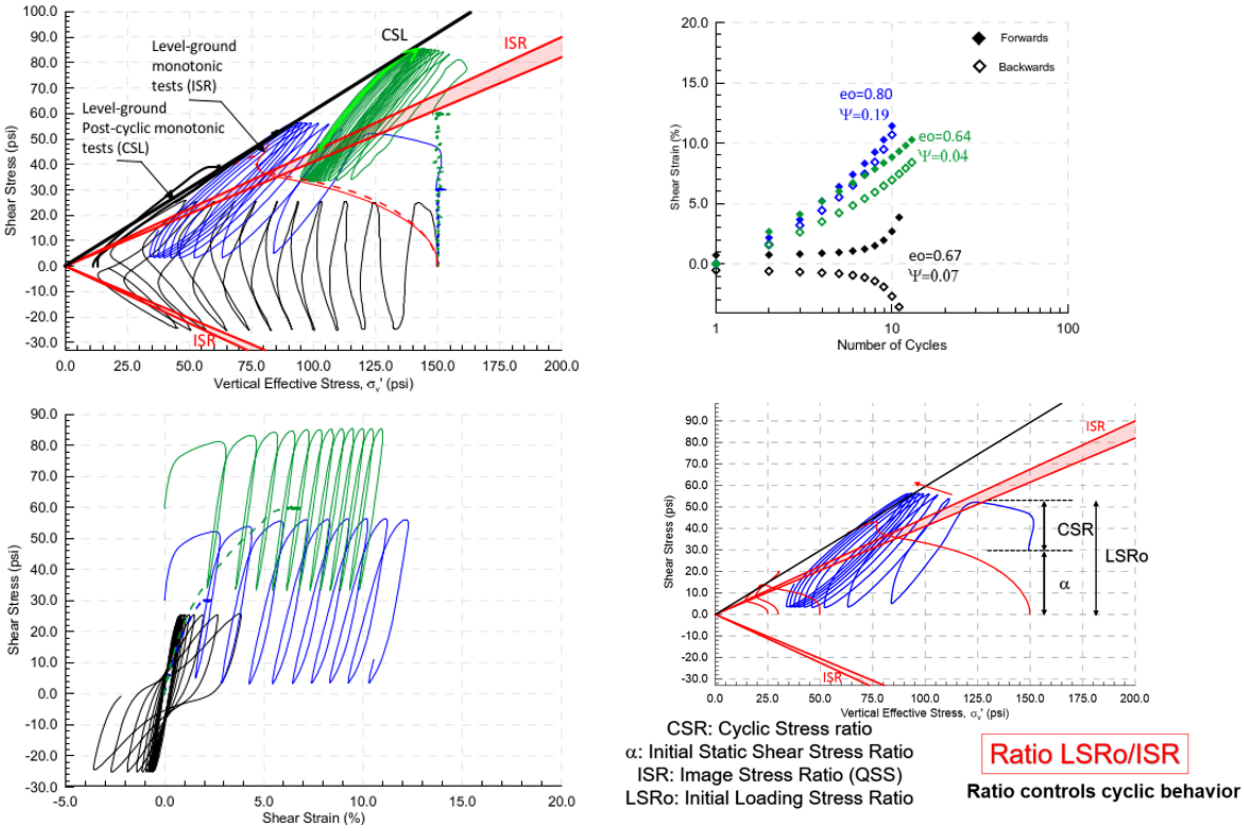

Figure 8: Cyclic DSS tests with static bias (0, 0.2. and 0.4) on the underflow sand tailings with respect to their location to ISR and illustration of Ratio of LSRo/ISR concept (Jefferies and Been, 2016)

Dilation during cycles is shown as a temporary increase in the effective vertical stress. The test with static bias of 0.2 also depicts ratcheting and progressive increase in shear stress once the stress path crosses the ISR. In summary, the tendency for tests with static bias of 0.2 and 0.4 is to enhance dilative response between cycles, accompanied by a slight increase in shear resistance during cyclic loading, depicting an additional ductile response compared to level ground tests.

As shown in Figure 9, the cyclic accumulation of strains appears to be controlled by the location of the initial static shear stress and confining pressure with respect to its ISR (Jefferies and Been, 2016), which is ratio LSRo/ISR as defined in Figure 8 for the same number of loading cycles (~10-11). This concept is introduced to gain insight into the cyclic loading behavior of underflow sands in terms of accumulation of shear strains.

Further comparisons with static bias cyclic tests on denser Monterey sands performed by Kammerer et al. (2002), as shown in Figure 9, also indicate that permanent deformations appear to be controlled by the state parameter and the LSRo/ISR ratio.

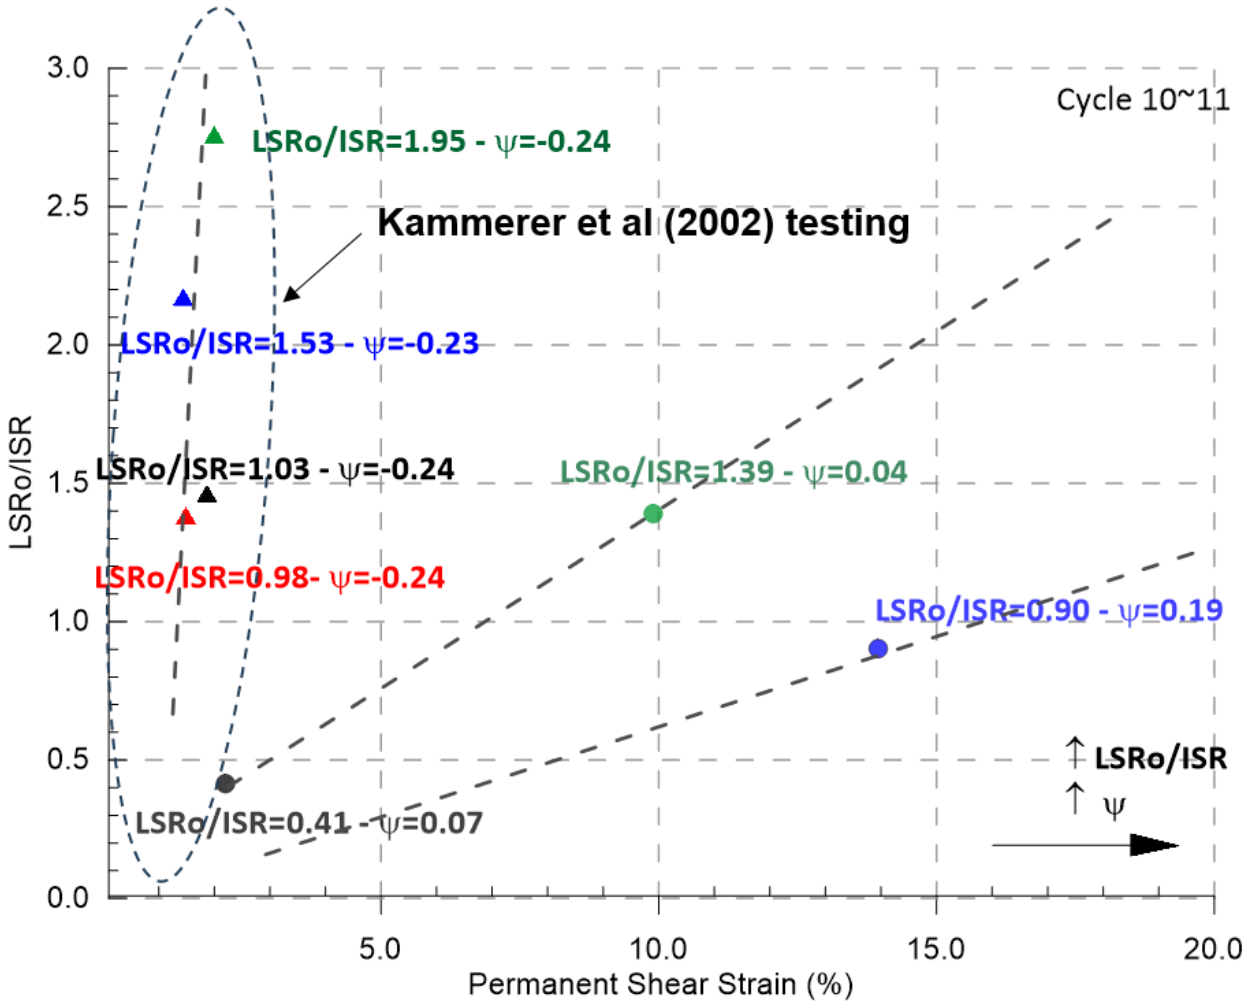

Figure 9: LSRo/ISR (Jefferies and Been, 2016) and state parameter as an index of permanent strain potential from cyclic DSS testing

Post-cyclic testing

One post-cyclic DSS test was completed on a sample of the underflow sand tailings after cyclic loading on the test with a static bias of 0.2, initial state parameter (ψ) of 0.19, and consolidated void ratio (e_c) of 0.8 to contrast with the test with non-static bias (alpha=0) with initial state parameter (ψ) of 0.07 and consolidated void ratio (e_c) of 0.67 (see Table 1). As a comparison, level ground post-cyclic testing was conducted in 2016–2017 with consolidated void ratios between 0.63 and 0.78, and initial state parameter less than 0.11 (denser).

The results of static bias and level ground tests in terms of test path (shear stress vs. vertical effective stress), shear stress vs. shear strain, and excess pore pressure ratio (r_u) vs. shear strain are shown in Figure 10. Generally, the static bias test (blue) indicates dilative excess pore water pressure response with increasing shear strain with a slight contractive behavior for shear strains larger than 12 percent. Level

ground post-cyclic testing also shows dilative excess pore water pressure response as they move to critical state conditions.

As shown in Figure 10, post-cyclic strengths were generally estimated at 15 percent strain for the level ground tests and for tests with static bias.

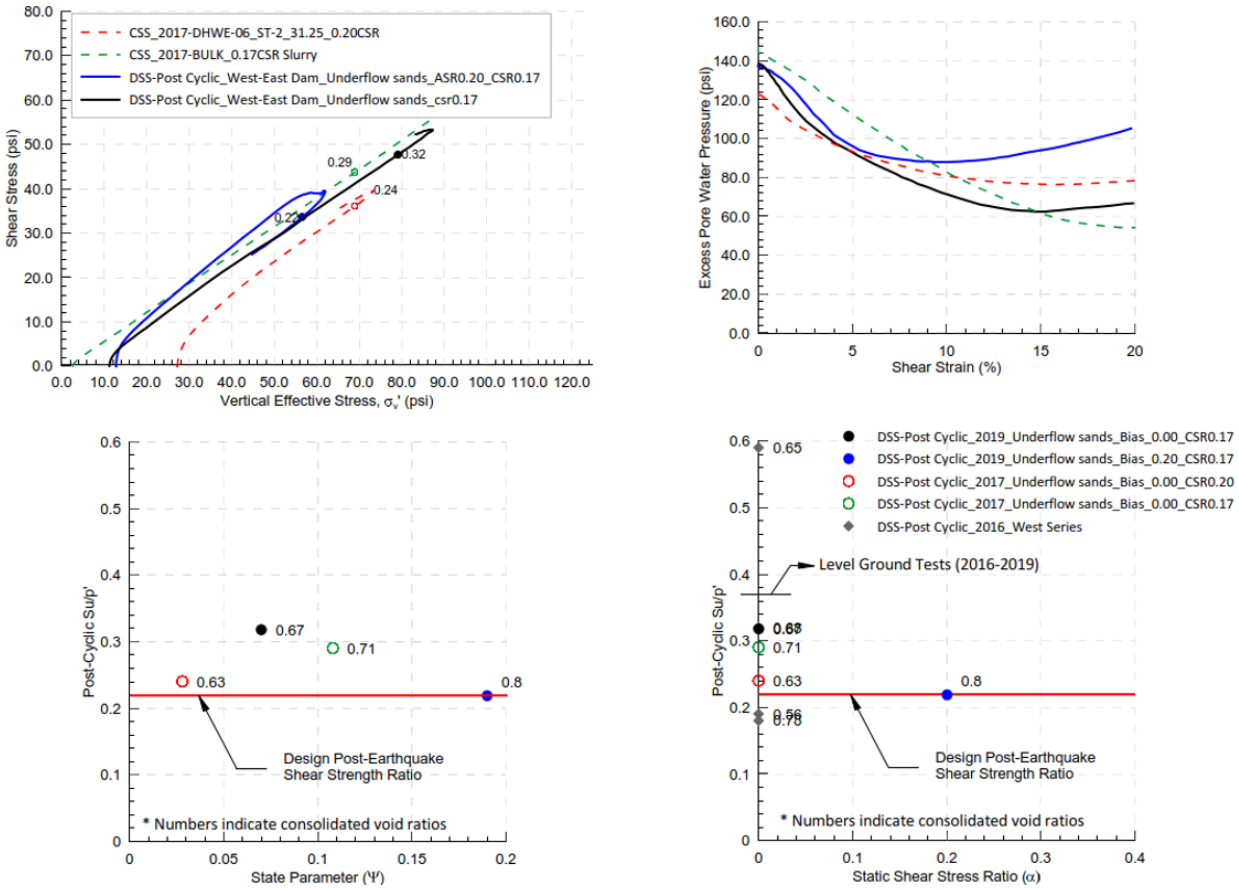

Figure 10: Underflow sands tailings post-cyclic DSS testing results

Because the volumetric response (e.g., excess PWP) levels off at around 15 percent strain, this was selected; thus, this level of strain is nearly compatible with critical state conditions. Post-cyclic monotonic loading for static bias tests indicated a post-cyclic strength ratio of about 0.22. The level ground post-cyclic tests that were conducted indicated a similar range of post-cyclic strength ratios, i.e., ratios between 0.18 and 0.32. Therefore, there is no systematic difference between level ground and static bias on post-cyclic strength results.

Conclusion and recommendations

Preliminary results of the DSS testing program on underflow sands under static bias suggest that tailings strain accumulation may be controlled by the initial state parameter and the ratio LSRo/ISR.

Static bias cyclic DSS tests on underflow sand tailings at the densities and stress states selected for this program indicated a loss of stiffness without a loss of shear strength to levels below those associated with the CSR selected for the cyclic DSS tests, which is characterized as cyclic mobility behavior. Cyclic loading caused a ratcheting and progressive increase in shear stress with accumulating cycles once the stress path crossed the ISR, which resulted in limited excess pore pressure development for a given initial static shear stress ratio.

The static bias testing has not been shown to provide a significant benefit or detrimental effect on the cyclic behavior. As compared to the level ground testing, the static bias testing results in a stress path closer to ISR or Phase Transformation Line (PTL), and thus accumulates more strain without reducing the strength during cyclic loading.

The presence of a static bias did not appear to influence the measured post-cyclic strengths, which is consistent with known critical state soil mechanics concepts.

Additional static bias testing on underflow materials at high void ratios above, slightly below/above CSL and low stresses are recommended to investigate the effect of static bias at extreme potentially brittle behavior to lightly contractive/dilatant conditions. This testing will provide insight for bounding the cyclic response under sloping ground conditions for a full range of behavior.

Cyclic Response of Mine Tailings at Field and Laboratory Scales – Example Using a Novel Database

Cody Arnold, Georgia Institute of Technology, USA
Jorge Macedo, Georgia Institute of Technology, USA

Abstract

Cyclic liquefaction induced by seismic loading from earthquakes is a major concern for countries with active mining industries and moderate seismicity such as Peru, Chile, and the USA. Cyclic liquefaction is more likely to induce flow failure as compared to other failure modes, and has been associated with a large portion of failures in seismic countries like Chile. Chile is a leading provider of copper and lithium to the global market, and the country's ability to sustain such a large mining sector could be hindered by its ability to safely store its tailings. Mine tailings have been shown to have unique mechanistic responses dissimilar to that of traditional soils (i.e., sands and clays). Much of engineering practice relies on techniques and procedures developed from data derived from sands and clays. As such, our understanding of the cyclic behavior of mine tailings needs continued research interest to extract new insights into their unique behavior. This paper utilizes a recently developed database focused on the cyclic response of mine tailings to highlight some insights into their peculiar behavior. Specifically, their unique range of material properties and resulting liquefaction curves, the applicability of existing factors in the liquefaction assessment of these materials as compared to sands, and a comparison of in-situ and laboratory-derived cyclic resistances are showcased.

Introduction

The design of sustainable tailings storage facilities (TSFs) is of major concern to both the countries they lie within and the countries that benefit from the extracted resources. The Paris Climate Agreement was adopted by 196 member countries of the United Nations in 2015. The agreement aims to keep global warming below 2 degrees Celsius through the transition from fossil fuels to more sustainable energy solutions (e.g., wind, solar, hydroelectric, electric cars, etc.). Many countries have implemented legislation to match. As an example, the U.S.A. aims to reduce its greenhouse gas emissions by 50% below 2005 levels by 2030. However, with this transition to renewables comes increased demand for the raw materials required to implement such technologies. As an example, the demand for copper, which is utilized in a wide

array of renewables, is expected to double from 25 million metric tons in 2022 to over 51 million metric tons by 2050 (S&P Global, 2022). Similarly, the demand for other metals is projected to increase as well (Eyzaguirre and Araya, 2021). This creates a major hurdle, because with the increasing demand and the degradation of ore grade (Bowker and Chambers, 2017), the amount of in-situ material that needs to be extracted for processing grows drastically. This leads to an enormous amount of waste material (tailings), which poses a direct threat to the environment and human life. Consequently, this has led to more dams being constructed in the past decade than any decades prior (Warburton et al., 2019), as well as dams being designed to hold larger volumes of waste. While the average number of yearly TSF failures has remained constant (Piciullo et al., 2022) the severity of failures (i.e., the amount of released waste) has been increasing (Piciullo et al., 2022; Bowker and Chambers, 2017).

After several high-profile TSF failures (e.g., Brumadinho, 2019; Fundao, 2015; Cadia, 2018) a consortium of agencies, one of which was the United Nations Environmental Program, released the global industry standards on tailings management (GISTM) (ICMM et al., 2020) with the goal of reducing TSF failures. Several notable tailings engineers also conducted their own studies seeking to highlight the contributing factors to these failures. One such individual was Norbert Morgenstern, who evaluated fifteen TSF incidents and classified their contributing factors into three categories: engineering, operations, and regulatory. Morgenstern (2018) determined that engineering was the primary factor in the failures. Other independent studies (Been, 2016; Jefferies, 2021) have reached similar conclusions.

In a detailed look at failure causes by Piciullo et al. (2022), the three known major causes of failure are overtopping (23%), static (16%), and dynamic liquefaction (14%). However, despite dynamic liquefaction only being the third most common cause, it sees a disproportionally higher association with flow failures as compared to overtopping and static liquefaction (Halabi et al., 2022). This makes the seismic design of TSF in countries with active mining industries and moderate to high seismicity (e.g., Peru, Chile, USA) a major concern.

For instance, Chile is the leading producer of copper ore and the second largest producer of lithium in the world at 28% and 30%, respectively (USGS, 2023a; USGS, 2023b). Chile also has the largest reserves of copper and lithium (USGS, 2023a; USGS, 2023b), and therefore its ability to safely mine and store tailings in perpetuity is crucial to the global supply. However, between 1901 and 2013 the primary cause of TSF failures in Chile was earthquake-induced (cyclic) loading (Villavicencio et al., 2013) with nearly 50% of those involving flow failure. These studies highlight the lack of knowledge surrounding the cyclic response of mine tailings and the need for further research into their unique cyclic behavior.

Mine tailings are typically classified as silts or silty sands and have characteristics that separate them from naturally occurring silts (e.g., angularity, mineralogy, etc.). This poses a challenge to tailings engineers, as most engineering approaches for seismic design have been developed from databases and case

histories of sites mainly containing sands and a few natural silts (Seed and Idriss, 1982). Additionally, several studies have highlighted that the scaling of mechanical properties in mine tailings varies from that of naturally occurring soils (Macedo and Vergaray, 2021; Jefferies and Been, 2016) even at similar gradations (Ishihara et al. 1980; Geremew and Yanful, 2012). This paper utilizes a recently developed database (Arnold and Macedo, 2024) focused on the cyclic response of mine tailings to look at unique trends in their behavior, as well as to assess existing procedures for seismic design. Specifically, the scaling factor for overburden stress (K_σ) is assessed for a selected tailing from the database in conjunction with past trends for sands. Additionally, the Boulanger and Idriss (2014) method for estimating the cyclic resistance (CRR) from cone penetration testing (CPT) is compared against laboratory-based estimates from cyclic simple shear (CSS) tests, for a selected tailing.

Database

A recently developed database (Arnold and Macedo, 2024) focused on the cyclic response of mine tailings grants a novel opportunity to study the unique response of tailings materials. As shown in Figure 1a, there is a wide range of particle size distributions (PSD) present within the database. The database contains about 130 CSS tests on 20 different mine tailings gradations. As previously mentioned, mine tailings are typically identified as non-plastic silty sands to sandy silts with fine contents (FC) typically ≥ 35%, which is indeed the case for many of the tailings in the database, as highlighted by the histograms in Figures 1b and 1c. This does however highlight an existing gap with regard to tailings that do contain plasticity, as they are not as well represented.

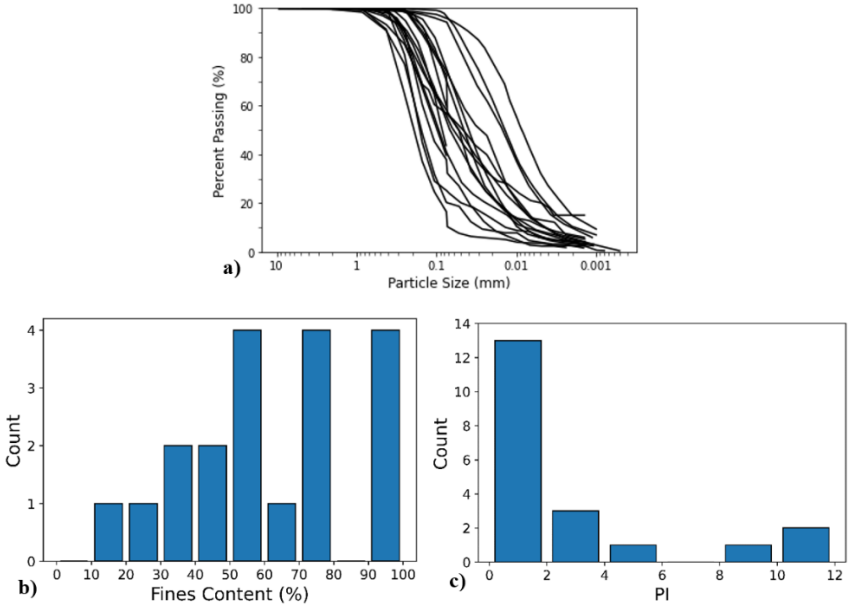

Figure 1: Range of a) PSD, b) FC, and c) PI for available mine tailings within the database (Arnold and Macedo, 2024)

The database is also unique in that it offers a robust amount of secondary information on its materials in the form of critical state line (CSL) via triaxial testing and in-situ information via CPT. To discern the materials by how much data is available on each they are placed into one of three classes: A, B, and C. Class A is the most numerous and indicates those materials containing all three data types (CSS, CSL, and CPT). Class B denotes those with CSS and one other data type (CSL or CPT), and class C denotes those with only CSS data available. Furthermore, supplemental data (e.g., FC, plasticity index (PI), ore type, etc.) regarding the materials is also made available, when possible.

Insights

The cyclic resistance of soils can be assessed in several ways but the use of CSS testing is quite commonly used. Estimating the cyclic resistance requires a minimum of 3 CSS tests to derive a liquefaction resistance curve. However, it is not uncommon for 4 or 5 tests to be used for greater accuracy. The liquefaction resistance curve relates the cyclic stress ratio (CSR) to a predefined failure criterion (N_{liq}), typically associated with a strain criterion (i.e., 3.75% single amplitude). The failure point of each test is then plotted CSR against N_{liq} in log scale and is fitted by a power law. Equation 1 represents a resistance curve with fitting parameters *a* and *b*.

$$(1)\quad \boldsymbol{CSR = aN^{-b}}$$

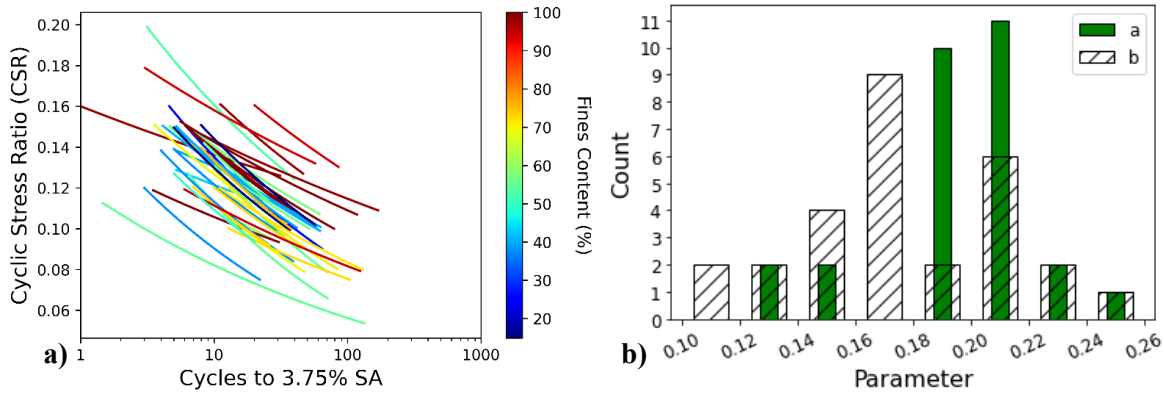

Figure 2: a) Liquefaction resistance curves for database materials labeled by FC and b) range of fitting parameters (*a* and *b*) (Arnold and Macedo, 2024)

The resistance curve is then used to further interpret a cyclic resistance of an equivalent earthquake loading. For instance, it is quite common to consider 15 cycles (CRR_{15}) in liquefaction-triggering procedures such as the Seed and Idriss (1982) procedure. Thus, deriving CRR_{15} at a given confinement and density requires the previously mentioned 3 to 5 CSS tests. Figure 2a shows the liquefaction resistance curves from the database labeled by FC, and the resulting fitting parameters are shown in Figure 2b. In general, *a* is lower than what is typically seen in sands (~ 0.27). This is further highlighted by Figure 3a

which shows that the database tailings need only relatively low CSR values to liquefy, even under high-stress states (a significant number of tests ≥ 300 kPa).

Another aspect to highlight is the slope of the resistance curves which is captured by the *b* parameter, which is on average around 0.19 (Figure 2b). This is notable as sands have typical b values on the order of 0.34 (Idriss and Boulanger, 2008). In fact, it is more similar to the *b* value seen in clays (~ 0.14 - Idriss and Boulanger, 2008) which is interesting as mine tailings would typically be expected to show a more "sand-like" response based on their material properties. For instance, considering the fact that most of these are non-plastic tailings (Figure 1c) the method from Idriss and Boulanger (2006) would classify them as sand-like (PI ≤ 7). This discrepancy highlights the challenges in designing for these materials as they exhibit "sand-like" responses but have significant compressibility more akin to clays.

The compressibility of these non-plastic tailings is further exemplified by the magnitude of their CSL slopes (λ_e). Figure 3b shows the range of λ_e for the tailings within the database, on average they are around 0.07. This is twice as large as λ_e typically reported for common testing sands (~ 0.033) and for natural sands (~ 0.037) as reported by Jefferies and Been (2016).

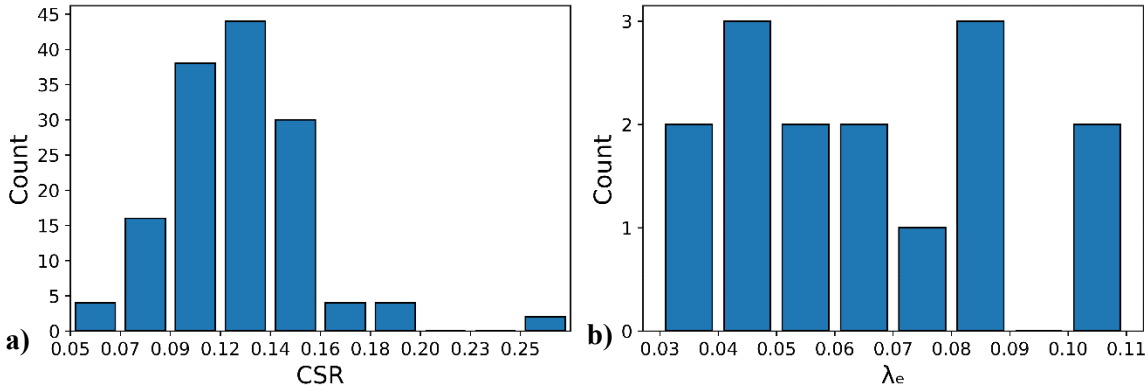

Figure 3: Range of a) CSR and b) λ_e for available mine tailings within the database (Arnold and Macedo, 2024)

Overburden stress effect

As previously discussed, the K_σ scaling factor plays an important role in the liquefaction assessment of soils. This is especially true in large TSF as the large height to which these structures are built is accompanied by large overburden stresses. The original scaling factors were derived from case histories on predominantly sandy soils. These factors denoted that increasing vertical stress would negatively affect the cyclic resistance (i.e., increasing confinement results in lower K_σ). Several authors since have proposed their own trends for K_σ in sands. For instance, shown in Figure 4 is the consensus curve proposed by Hynes et al. (1998) for sands as well as the semi-empirical trends proposed by Idriss and Boulanger (2006) based on case histories for non-cohesive soils (PI ≤ 7).

Conversely, data for mine tailings has been shown to indicate little or even a positive effect from increasing confinement. The data from Ingabire (2019) shows a base metal tailing at two varying relative densities (D_r); which are close to K_σ values of 1. A material from the database is also plotted, indicating an agreement with the Ingabire tailings. The chosen material (5_3) is non-plastic with about 40% fines. For both sands and tailings, researchers have noted that the looser the material the less impactful K_σ will be. However, for the tailings shown here even denser states have significantly less effect from K_σ than has been seen in sands. This has been noted by other authors as well (Sanin, 2005; Sanin, 2010; Verma, 2019; Al Taarhouni et al., 2011). Some authors have also noted a positive effect from K_σ (Wijewickreme et al., 2005; Sadrekarimi and Jones, 2019).

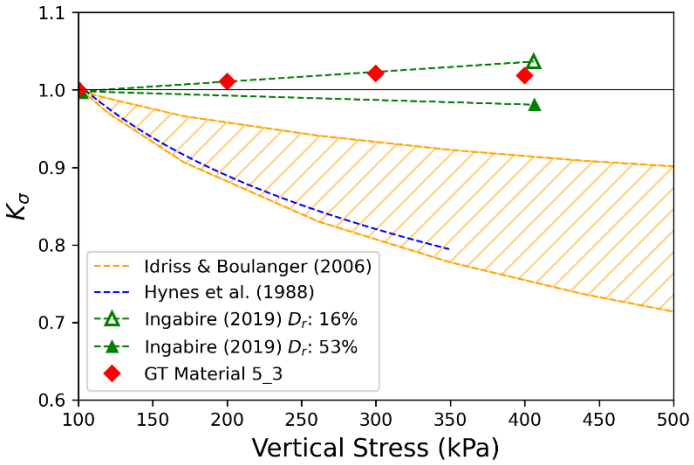

Figure 4: Kσ for GT material 5_3 compared against published trends

In summary, the effect of overburden stress and how it will ultimately affect the scaling factor (K_σ) in mine tailings is largely unknown. Despite the numerous studies that exist to date there does not yet seem to be a consensus on how to approach this for mine tailings materials. In the development of K_σ trends for sands large databases of either laboratory testing or case histories were required. This is where mine tailings suffer from a large knowledge gap as there are very few databases available to utilize. We expect that the database referred to in this study would be instrumental in allowing for further insights into the K_σ factor applicability to mine tailings by conducting more comprehensive assessments similar to those shown in Figure 4.

Comparison of field-corrected laboratory derived cyclic resistance with CPT estimates

As discussed in the previous section, the estimation of cyclic resistance for a given soil under a given demand can be estimated via laboratory testing (i.e., CSS) however, several methods (e.g., Boulanger and Idriss, 2014) exist for estimating from in-situ testing (i.e., CPT). These types of methods are very desirable, especially in the early stages of design, as it can take time to acquire samples and perform the necessary

tests. The validity of these in-situ estimations is of great interest and given the availability of CPT and CSS information within the database it is worthwhile to compare the two. Other authors have made similar comparisons, however for natural soils (Mijic et al., 2021).

Figure 5 showcases material 4_1 from the database with both the Boulanger and Idriss (2014) interpretation as well as the laboratory-derived CRR_{15}, with a correction factor of .9 (Seed, 1979). The laboratory samples were recovered from 7.5 m and 10.5 m; however, the tested specimens were reconstituted in the laboratory. Given this, it is surprising to see that the laboratory and field-derived CRR values are quite similar. Even for fully intact specimens, many factors could result in differences between the two interpretations (i.e., in-situ fabric). More comparison between in-situ and laboratory estimates, as those presented in Figure 5 are encouraged as it is quite difficult to recover undisturbed tailings samples (Wijewickreme et al., 2005), and most procedures for assessing the cyclic resistance have been developed for soils with low fines content and cannot be assumed to apply directly to tailings. The recent database developed by Arnold and Macedo (2024) could contribute to that direction, hopefully with more contributions from the tailings community.

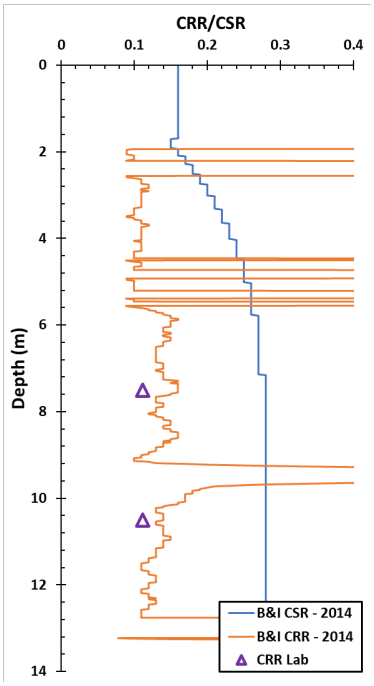

Figure 5: Comparison of field-adjusted laboratory derived CRR and field estimated CRR for material 4_1

Conclusion

This paper highlights the usefulness of a recently developed database on the cyclic response of mine tailings (Arnold and Macedo, 2024). The database provides a wide range of different mine tailings gradations with many having field (CPT), cyclic (CSS), and critical state (CSL) information available. This presents a novel

opportunity for investigating the unique behavior of these materials and assessing the applicability of procedures developed for sands and clays. Initial insights from the database are shown herein.

The database tailings are comprised of mostly non-plastic sandy silts to silty sands with FC ≥ 35%, on average. Their liquefaction resistance curves highlight a unique response that is influenced by their compressibility, which is shown to be more significant than in natural silts and sands. The overburden stress correction factor (K_σ) has been studied heavily in sands by many authors and the expected behavior is a negative effect of cyclic resistance with increasing confinement. However, a mine tailing from the database is plotted against these trends showing an inverse behavior, increasing resistance with increasing confinement. This raises questions regarding the applicability of existing K_σ relationships to mine tailings materials.

Lastly, the estimation of cyclic resistance via in-situ testing (i.e., CPT) (Boulanger and Idriss, 2014) is compared against the laboratory-derived values. The results show good agreement between the field and laboratory values, which is surprising considering that the laboratory specimens were reconstituted. This could be because mine tailings are relatively young materials geologically and there is not much difference between in-situ fabric and laboratory reconstructed specimens (e.g., lack of field bonding). Estimating the cyclic resistance from reconstituted specimens is quite common considering the challenges associated with recovering intact tailings samples. More comparisons such as this are encouraged to gain confidence in the laboratory and field-based estimates of cyclic resistance; particularly, because field-based methods have not been formulated for mine tailings specifically.

Some Considerations on the Stability of Tailings Dams Subjected to Blasting Vibration

Ezra Coyle, SLR Consulting Ltd, USA
Shayan Hashemi, SLR Consulting Ltd, Canada

Abstract

Ground vibration guidelines are typically established for blasting sites to prevent damage to adjacent facilities or infrastructures. However, blast induced vibrations present significant challenges to the geotechnical engineer during design and construction of the tailings dams, in large part due to the considerable uncertainty regarding the shear strengths of the different components of the structure. In addition, blast induced vibrations are associated with short duration high frequency pulses, which are fundamentally different from ground vibrations caused by earthquakes. The objective of this study is to review the application of the pseudo-static approach in assessing the stability of tailings dams subjected to blasting vibrations.

The facility analyzed in this paper is a downstream, raised zoned rockfill embankment with a two layered filter system on the upstream slope. The facility is in operation, and drill and blast activities are planned in the tailings facility basin for rock quarrying purposes. A significant potential impact from blasting near the dam would be the impact to the integrity of the filter materials placed on the upstream slope of the dam. Dynamic loads that exceed the design peak ground acceleration can lead to potential sloughing of the filters.

This paper presents the method and results obtained by the pseudo-static approach to analyze the stability of the slopes subjected to blast vibrations. The blast vibration at the bedrock is treated as a simple harmonic motion in the horizontal direction. Maximum allowable peak particle velocity values are proposed for different critical sections of the dam. The results show that the potential slough in the filter layers upstream of the dam is identified as a credible failure mode that governs the dam safety and appropriate vibration limits. The study highlights the importance of monitoring and understanding the properties of the different components of the tailings dams that may be impacted by blasting vibrations.

Introduction

While earthquake considerations for the design of tailing storage facilities (TSFs) are commonly practiced

within the tailings industry, methods and considerations for blasting induced vibration are less common. Blast induced vibrations are associated with short duration high frequency pulses, which are fundamentally different from ground vibrations caused by earthquakes. Regardless, it is intuitive for the sake of dam safety, that some limits must be prescribed when blasting in the vicinity of TSFs. This paper explores a common method for determining appropriate blasting limits and offers some commentary on its shortcomings in the application to one specific facility, while proposing some additional methods and considerations.

Problem definition

This study was carried out to assess the impacts of blasting from a proposed quarry development on the embankments of a particular TSF. Figure 1 shows a typical cross-section of the TSF in question. The TSF is a 3.1 km long zoned rockfill embankment with an upstream slope at an inclination of 2.5H:1V and a downstream slope inclination of 2H:1V, and a crest width of approximately 10 m. The TSF was constructed with Select Mine Fill (SMF) and Mine Rock Fill (MRF), sourced from blasted rock from an adjacent open pit. SMF is a selective rock fill used at the upstream slope of the TSF as a transition layer between MRF and a coarse filter layer. This facility employs a two-layer filter system on the upstream slope of the embankment, which is composed of a fine filter material (sand) underlain by coarse filter material (gravel). The fine filter is overlain by an upstream HDPE liner. The proposed quarry was located immediately within the TSF basin.

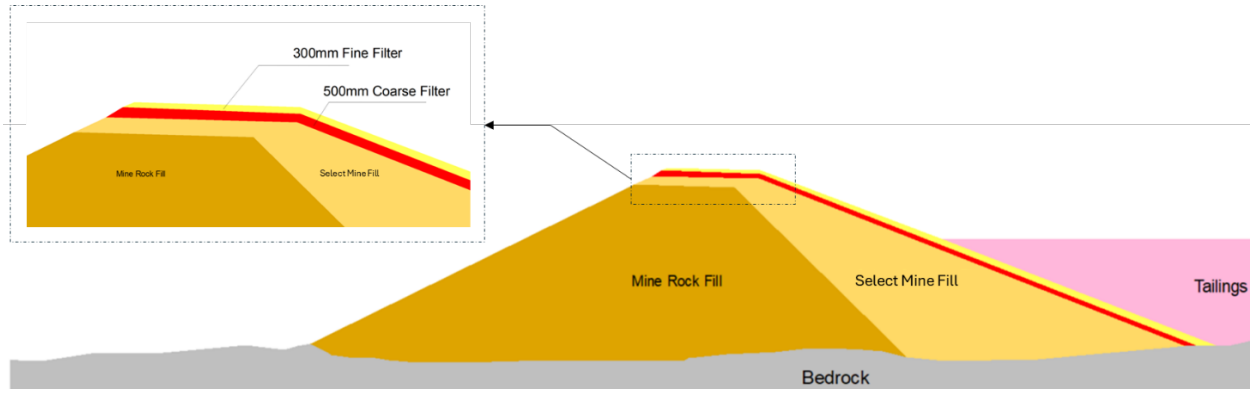

Figure 1: Typical cross-section of the TSF

Methodology

Identifying TSF critical components

Intuitively, downstream failure of the embankment is considered primarily in relation to vulnerable components and failure modes of the TSF. However, after a cursory examination of available limit equilibrium stability analyses, the fine filter on the upstream slope is identified as the most critical

component of the dam, when subjected to ground motions. If the fine filter were to slump, it would not be able to perform its primary purpose (convey seepage if there is any) and this could lead to damage or further damage of the overlying HDPE liner. Repairing the filter in the instance of a slump could be very difficult, especially if the water depth is significant, and could potentially lead to processing plant impacts.

Finding the yield acceleration

Finding the limits of the filter under pseudo-static loading was the first step in defining blast limits for our TSF. Blasting induced vibration will create an inertial force that is proportional to the mass of the slip surface:

$$F = KW$$

Where K is the response peak ground acceleration coefficient and W is the weight of the soil mass in the slip surface. A simple pseudo-static approach was utilized here, in which back analyses of the dam stability are carried out to infer a minimum operating yield acceleration, assuming the Factor of Safety (FoS) could have been as low as unity at that time.

Pseudo-static Limit Equilibrium (LE) analyses were carried out using GeoStudio SLOPW/W software to estimate the yield acceleration at critical sections. Two sections of the TSF at approximately Stations 06+00, and 11+00 have been considered in the analyses, based on proximity to the blasting area and height of the structure. Seepage analyses were carried out to estimate the steady-state phreatic surface considering the pond operating using the SEEP/W software. The Morgenstern and Price method of slices for the calculation of rigid body forces and slip surface optimization were adopted in the analyses. The geotechnical properties of the TSF were established from engineering judgement and experience with similar materials and projects. Table 1 summarizes the material parameters used in the stability analyses. No undrained materials were modeled initially.

Table 1: Material parameters used in the stability analyses

Material	Unit weight (kN/m^3)	Shear strength
Mine Rock Fill	21	ϕ' = 38, c' = 0 kPa
Select Mine Fill	20	ϕ' = 32, c' = 0 kPa
Fine Filter	19	ϕ' = 35, c' = 0 kPa
Coarse Filter	20	ϕ' = 35, c' = 0 kPa
Tailings	11	ϕ' = 0, c' = 10 kPa

The failure criterion was set based on the potential sloughing of the filter layers along the unsupported slope; therefore, the slip surface was limited to the filter layers extending from the crest to the upstream toe

of the dam. Figure 2 shows the results of the stability analyses in the studied sections. The TSF yield acceleration was assessed using the pseudo-static analysis and calculated as 0.21 g for both sections.

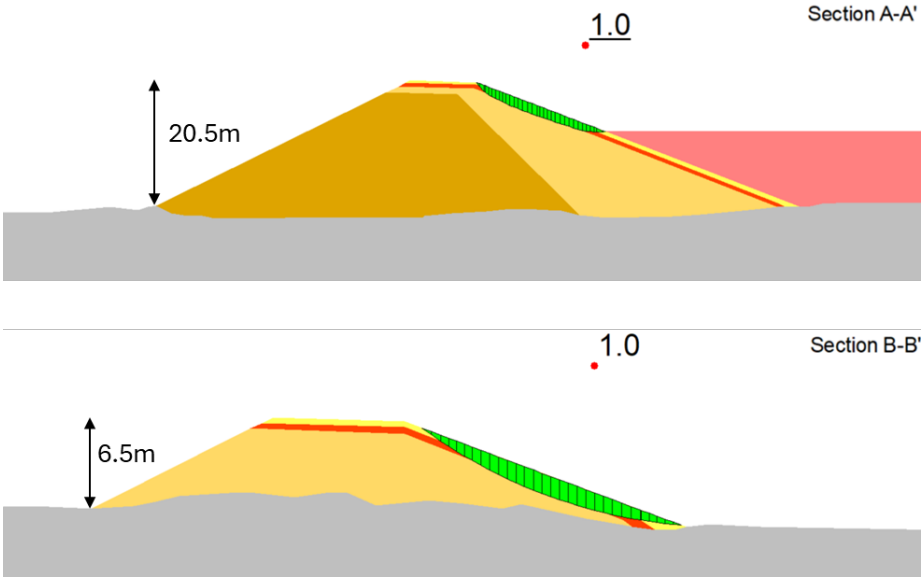

Figure 2: Stability analyses results for Sections A-A' and B-B'

Relationship to PPV

Relating blasting and TSF engineering disciplines to one another requires a relationship between yield accelerations and the associated Peak Particle Velocities (PPVs). To do so, a simple harmonic motion is firstly defined as:

$$x = PPD\sin(\omega t + \theta)$$

$$\dot{x} = PPD\cos(\omega t + \theta)$$

$$\ddot{x} = -PPA\sin(\omega t + \theta)$$

Where x is displacement, $\dot{x}$ is velocity, $\ddot{x}$ is acceleration, ω is circular frequency of the ground motion, θ is phase shift, PPD is peak particle displacement, PPV is peak particle velocity, and PPA is peak particle acceleration equal to ωPPV.

The response ground yield acceleration can be calculated from the input bedrock ground motion (Wong and Pang, 1992):

$$K = K_a(\frac{PPA}{g})$$

Where K_a is the magnification factor determined from response analysis and g is the acceleration of gravity. By combining the abovementioned equations, the limiting PPV (or PPV_c) is estimated as:

$$PPV_C = \frac{K_C g}{\omega K_a}$$

Where PPV_C is the PPV maximum limit, K_c is the yield acceleration coefficient, g is the gravitational acceleration, and ω is the circular frequency of the ground motion and K_a is the magnification factor determined from response analysis. K_a varies with the frequency of the induced vibration and the fundamental period of the slope. K_a for a damped single-degree-of-freedom system subjected to a simple harmonic forced vibration is

$$K_a = \sqrt{\frac{1 + 4\lambda^2\alpha^2}{(1-\alpha^2)^2 + 4\lambda^2\alpha^2}}$$

Where λ is the soil damping factor. A soil damping factor of 0.2 for the fundamental mode of vibration has been assumed. A can be evaluated from the division of input vibration frequency by natural frequency of slope:

$$\alpha = \frac{\omega T_1}{2\pi}$$

Where T_1 is the fundamental period of the slope. An approximate method to estimate T_1 is (Wong, 1991):

$$T_1 \approx \frac{3.3h}{S}$$

Where H and S are height and shear wave velocity of the slope, respectively. Accordingly, in blast monitoring records for similar patterns in the area, the dominant frequency of the blast ranged from 30 to 40 Hz. A design frequency of 30 Hz was conservatively assumed for the analysis. Values of ωK_a for different V_s/H and F are plotted in Figure 3 (Wong and Pang, 1992).

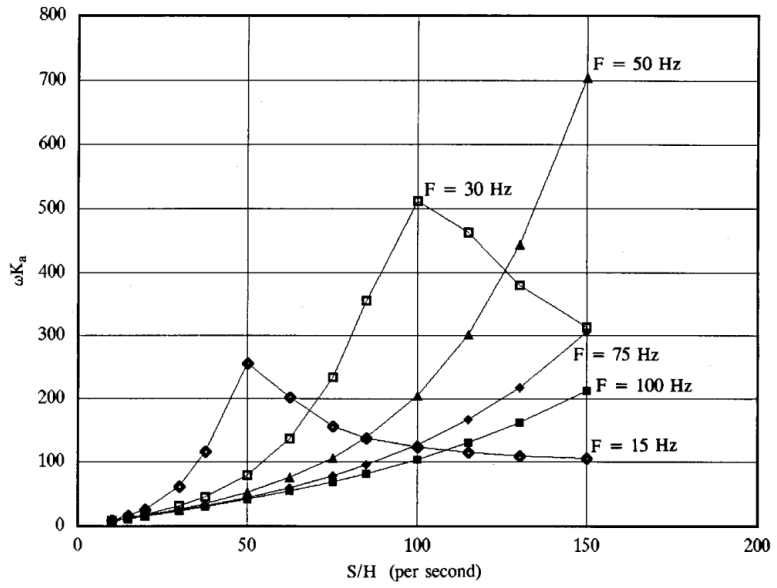

Figure 3: ωKa versus V_s/H for slopes with horizontal bedrock based on single-degree-of-freedom model (Wong and Pang, 1992)

Outcomes

Table 2 presents the calculated PPV limits for different structures within the TSF based on the single-degree-of-freedom method. Pseudo-static analyses representing the worst-case condition of the TSF filters sloughing has shown that PPV limits provided in Table 2 will produce a FoS against slope instability of greater than unity. The pseudo-static analysis approach is considered conservative (Wong and Pang, 1992). As more experience is obtained through blasting within the quarry, additional optimizations may be possible for the recommended PPVs.

Table 2: Calculated maximum PPV limits

Location	Distance from initial blasting location (m)	Yield acceleration	Limiting PPV (mm/s)
STA 06+00	300	0.21g	7
STA 11+00	480	0.21g	22

PPV attenuation model

The proposed limits were then compared with anticipated PPVs from surface blasting. A common method for predicting PPV from blasting is as per the US Bureau of Mines (1959) according to:

$$PPV = k\left(\frac{D}{\sqrt{W}}\right)^{-b}$$

Where D is distance (m), W is explosive charge per delay (kg), and k and b are site-specific factors. The blasting design was then conducted to yield anticipated PPVs at the upstream toe of the TSF below the limits shown in Table 2. Factors of safety were also added to the prescribed limits, to capture varying degrees of uncertainty associated with the analyses.

Monitoring plan and risk mitigation measures

Based on the critical parameters, the following monitoring was recommended to be conducted during the blasts at the TSF quarry:

- Monitoring PPV, PPA, and blast wave dominant frequency using seismographs as the main products of the blast.
- Porewater pressure monitoring at vibrating wire piezometer locations in the TSF to measure any excess pore pressures induced by blasting.
- Monitoring deformations to confirm that there are no excessive displacements or settlements.

The intent of the monitoring plan was to collect data to refine understanding of wave propagation so that the blast plan can be optimized for rock fill production while respecting dam safety constraints. An

important assumption of the methodology is that failure will be triggered once the blast induced parameters exceed the proposed limits.

Method shortcomings

General shortcomings

While the method outlined presents some rigor around prescription of specific blasting limits, the disastrous earthquakes in Alaska and Niigata in 1964 produced a realization that pseudo-static methods of analysis did not give reliable predictions for stability during earthquakes, with strength reduction during cyclic loading identified as one of the key issues (Jefferies and Been, 2016). Subsequently, relying on pseudo-static methods exclusively is no longer common in TSF best practice, and inconveniently, pseudo-static analyses were the basis of our blasting prescription method described above.

Undrained loading

In the instance of our facility, a saturated (or near saturated) filter could be prone to undrained failure if loaded too rapidly. As the filter is placed loosely to promote drainage, it will almost certainly be contractive and potentially be prone to undrained failure, potentially initiated by blasting. Other facilities may have materials in their cores or foundations that also may be prone to undrained failure.

While performing undrained stability analyses of the filter will give an estimation of its stability in the instance of undrained loading, it will not be linked back to the prescription of any blasting limit; i.e., any blast of any magnitude could or could not trigger undrained failure.

Liquefaction potential

Regarding potential liquefaction of the filter (if saturated), CPTu based triggering methods are not practical, given an only 300 mm layer thickness of filter. This leaves only laboratory testing to determine the filter's resistance to potential liquefaction (Cyclic Resistance Ratios [CRR]) when exposed to varying Cyclic Stress Ratios (CSRs) from blasting. Relationships for duration – number of cycles – Moment Magnitude (Mw) do exist; thus, the Magnitude Scaling Factor (MSF) for calculation of the CSR could be completed, in combination with earlier derived accelerations. Limiting anticipated blasting PPV limits to a CSR would then provide additional prescription around blasting limits.

This was not completed in our study but will be perused if further blasting of higher charge weights or higher predicted PPVs are to take place.

Conclusion

In conclusion, while earthquake considerations for the design of TSFs are commonly practiced within the

tailings industry, methods and considerations for blasting induced vibration remain less common. Despite this lack of common practice, it is essential for the sake of dam safety to prescribe limits when blasting near TSFs. This paper has explored a common method for determining appropriate blasting limits, highlighted its shortcomings in application to a specific facility and others, and proposed additional methods and considerations to enhance similar assessments.

Primary shortcomings of the method include an inability to model strength reduction during cyclic loading, including undrained behavior and potential liquefaction, if materials are susceptible. This shortcoming is not only relevant to this specific case study's fine filter, but to all dams encompassing a loose potentially saturated material, be they foundation units, embankment fills, filters and cores, or the tailings themselves in instances of upstream raises.

Some methods to safeguard against these shortcomings are identified; however, they do not do well in linking back to prescribe specific blasting limits, or to helping identify if a particular blast will impact dam stability and subsequent dam safety.

The geotechnical control process for tailings stacking is crucial to ensure structural stability under both geomechanical and critical state conditions throughout operational phases and post-closure. Tailings exhibit distinctive characteristics compared to natural soils due to their production process involving physical and chemical stages, prompting extensive research into methodologies for controlling geotechnical parameters to improve compacted tailings layers.

Material compaction is regulated through various methodologies, including Hilf tests, Proctor tests, nuclear densimetry, non-nuclear densimetry, and penetrometer tests. In the stacking process of iron ore tailings, the presence of significant iron percentages (ranging approximately from 10% to 30%) poses challenges in conventional testing. Variations in density, influenced by the variability in iron content, result in compaction determinations exceeding 100%. The variation in the magnetic field influences densimetry tests. Penetrometer studies encounter difficulties due to the high resistance exhibited by tailings post-compaction.

To achieve better control over critical state parameters and susceptibility to liquefaction both during operation and post-closure, as well as indirectly monitor the degree of compaction, studies utilizing void ratio tests in the field have demonstrated linear results. In order to establish the control parameters, the critical state line of the tailings was drawn up through laboratory tests using techniques such as those described by Jefferies and Been (2016) and Viana et al. (2021). By determining the void ratio, which relates to the stresses to which the pile will be subjected at its maximum height, we determined the maximum void ratio that the layers of the pile could have, maintaining the structure on the dilatant side and thus not being susceptible to liquefaction.

Introduction

In mineral extraction activities, various quantities of materials are extracted and generated in different stages of the process. The ore extraction process, the location and depth of deposits, the available technologies at extraction sites, and the processes involved are among the several factors that determine the amount of waste generated by mining activities. The main types of waste generated are overburden and tailings. Overburden consists of materials from the extraction activity, due to the layers of soil covering the ore. Tailings result from the beneficiation process of these mineral substances within plants, which can involve purely physical or physico-chemical stages. Among the purposes of beneficiation are standardizing the size of fragments, removing minerals without economic value associated with the mined rocks or soils, and increasing the quality and physico-chemical purity of the final product. In most cases, minerals found in nature require beneficiation to improve their properties (Luz and Lins, 2018).

Figure 1 presents a schematic representation of a mineral exploration process involving physical stages.

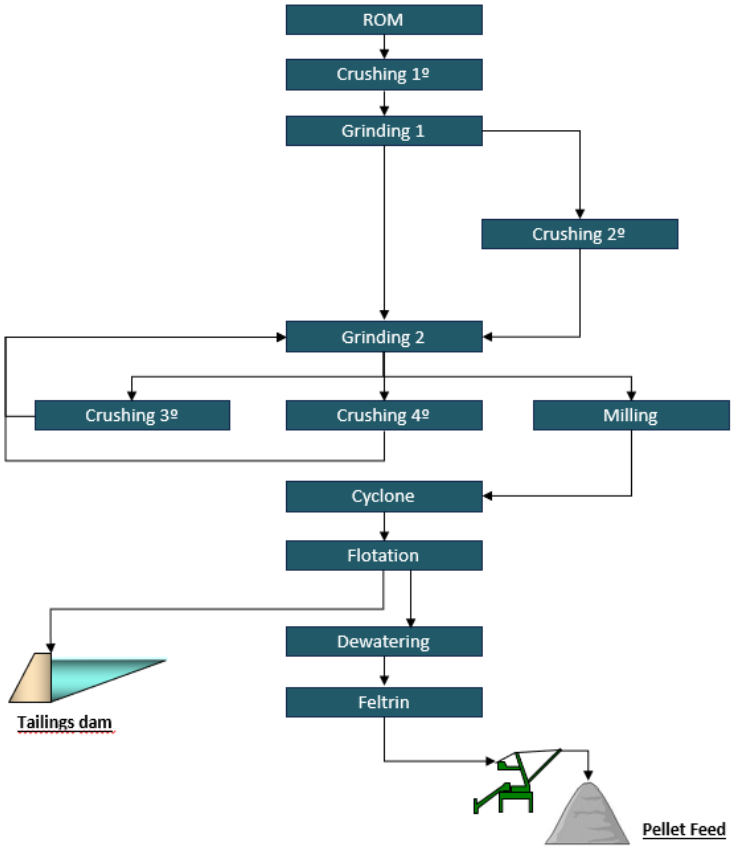

Figure 1: Macro flowchart of the mineral exploration process (Eloi et al., 2024)

Mining tailings are the materials generated in the separation process of ore from concentrate, composed of very fine particles and, in some cases, chemical residues from the ore beneficiation stage (IPEA, 2012). Since tailings result from a sequence of physical and chemical processes, they exhibit various characteristics influenced by the beneficiation process, such as particle size distribution, particle shapes, density, mineralogical composition, and moisture content. Due to these beneficiation-influenced characteristics, tailings differ from those expected of natural soils (Vick, 1983).

In the exploration of iron ore, the beneficiation process of hematite, one of the main iron oxides, is notable. During the separation process, fine-grained tailings are formed (Gomes, 2017), characterized by high saturation levels. These can be categorized based on their particle size distribution into silts and clays or sands. Silts and clays tend to exhibit characteristics of high compressibility and plasticity in their particle size distribution, making them difficult to settle. Sandy tailings, on the other hand, have high shear strength and permeability.

Due to the high saturation levels of iron ore tailings, controlled stacking processes are preferred over dam disposal methods. Filtering processes are therefore implemented to remove water from the tailings. This involves hydro cyclones with the addition of flocculants to improve material density, thickening with flocculants and coagulants to adjust saturation and separate materials, and filtration using either disc filters or filter presses, depending on the technology used. After filtration, the thickened and filtered slurry is conveyed via conveyor belts to temporary stacking areas, where the tailings are stored before being transported to the controlled stacking site.

Figure 2 illustrates an iron ore tailings filtration plant with labeled structures, operating in the context of this study.

Figure 2: Disc filter tailings filtration complex

Methodology

This work demonstrates the geotechnical control systems used in the iron ore tailings stacking process, as well as the results obtained from a case study. These processes are divided into controls for the filtration plant, controls for stacking to ensure approved layers of compacted tailings, and instrumentation controls to measure structural safety factors throughout stacking and post-closure.

The geotechnical controls at the filtration plant include iron content analyses, crucial for understanding the densities at which tailings are directed to the compaction areas, moisture content analyses of filtered tailings leaving the plant, and particle size distribution analyses of the tailings after filtration.

Geotechnical controls during the stacking process consist of field controls such as moisture control, compaction control, void ratio and particle size distribution, and laboratory control tests to assess the geomechanical parameters of strength. Additional campaigns with SCPTU tests are conducted to further verify the strength parameters of compacted tailings.

Various instruments including piezometers, inclinometers, load cells, settlement meters, water level meters, and flow meters in drains are installed in the structure to constantly monitor parameters that can affect safety factor models of the structure.

Data and discussion

The geotechnical analyses conducted in the iron ore stacking process aim at ensuring stability and operational safety of the structures. Control over material characteristics imposes limits on the process, such as the compaction energy to be applied or the rates of structure raising when assessing pore pressure dissipation. Regarding iron ore tailings, given their predominant particle size distribution of silts and sands and thus their high susceptibility to liquefaction, recent studies demonstrate the necessity of compaction control for stacking, to prevent material from exhibiting contractive behavior.

Geotechnical controls applied at the filtration plant

In the filtration process, initial controls are carried out to verify if the produced tailings are within acceptable limits for the stacking project. Should the material fall outside specified ranges, it is directed to areas where it can be disposed of without controls, such as exhausted pits or active dams.

The first test conducted is to assess the iron content in the tailings. Higher iron contents are known to be associated with increased fines, which directly influence the moisture content of the tailings. This, in turn, requires more effort in drying the material before compaction, impacting the processing times related to work areas for tailings, initial moisture content affecting drying time, and fleet capacity. Therefore, setting a limit on the iron content indirectly controls the moisture content of the material. Another geotechnical control related to iron content is the density of the material. Higher iron percentages increase

material density, leading to variations in the amount of material mass required to define stacking layers with controlled volume. In the case under study, a 25% iron content limit was implemented to indirectly control the geotechnical parameters of density, moisture, and particle size distribution.

In this studied complex, material sampling for iron content evaluation occurs every fifteen minutes, with analyses performed on a composite of every four samples mixed, thus representing hourly production of iron ore tailings.

As mentioned in the previous paragraph, moisture control directly correlates with the required work time for tailings to reach suitable compaction conditions. This ensures that the material is compacted near its optimal moisture content as determined by Proctor tests, achieving the required compaction level to maintain dilatant behavior. Moisture tests are conducted on fractions of the plant using the halogen moisture analyzer method, providing timely results. Table 1 illustrates moisture and iron content control over a 24-hour period for materials processed in this system in the year 2024.

In the samples collected at the plant, particle size distribution controls are conducted using laser granulometry tests. As mentioned, variations leading to higher fines content can affect the material's moisture content, thereby increasing drying time. Larger particle sizes can promote the formation of permeable zones within the stacking, potentially creating water pockets that may result in localized excess pore pressures and points more susceptible to liquefaction. Therefore, a particle size distribution range has been specified for this additional control of the filtered tailings.

Table 2 illustrates the particle size fractions evaluated at the plant in the same samples mentioned in Table 1.

Geotechnical controls applied in stacking operations

After the filtering process, the reject material meeting predetermined parameters within established limits is directed to stacking areas. These materials are transported by heavy-duty vehicles and spread out, worked to reduce moisture, and compacted in compacting squares using earthmoving equipment. In this context, the initial controls related to the rejects are those concerning the material's working moisture content in the field. To achieve this, Proctor tests with standard energy are conducted every 3,000 m³ of material to determine the working moisture content in subdivided areas in the field.

Figure 3 presents results from Proctor tests with standard energy conducted on rejects from the studied site. As indicated by the results, the optimum moisture content for compaction typically ranges between 9% and 13% in most cases. Based on conducted studies and understanding that the material can perform within these limits, it was decided to eliminate controls for deviations from the optimum moisture content

reference value and to require that the material should only be within this moisture range. Thus, according to Figure 4, it is evident that the majority of materials fall within this sample range.

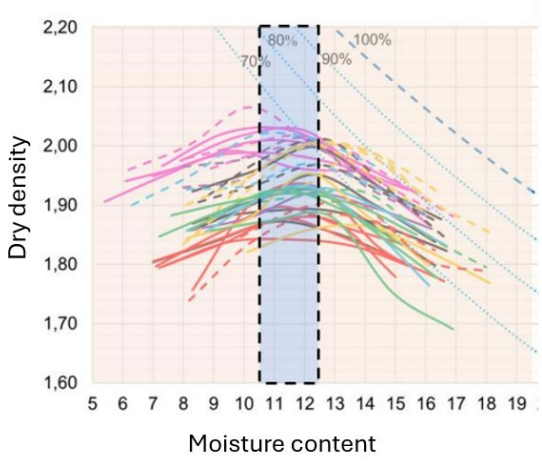

Figure 3: Proctor tests with standard energy on samples from a period

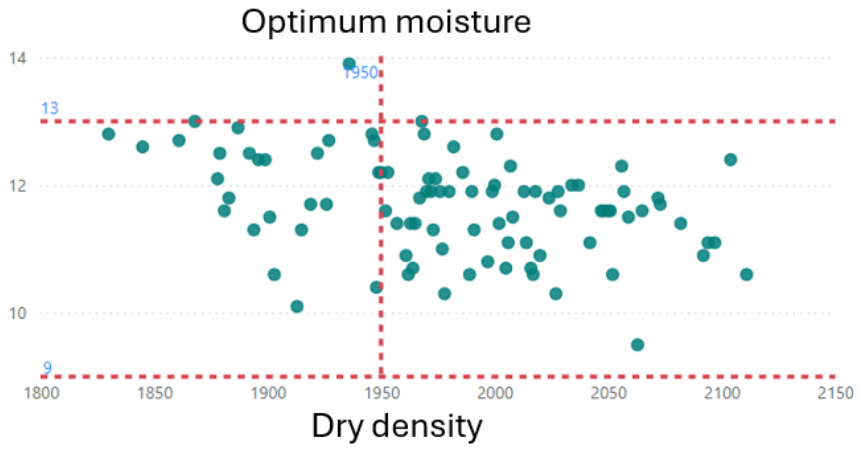

Figure 4: Relationship of moisture tests analyzed within the range over a period

With the results from Proctor tests with standard energy determining the optimum moisture content, and the material being within the established moisture range, the material is compacted in layers of 35 cm thickness with a permitted variation of 5 cm. After compaction, tests to determine the void ratio of the reject material are conducted to verify if the results maintain the material in the dilatant branch when evaluating the critical state lines of the material. Laboratory studies to determine the critical state lines have shown that these vary according to the material's gradation. For the sake of safety, the designers and the Engineer of Record for the structure have determined that the void ratio for approval of the material in this stacking case study should be 0.60. Hence, a control regarding void ratios for approval of the layers is conducted throughout the stacking process, as depicted in Figure 5.

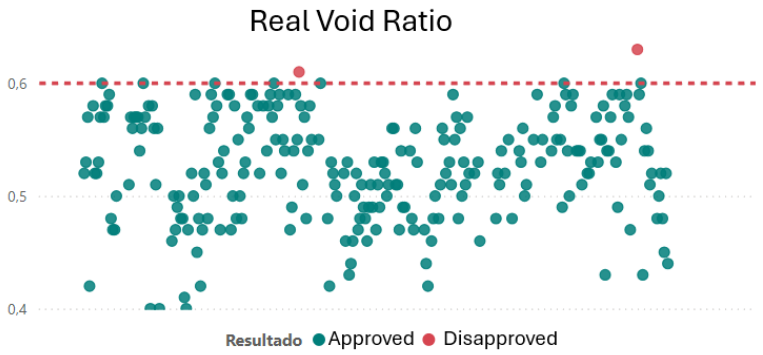

Figure 5: Relationship of tests approved by void ratio and failed tests over a period

As a reassessment parameter for plant results and to verify potential grain breakage, characterization tests such as sieving, and sedimentation tests, are conducted in accordance with ABNT NBR 7181 every 3,000 m³. These tests are not criteria for material rejection but serve solely as investigative measures to understand material characteristics after compaction.

Drained and undrained triaxial tests and oedometer tests are performed on blocks extracted every 3 meters of stack height. These tests verify the strength and compressibility parameters of the materials. The objective of these campaigns is to ensure that the parameters used in the safety factor models for the stack remain consistent. In the same blocks, tests are conducted to recharacterize the materials, ensuring that the characteristics of compacted rejects do not vary with stack height. Figures 6 and 7 illustrate the results of tests conducted on blocks from the stack under study.

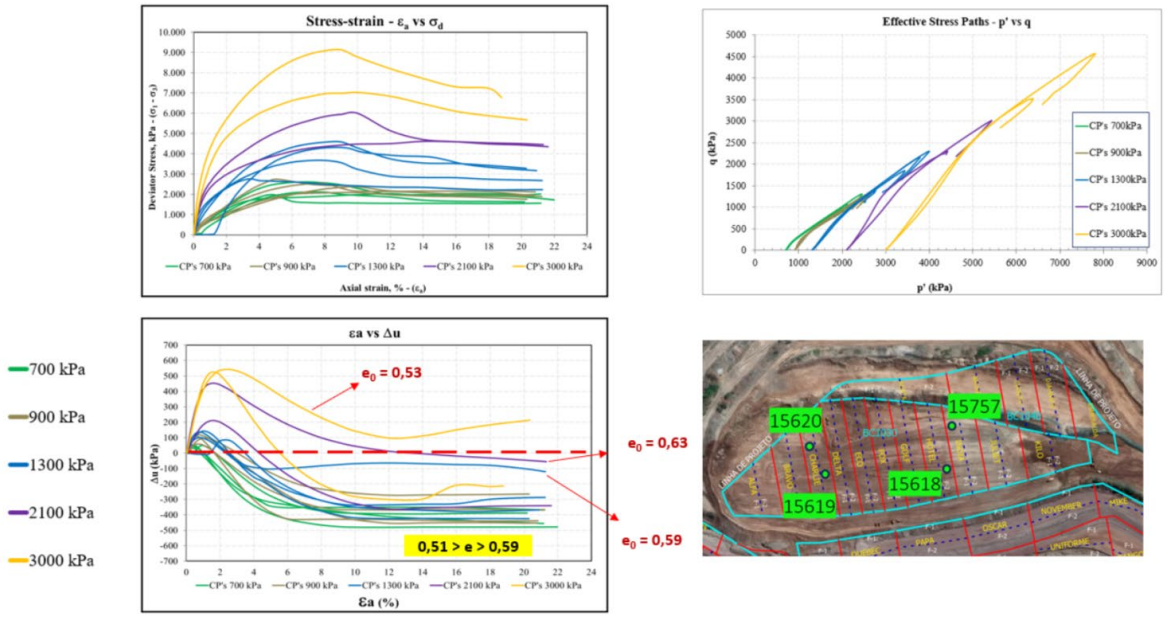

Figure 6: Results of undrained triaxial tests conducted on the reject material

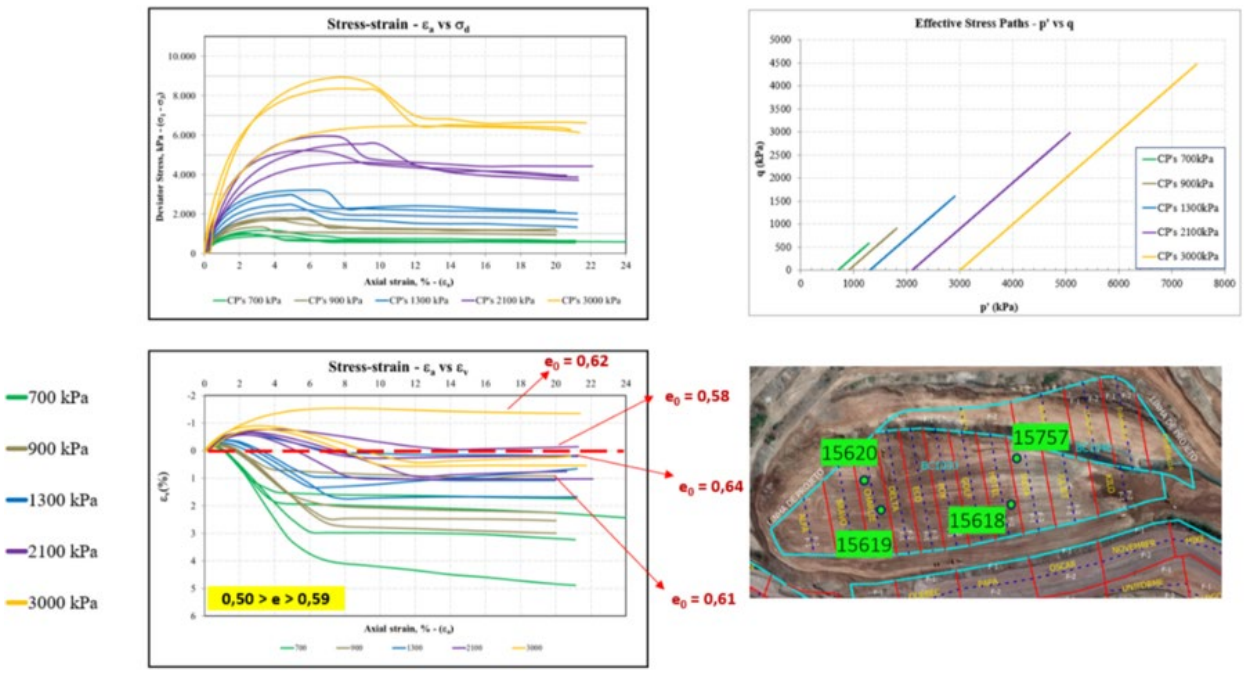

Figure 7: Results of drained triaxial tests conducted on the reject material

Geotechnical control through piezocone tests with pore pressure measurement, dissipation tests, and seismic tests are conducted with the objectives of identifying areas of excess saturation, estimating material stiffness for numerical analysis, and reevaluating material behavior. These tests are repeated annually after rainy periods, and their quantitative determination is defined by the Engineer of Record for the structure.

Geotechnical controls through instrumentation

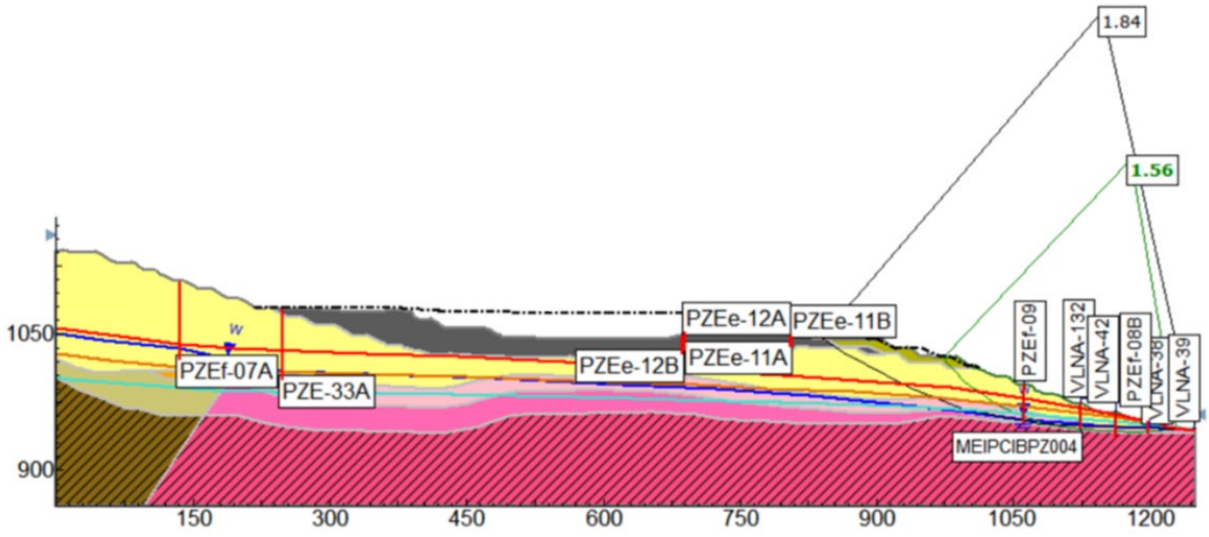

Figure 8: Safety factors of one of the structure sections evaluated based on monitoring instrument data

As described by Hawley and Cunning (2017), permanent waste and overburden stacks must have instrumentation and monitoring plans for the risks involved throughout the structure's lifespan and after closure. Among the instruments installed in iron ore tailings stacks are piezometers, load cells, settlement gauges, surface markers, geophones, inclinometers, water level meters, and flow meters in drains.

All instruments aim to assess the structure's behavior with respect to operational safety factors. To establish control levels for geotechnical structure instrumentation, as outlined by the Bureau of Reclamation (2014), potential failure modes affecting the structure must first be identified. Control levels for each instrument's purpose listed above were defined during pre-operation phases, throughout operational years, and after structure closure. Figure 8 illustrates the safety factors derived from models developed monthly by the structure's Engineer of Record, based on readings from installed instruments.

Conclusion

Geotechnical controls associated with various stages of the stacking process of filtered iron ore tailings aim to ensure the stability of structures during operational phases and post-closure. The physical and mineralogical characteristics of the tailings, such as iron content, moisture content, and particle size distribution, directly influence the workability of the material and are therefore crucial to monitor during the filtration stage.

Control during compaction stages aims to ensure that the material placed in the structure meets design strength requirements and predetermined model characteristics. Void ratio control was developed to monitor the critical state of the material, consistently maintaining its dilatant characteristics. The high susceptibility to liquefaction of tailings, due to their silty and sandy nature, necessitates careful control of these parameters, particularly highlighted after recent incidents of tailings dam failures due to liquefaction.

Studies conducted on the stacking process have shown that compacted tailings exhibit high resistance during SCPTU penetration tests, indicating a need for further development in future studies to enhance the performance of such tests.

Instrumentation of iron ore tailings stacks during operational phases serves not only to monitor anomalous behaviors but also to ensure the stability of the structure, which is evaluated in studies aimed at determining safety factors for the structure.

2D and 3D Numerical Analyses of a Trial Embankment Construction over a Tailings Storage Facility

Alfonso Cerna Diaz, AECOM, USA

Pooya Sheykhloo, AECOM, USA
Richard Davidson, RRD LLC, USA
Theo Gerritsen, Rio Tinto, Australia

Abstract

Constructing a trial embankment over an inactive tailings storage facility (TSF) aided understanding of the consolidation and shear behavior that would take place during construction of a new embankment founded on an inactive TSF. Based on a series of 3D finite difference and 2D/3D finite element flow-deformation back analysis on a well-controlled trial embankment construction, the deformation and excess pore pressures of the tailings dam were found to be controlled by the underlying tailings state and permeability. Given the uncertainty in the use of the constitutive model, hydraulic conductivity, and dimensionality applied to tailings, this paper provides insight into the use of two-dimensional and three-dimensional plasticity-based and consolidation models to capture flow-deformation at a "system-level" to evaluate the deformation and stability of tailings dams, to be used as part of performance-based evaluations as recommended by GISTM. This back analysis study highlights the use of consolidation/coupled modeling for tailings dams involving construction limits that permit partially drained conditions.

Introduction

Key aspects to verify adequate performance of current or future tailings storage facilities (TSFs) are geotechnical evaluations to identify preferred construction methods for expansion of TSFs, assess potentially fatal flaws of design, evaluate ground improvement methods, and establish construction requirements or operational criteria. Routine geotechnical analyses are performed based on field investigations and laboratory testing, to assess the material behavior of soft and very loose tailings; these analyses are limited to the boundary conditions imposed in the laboratory and by in-situ testing. A field performance using a trial embankment offers a unique opportunity to evaluate tailings behavior on a large scale, providing a site-specific case history to a TSF project, thus helping to reduce and manage risks and

uncertainties. This leverages GISTM good practice guide recommendations on performance-based approach evaluations (ICMM, 2021).

In this paper, using the Settle3 uncoupled finite difference (FDM) approach and the 2D/3D NorSand PLAXIS fully coupled finite element method (FEM) modeling of a well-characterized trial embankment case history, the role of compressibility and permeability in capturing settlements and excess pore water pressures (PWP) is assessed. The results indicate that all modeling approaches with a "best estimate" of compressibility and permeability values, following the recorded construction sequence, can reasonably capture recorded settlements and the Excess PWP distribution with 3D coupled formulation, giving a more realistic PWP distribution during construction loading.

Field-scale construction program

A case history of the response of a 30-ft trial embankment with 4H:1V slopes on wick drain treated area, 6H:1V slopes on a non-treated area and a plan area of ~450' × 300' constructed over soft fine-grained mine tailings to capture a real-world shear and consolidation response in mine tailings. The trial embankment consists of a compacted embankment constructed over a non-wick untreated area and a wick treated area. Wicks were installed beneath one-half of the embankment on a 9 ft triangular spacing to a depth of 100 ft to reduce excess pore water pressures during construction. A detailed field monitoring program of settlements, PWP, and movements was carried out over a five-year time period from 2010 to 2015. The general subsurface conditions consist of a ~70 ft contractive decant pond clay (DPC) layer underlain by a thick dilatant whole tailings (WT) layer. The DPC in the South Impoundment was deposited in areas of the impoundment where tailings slurry was allowed to slow and pool. This included the historic decant pond areas. Flow channels formed at a sufficient distance from the single point discharges created enough quiescence for the finer-grained particles to settle out of suspension. Generally, whole tailings (WT) were deposited from the deltaic processes resulting from single point discharge and peripheral spigoting since the mid-1980s.

Details of the trial embankment, including profile instrumentation layout and construction photographs, are shown in Figure 1. Nested vibrating wire piezometers were installed at nine locations along the long axis of the embankment centerline. Three nested piezometers were installed beneath the crest, two at mid-slope, two at the toe, and two approximately 30 ft from the toe at depths ranging from 5 to 130 ft below the ground surface. Settlement plates and survey monuments were installed to evaluate settlements and horizontal movements within the trail embankment area.

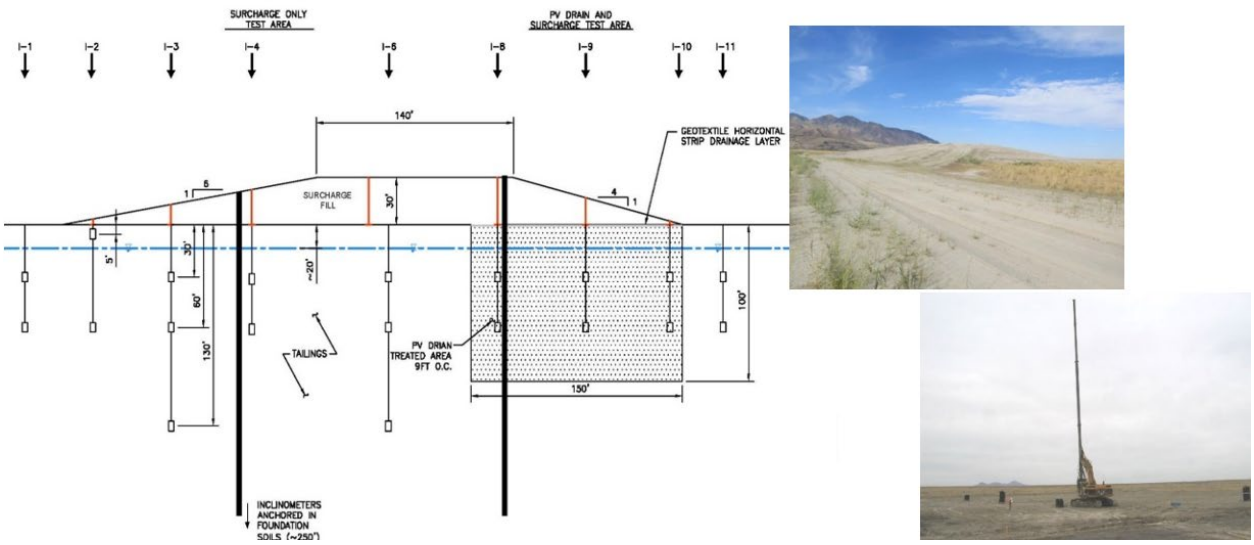

Figure 1: Trial embankment plan view, instrumentation layout and construction

The imposed trial embankment height and construction rate, along with observed field settlement and Excess PWP, are shown in Figure 2 at the non-treated locations.

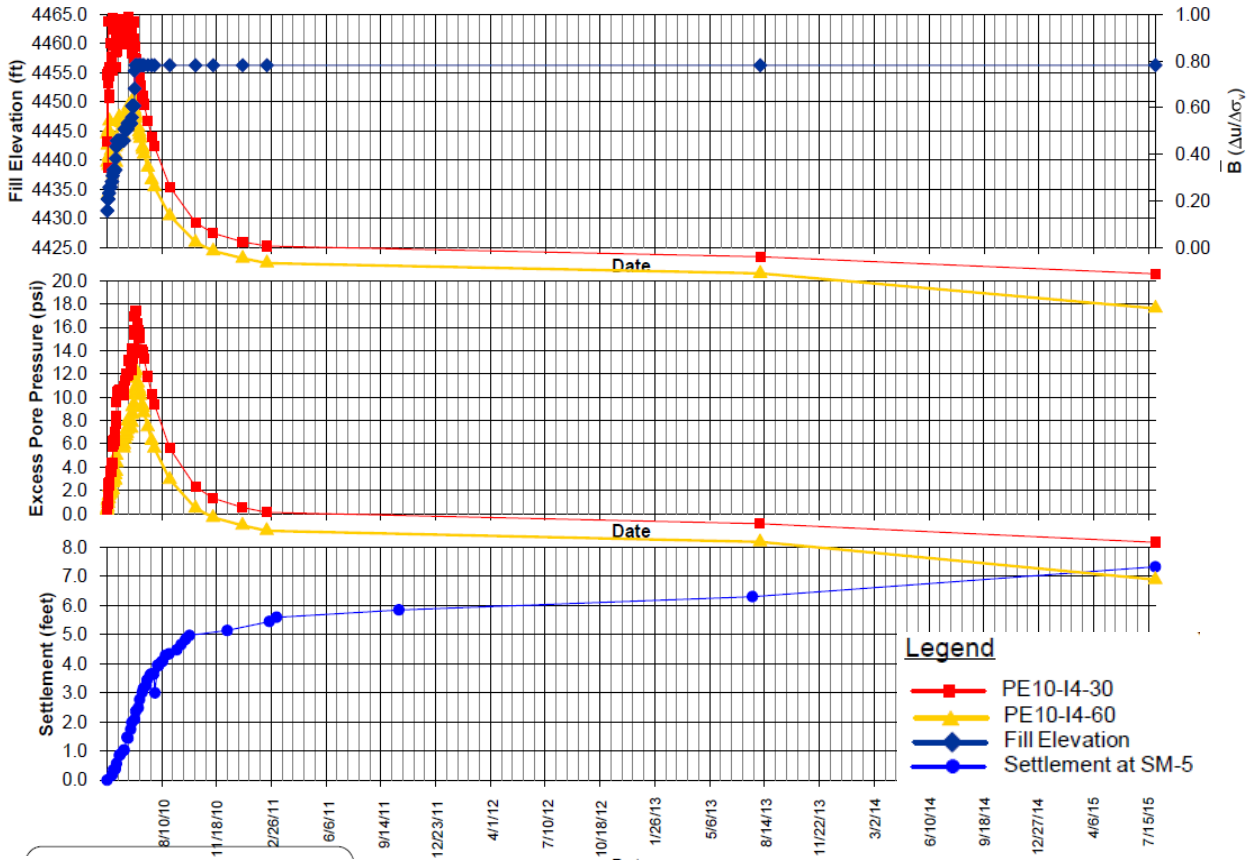

Figure 2: Trial embankment fill elevation, construction rate, B bar, Excess PWP, and settlements over 5 years

Piezometers in the untreated area indicate high loading induced Excess PWP with B-values of nearly 1.0, suggesting that the fill loads were supported in pore pressure. In contrast, deeper tailings did not generate significant Excess PWP. Wick drains reduced Excess PWP by ~50 percent. PWP returned to pre-construction eight months after the completion of the embankment in June 2010, as shown in Figure 2.

Field and laboratory testing program

The site investigation program included 2008 and 2010 CPT soundings, and 2010 and 2014 drill hole investigations. This information is summarized in Figure 3.

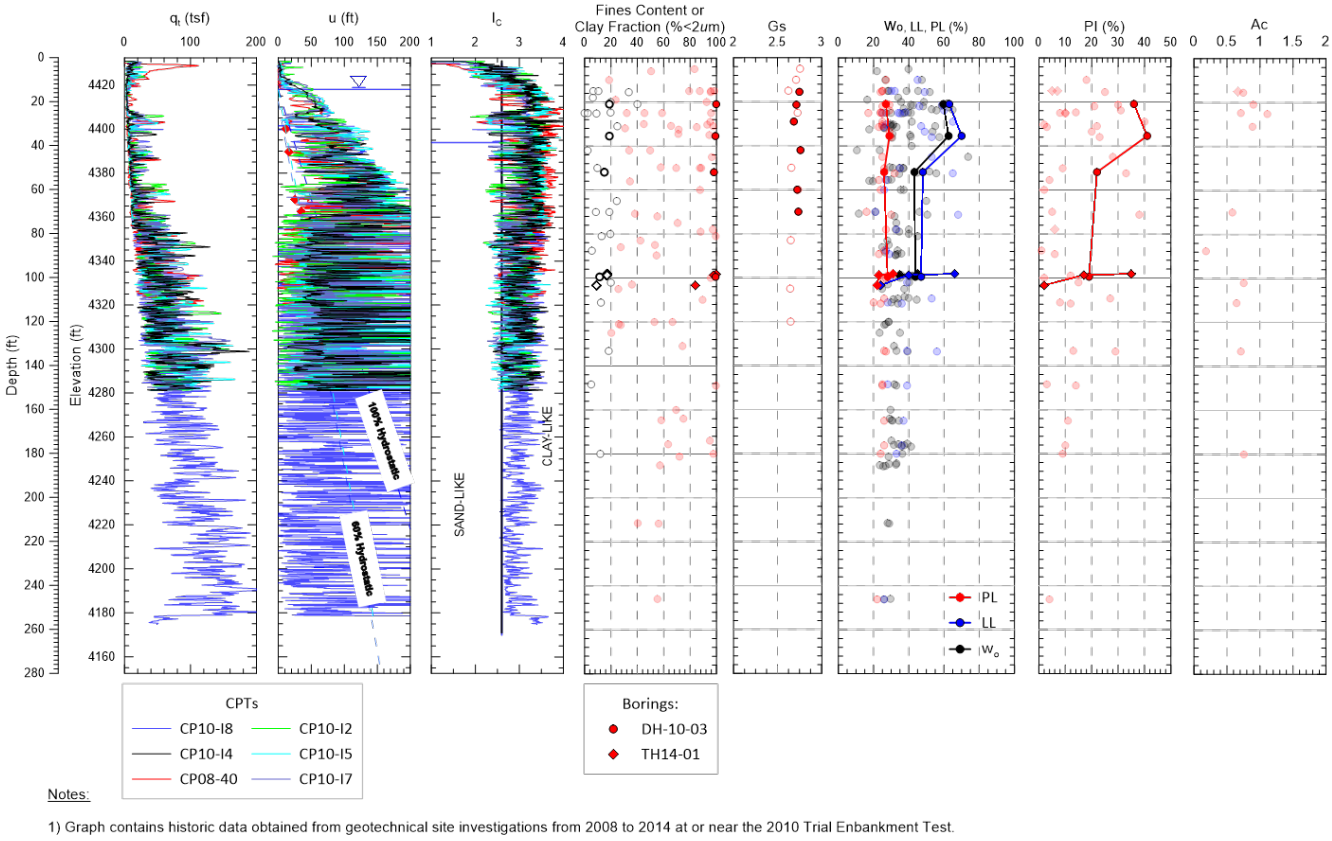

Figure 3: Trial embankment CPTs tip resistance, pore pressure response (u2), Ic, and index testing

The data from CPTs in Figure 3 shows that tip resistances are generally less than 20 tsf in the first ~60 feet, with associated contractive response (e.g., positive Excess PWP), and range from 20 tsf to less than 200 tsf from ~60 to 260 feet, with an increase of dilative response with depth (e.g., negative Excess PWP). PPD test locations and hydrostatic pore pressure measurements indicate that the percentage of hydrostatic varies between 70 to 100 percent below the trial embankment footprint. The soil behavior type index (Ic) traces show that within about the first 60 feet, the tailings material is predominantly clay-like, transitioning to slightly more sand-like behavior intercalated below 60 feet. The information gathered from

the 2010 to 2014 drill hole investigation also indicates this transition from clay-like material to sand-like material based on results from laboratory index tests results, showing a decrease in the Plasticity Index (PI) and Clay Fraction (CF) with depth.

Extensive laboratory testing programs performed during the past 30 years were used to evaluate the tailings shear and volumetric behavior. Engineering property testing included permeability, consolidation, DSS, and triaxial compression tests on undisturbed and reconstituted specimens.

Consolidation and strength tests were used to calibrate constitutive models used, while permeability testing was used to support the flow characteristics of the tailings. Triaxial testing was performed on both Shelby tube samples and reconstituted tailings to develop critical state lines for the materials (DPC and WT).

The DPC is a low to high plasticity silty clay (CL, CH) that can be found in various thicknesses along the impoundment. It has a low sensitivity based on the results of field vane shear tests and a review of the liquidity indices of the material. The material exhibits a contractive, nearly ductile, shear response under triaxial compression tests with an undrained shear strength ratio of 0.29 to 0.40. The CSL for the DPC along with shear-stress shear-strain and excess pore pressure are shown in Figure 4.

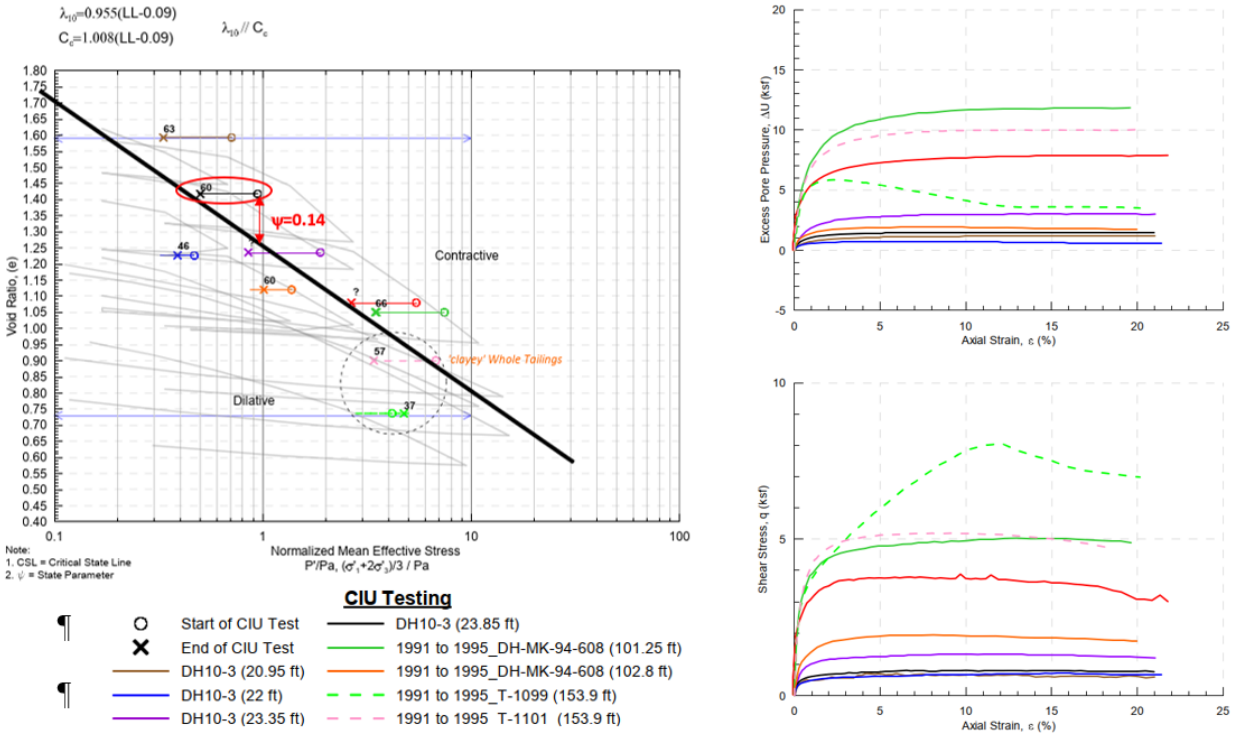

Figure 4: Decant pond clay critical state line and undrained triaxial testing results

The slope of the CSL is nearly parallel to the consolidation lines, compatible with clay-like behavior at the critical state. The DPC in the trial embankment area is slightly overconsolidated at the surface and

normally consolidated at depth. Generally, whole tailings (WT) material is characterized as contractive at surface and dilative at depth. This material was deposited from the deltaic processes resulting from single point discharge and peripheral spigoting since the mid-1980s. WT are typically composed of non-plastic to low plasticity, cohesionless tailings consisting of silty and sandy tailings. The CSLs for the whole tailings, along with shear-stress shear-strain, excess pore pressure, and stress path plots are shown in Figure 5.

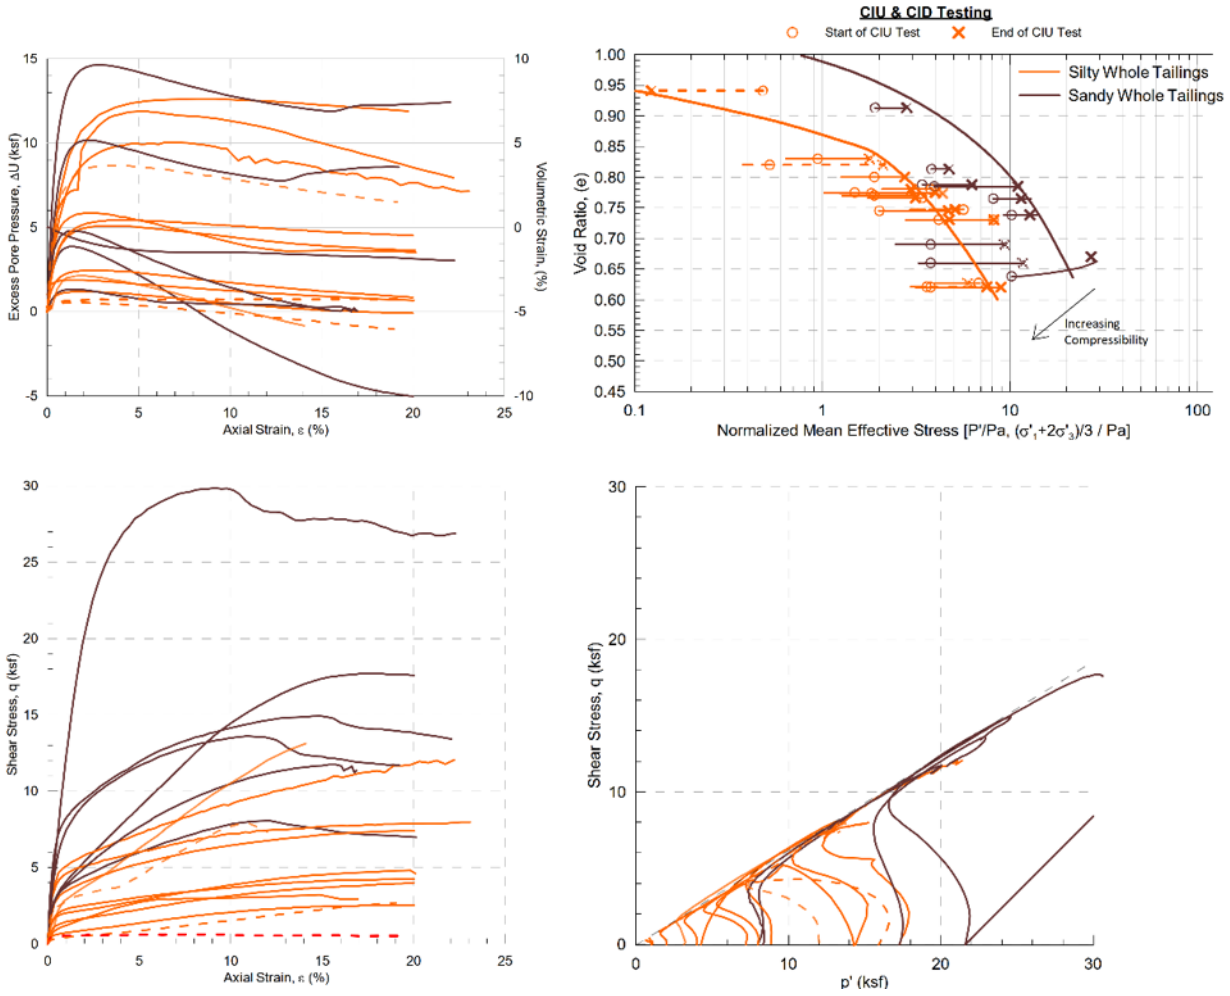

Figure 5: Whole tailings critical state lines and undrained triaxial testing results

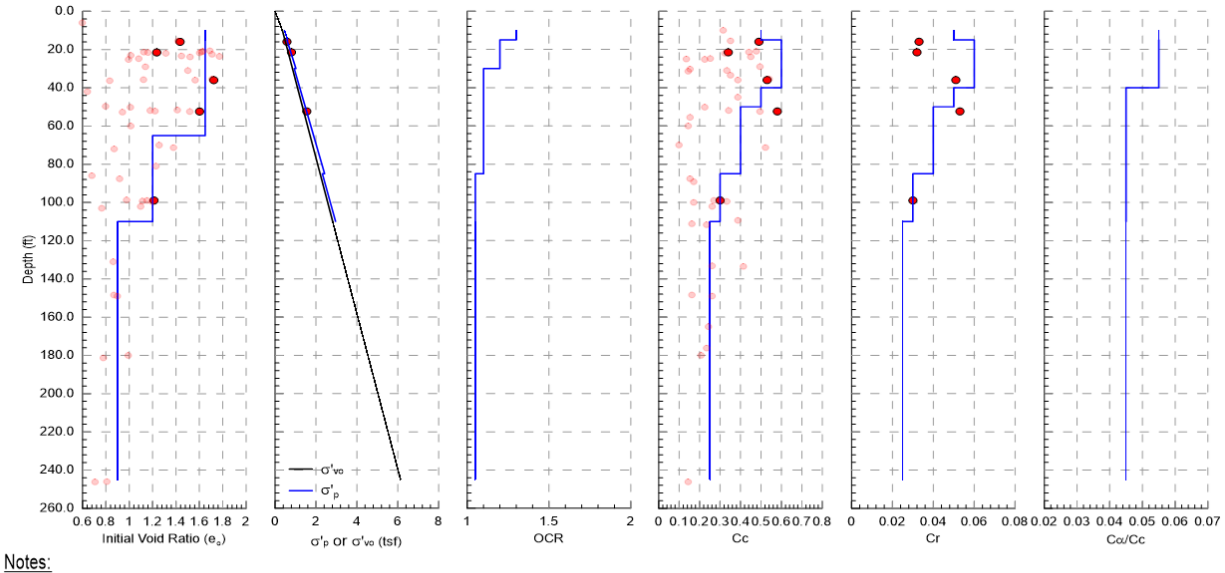

The scatter is explained by differences in gradation in the highly interbedded whole tailings materials, in which the far left CSL is representative of primarily non-plastic silty materials (ML), while the far right CSL range is associated primarily with silty sand materials (SM). Initial state parameters indicate that WT plots below/above and to the left/right of the estimated CSL, indicating dilative/contractive ductile behavior in the transition zone, consistent with CPT testing.

Numerical analyses

Pseudo 3D finite difference consolidation analysis

Settle3 is used for analyses of vertical settlement and consolidation under surface loads such as foundations, embankments, and surface excavations. Loads are calculated within the domain in three-dimensional components, while settlements and pore pressures are computed in one-dimensional form. Settle3D calculates total settlement as the sum of three components: (1) immediate settlement; (2), settlement due to primary consolidation; and (3) settlement due to secondary compression.

Immediate settlement occurs instantaneously with the application of the load and is calculated assuming linear elastic behavior using 1D constrained modulus and the change in vertical stresses. Primary consolidation settlement occurs as excess pore water pressures, generated initially by the imposed load, dissipate with time. Settle3D uses the 1D Terzaghi theory of consolidation solved via the finite different method, modified to account for changes in compressibility and permeability during primary consolidation. Settle3D uses a bi-linear material model in which the modulus is a function of the stress to describe the changes in compressibility. For the computation of secondary settlement, Settle3D uses the ratio between the secondary compression index and the compression index (Cα/Cc), denoted as the law of compressibility (Mesri and Godlewski, 1977, 1979) after the average degree of consolidation reaches 95 percent. The trial embankment was modeled using a 3D geometry based on as-built geometries, and construction staging based on actual loading (lifts) documented during construction of the embankment.

Notes:

1) Compressibility parameters (Cc, Cr) were obtained from consolidation tests at different depths marked as isolated red solid points
2) Solid lines represent values used in the consolidation model in Settle 3D

Figure 6: Compressibility parameters used for Settle3 FDM numerical model

Case history information used in the model calibration included data from an extensive consolidation laboratory testing program, whose compressibility parameters are summarized in Figure 6. Boundary conditions consisted of double drained at the base and surface, with no flow in the horizontal direction.

The results of the Settle3 analysis of the case history indicated that the model fully captured the total settlement magnitude observed at the trial embankment, as shown in Figure 7.

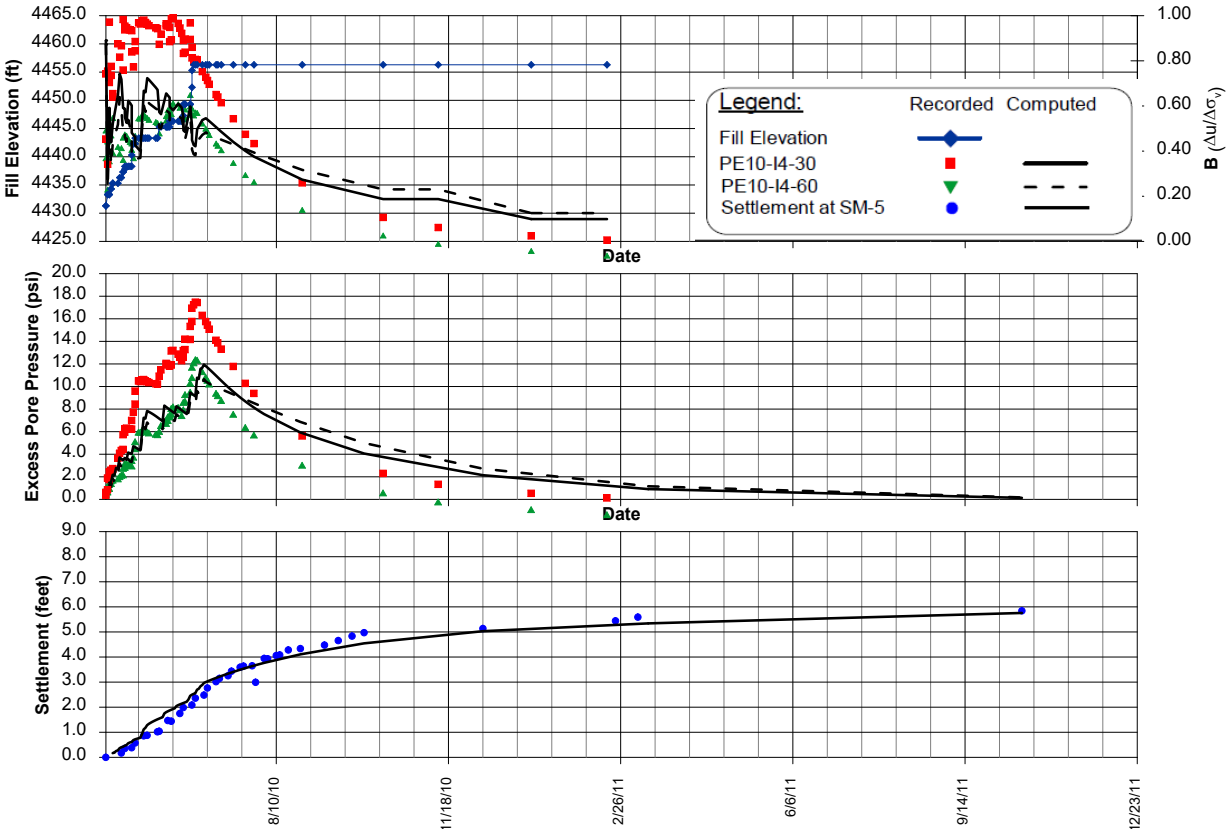

Figure 7: Computed (Settle3) and recorded settlement, excess pore water pressures and B bar for 2010 trial embankment crest (2010 to 2011) at I4 locations

The Settle3 analyses generally captured the time rate of consolidation and pore pressure generation and dissipation observed in the case history for both the non-wicked and wicked zone, as shown in Figure 8. As shown in Figures 7 and 8, the excess pore pressures generated in the non-wicked zone are slightly higher than those calculated from Settle3 and can be attributed to shear-induced pore pressures not captured due to the Settle3 formulation being derived entirely from compression loading.

Figure 9 also shows the resultant calibrated vertical permeability obtained from trial embankment case history. The calibration was carried out by systematically adjusting permeability values within an estimated range to develop a best estimate permeability distribution. As shown in Figure 9, the resultant calibrated permeability distribution with depth was found to be generally within an order of magnitude higher than the vertical permeability estimated from laboratory Incremental Load (IL) consolidation tests, flexible wall

permeability tests performed, and vertical permeability estimations from CPT Ic based correlations (Robertson and Cabal, 2015). In contrast, the calibrated permeability falls within the range of horizontal permeability (k_h) estimated from CPT correlations based on dissipation tests. This increase in the calibrated permeability accounts for the interbedded nature of the tailings that enhances horizontal flow in the field.

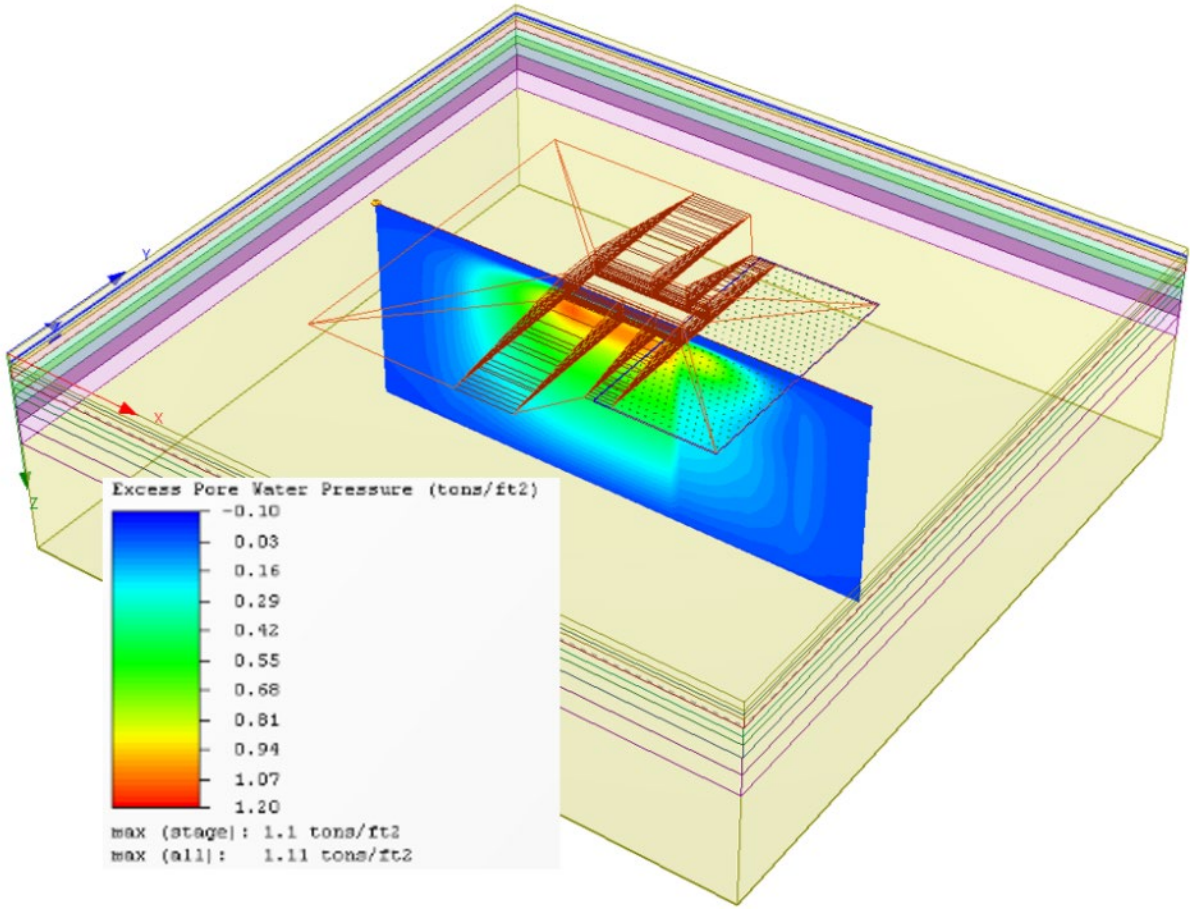

Figure 8: Trial embankment Settle3 maximum excess pore water pressures

2D Finite element NorSand analysis

The trial embankment material 2D FEM numerical model was broken down into two main materials (DPC and WT) for the PLAXIS model. The upper 60 feet are classified as soft tailings (DPC) and the lower 100 feet are classified as deep whole tailings (WT), with the phreatic surface set at 20 feet below the ground surface with 80 percent hydrostatic conditions. The NorSand constitutive model (Jefferies, 1993) was calibrated for each of these materials. NorSand was calibrated for the upper soft tailings and lower whole tailings, as shown in Table 1. Figure 10 presents the numerical calibration fits for laboratory shear strength tests on the two materials. Good fits to the laboratory data were obtained for both tests.

Table 1: Summary of trial embankment NorSand parameters

Material	Γ	λe	Mtc	N	χ	Plastic hardening (H)	Elasticity
Soft tailings (DPC)	**2.1**	**0.23**	**1.45**	**0.35**	**2.5**	**H_o=75, H_ψ=0**	**G_{ref}=176x10³ psf, n_g=1.0**
Whole tailings (WT)	**1.92**	**0.13**	**1.5**	**0.20**	**3.3**	**H_o=32, H_ψ=300**	**G_{ref}=510x10³ psf, n_g=0.65**

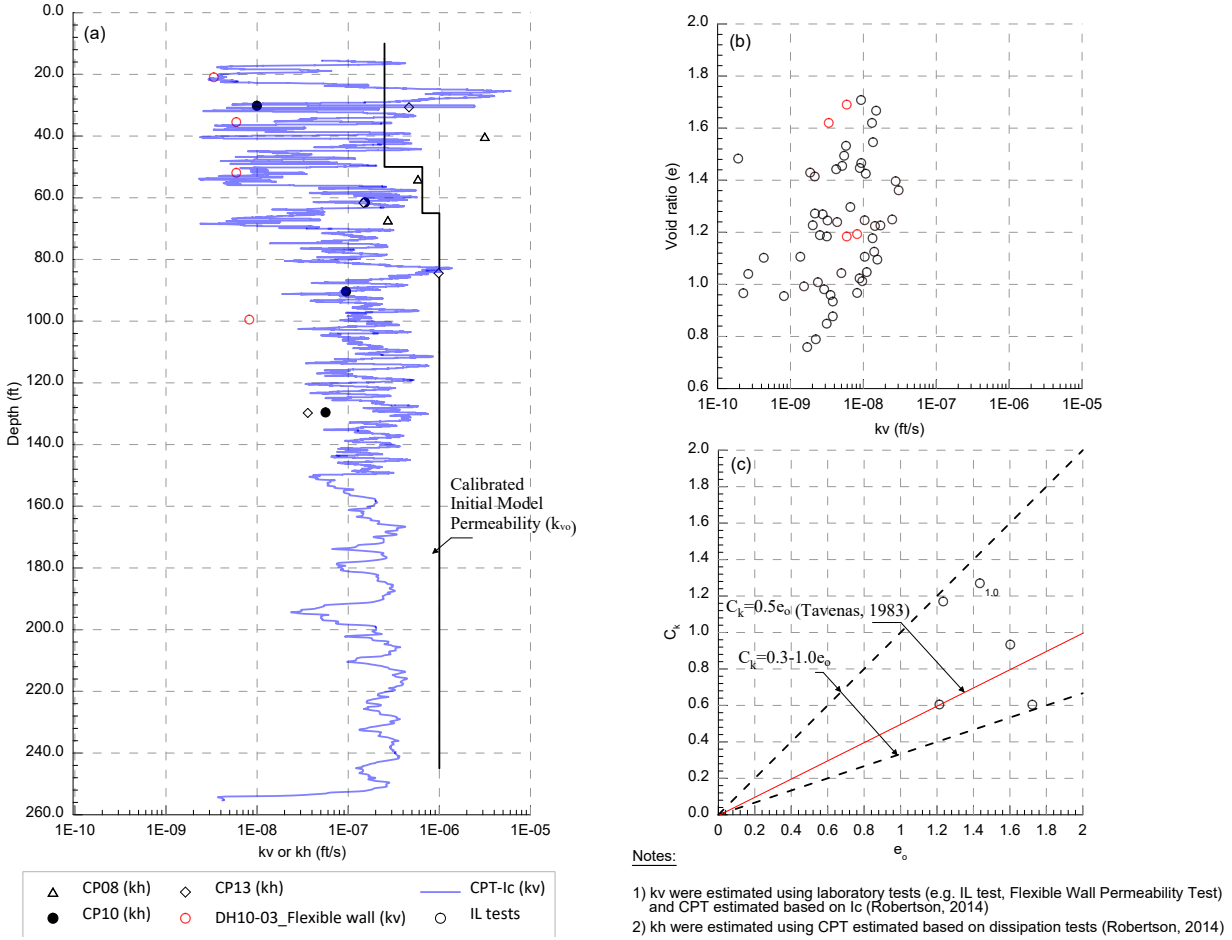

Figure 9: 2010 trial embankment laboratory, CPT, and calibrated Settle3 permeability (kv)

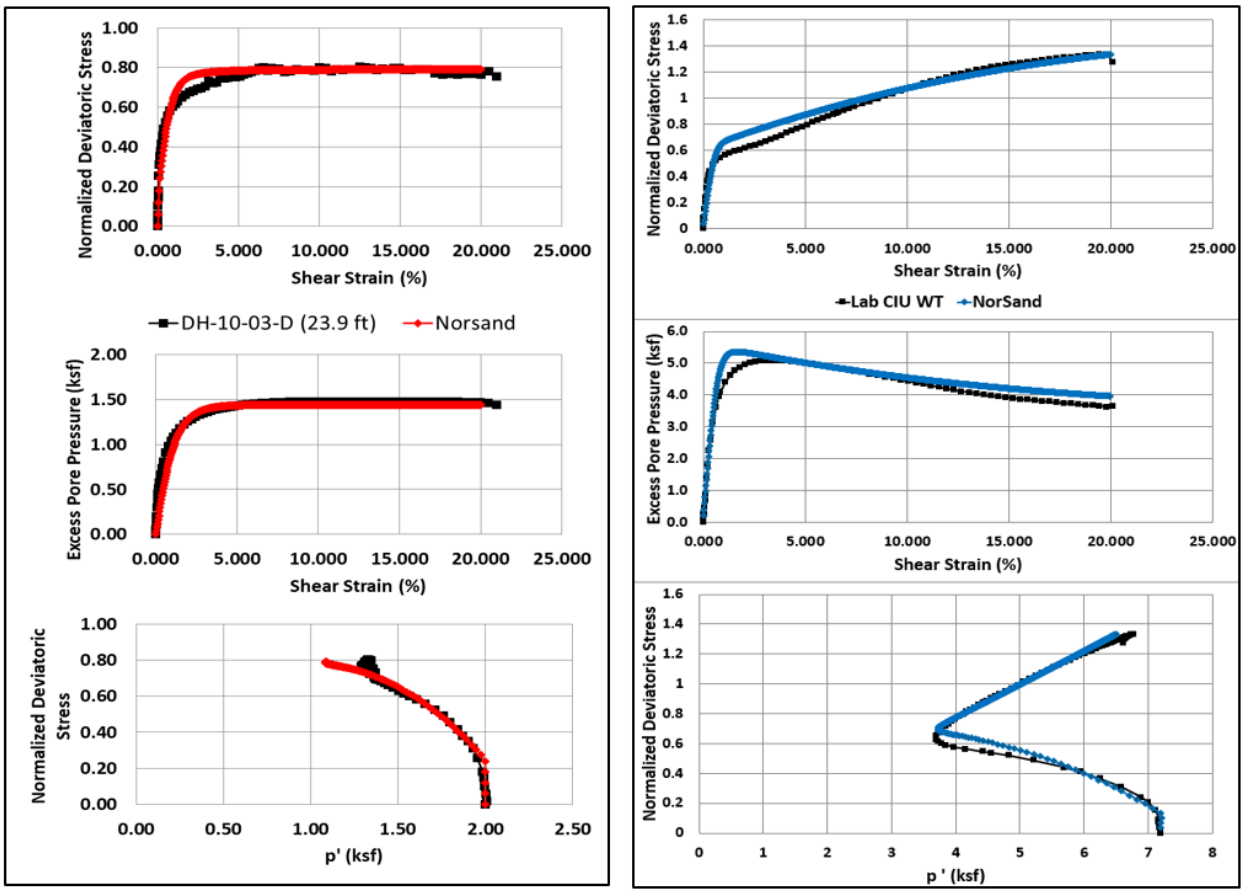

Figure 10: NorSand calibration results for soft tailings (left) and whole tailings (right)

Figure 11 presents the PLAXIS staged construction model, which includes the discretized foundation with upper soft tailings, and deep whole tailings NorSand properties. These foundation zones are further discretized into lifts of different permeability. The 30-foot-tall embankment is broken down into foot increments with loading and dissipation steps based on the actual construction sequencing with a total of 49 stages. Wicks are included on the right side of the model based on the as-built spacing. Boundary conditions consisted of allowing drainage in four directions of the model. The model was initialized with the foundation in place, using a gravity turn-on procedure and an assigned K_0.

The initial foundation state parameter and model conditions prior to embankment construction are shown in Figure 12, which presents CPT-based state parameter estimates using the Plewes method (Plewes et al., 1992) with 80th and 90th percentile lines that used G_{max} (1/5*G_{max}, 1/3*G_{max}, and G_{max}). The use of the Plewes method was considered appropriate at this stage of the study given the uncertainty in the application of the NorSand CPT widget, due to the lack of calibration chamber testing in low to high plasticity tailings to derive reasonable mapping factors (e.g., Cq, Shuttle and Jefferies, 2016).

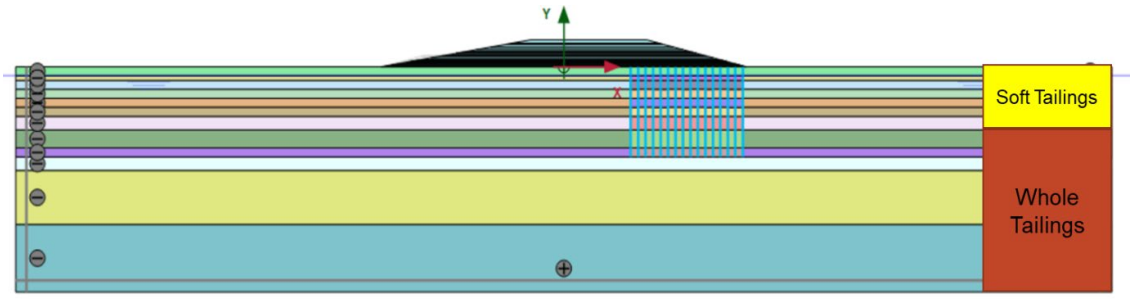

Figure 11: 2010 Trial embankment 2D FEM model (embankment, soil domain, and wick drains)

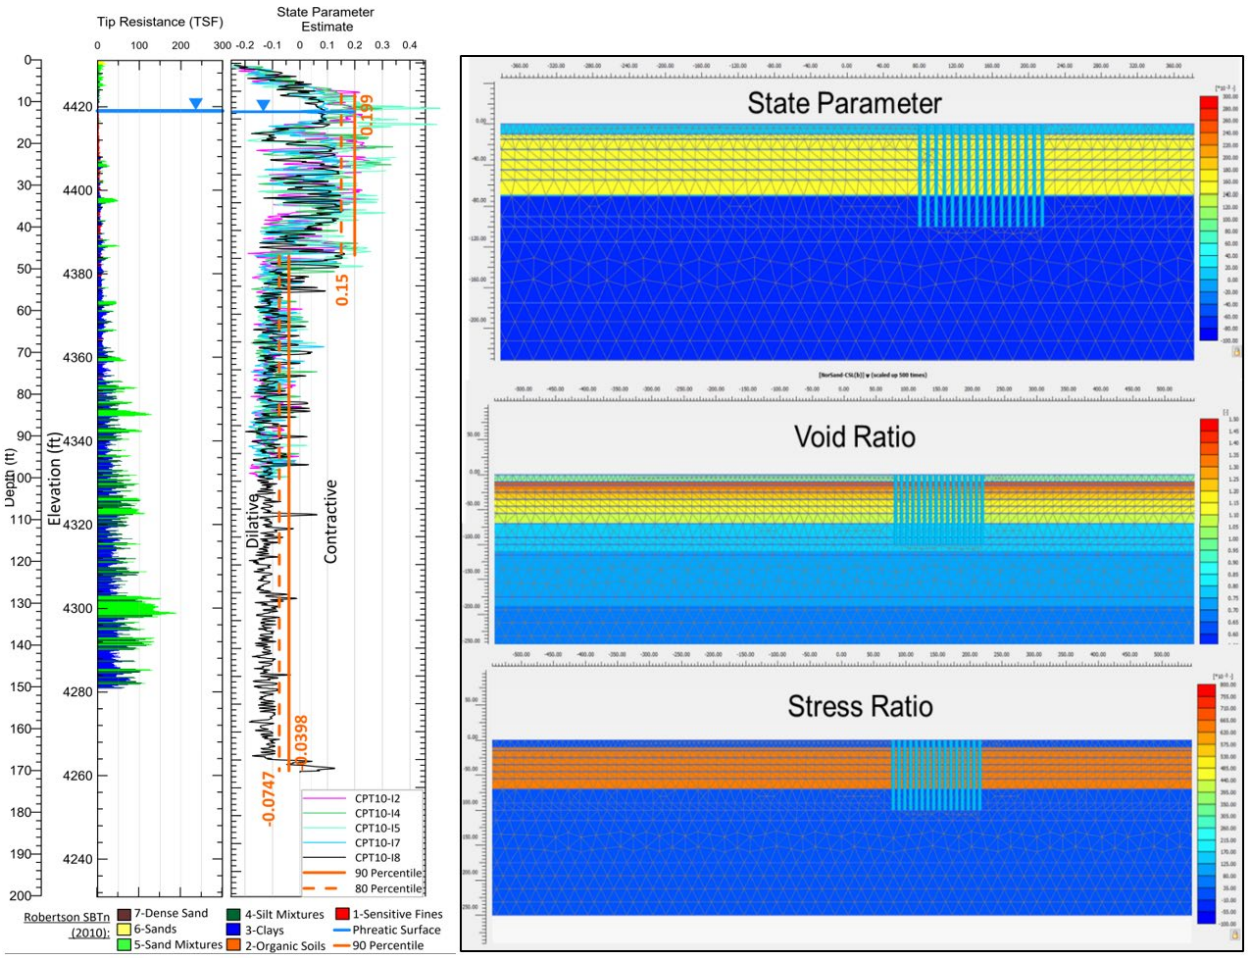

Figure 12: 2D FEM simulations using NorSand (a) initial characteristic state parameters; (b) initial model state parameter, void ratio and stress ratio profile

The goal of the model was to find the combination of a characteristic state parameter and G_{max} that results in the best time history match to settlement and pore pressures. The best match to time history data was obtained using the 80th percentile of state parameter and G_{ref} between $G_{max}/3$ and $G_{max}/5$, as shown by the settlement comparison in Figure 13, which presents the settlement time history match between settlement plates data and the NorSand model results. Consistent with this observation, as shown in Figure

14, single element calibrations of NorSand for DPC layer under oedometer compression loading paths show a better agreement with the compressibility of the IL consolidation tests for calibrations that use Gref=Gmax/5, while Gref=Gmax/3 tends to slightly underpredict the compressibility of the DPC consolidation tests. This highlights the importance of calibrating the Gref parameter for the NorSand model against key loading paths that reflect field conditions. This allows for sensitivity analyses using a range of Gref consistent with standard practice from undrained triaxial testing and drained compressibility-based testing.

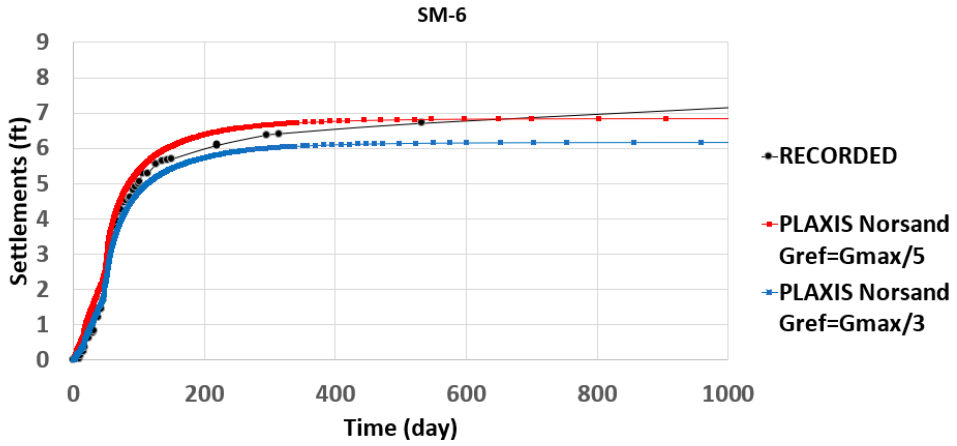

Figure 13: Trial embankment NorSand 2D FEM model settlement comparison for Gmax/5 and Gmax/3

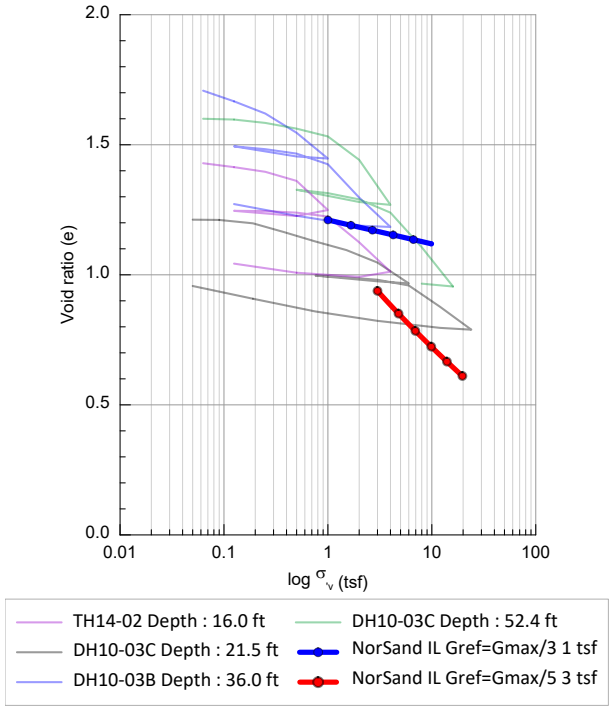

Figure 14: Trial embankment consolidation testing using oedometer in DPC and NorSand oedometer calibrations for Gmax/3 and Gmax/5

Additionally, as shown in Figures 15 and 16, consolidation beneath the trial embankment suggest that areas closer to the wick drains undergo large consolidation as Excess PWPs are dissipated much more rapidly with a state parameter above 0.18 at Ultimate Height, while areas near the left toe underwent shear-induced PWP with less dissipation throughout construction, with resulting state parameters below 0.14.

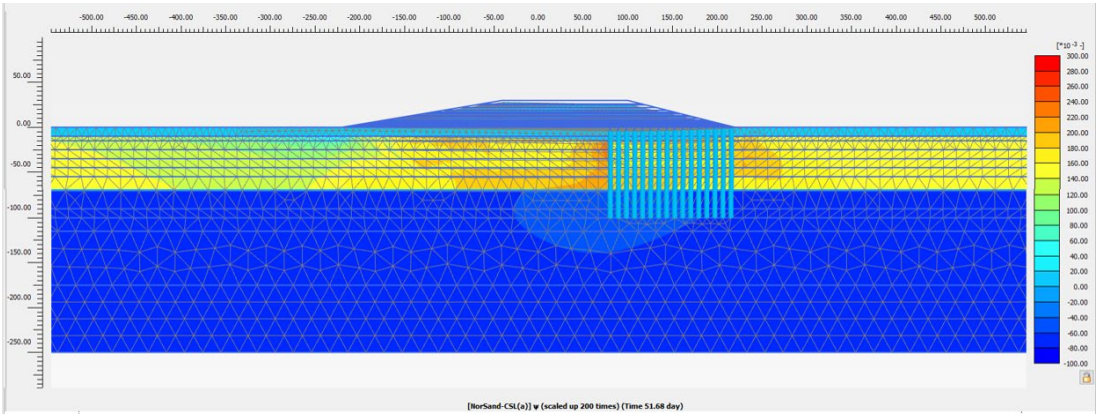

Figure 15: Trial embankment NorSand 2D FEM model state parameter at ultimate height

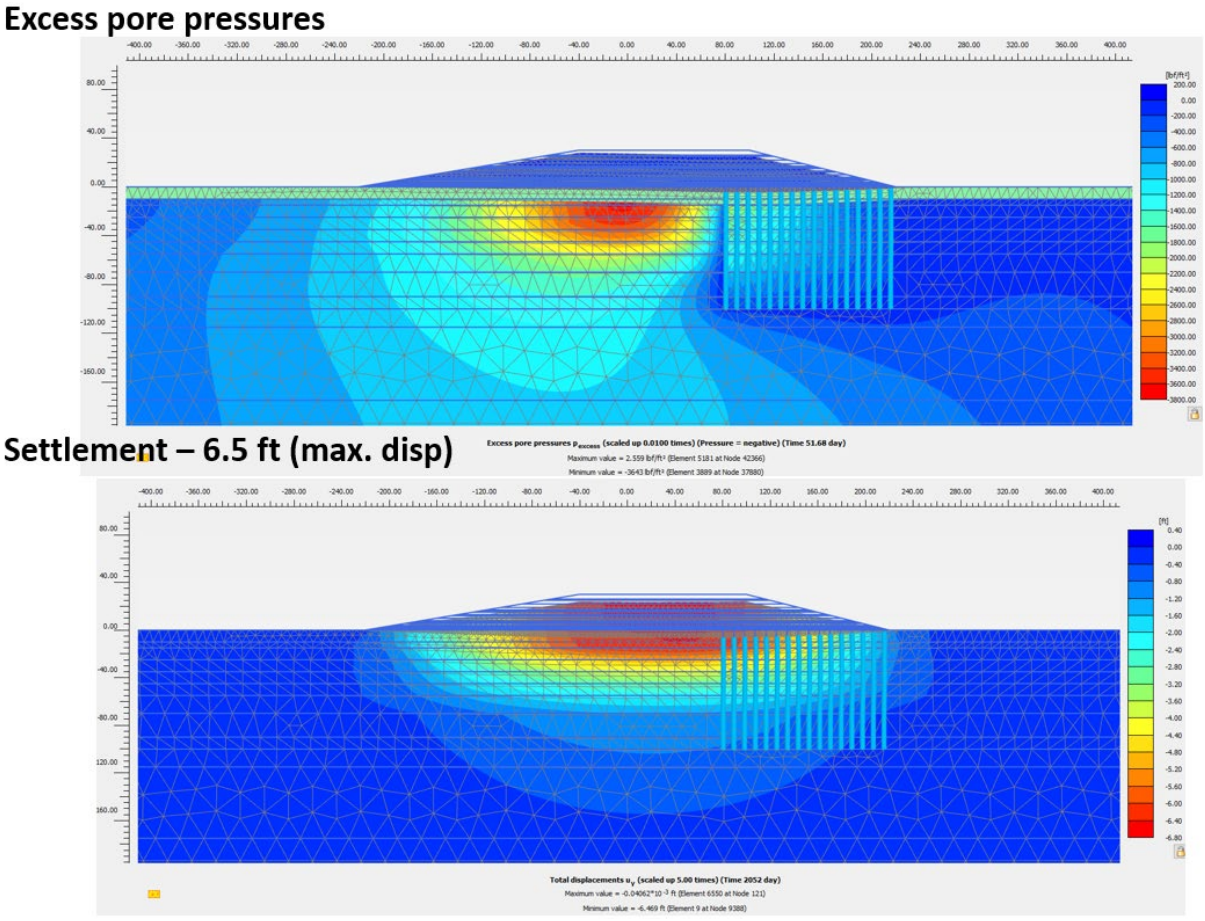

Figure 16: Trial embankment NorSand 2D FEM model Excess PWP and settlements at ultimate height

Unlike Settle3, the NorSand model was able to match the consolidation and shear-induced PWP time history and settlement behavior of the soft foundation tailings well, although it overpredicted the initial induced PWP for the piezometer located at 60 ft (PE10-I4-60), as shown in Figure 17. Internal results using the soft soil model (Vermeer and Neher, 1999) are also shown for comparison, showing good results with less shear-induced PWP for the piezometer located at 30 ft (PE10-I4-30).

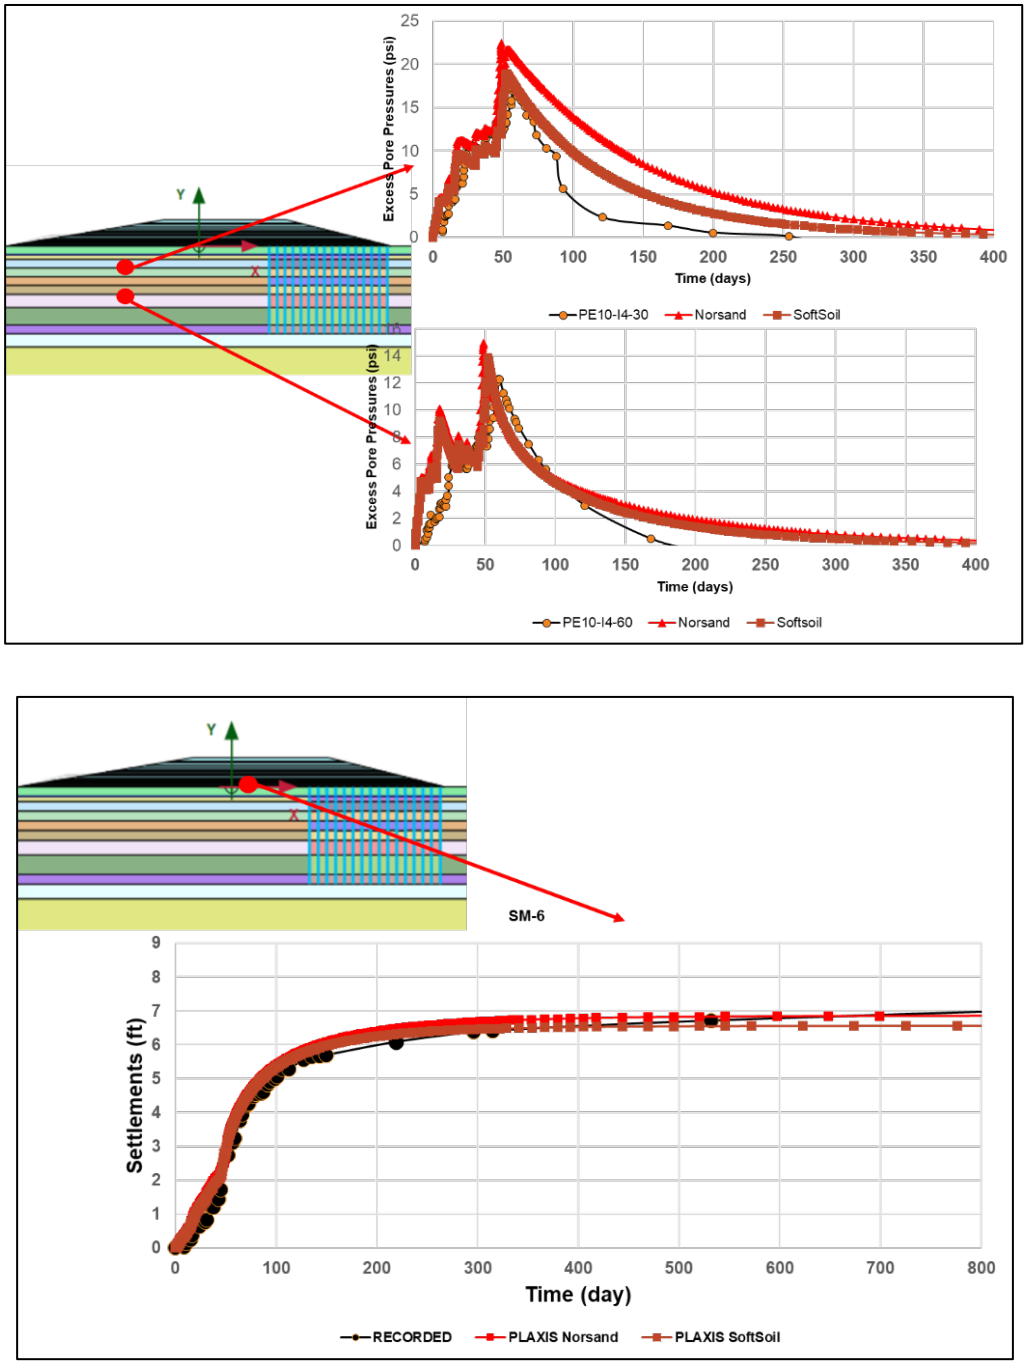

Figure 17: Comparison between recorded response and the 2D FEM model using NorSand and soft soil constitutive models (a) Excess PWP; (b) settlement

3D Finite Element NorSand analysis

As shown in Figure 18, a simplified preliminary 3D FEM model using NorSand was generated using the 3D formulation in PLAXIS 3D. It consisted of a 3D staged construction sequence, using a fully coupled consolidation scheme, and was established to mimic the approximate construction sequence. This 3D is compatible with the 2D simulations in terms of construction sequence, initial state parameter and PWP conditions, constitutive model parameters, and flow parameters (with the addition of a third-dimension component), although simplifications were made regarding distinguishing stages from loading/dissipation, along with the simplification of not including wick drains for the preliminary 3D analyses shown in this paper.

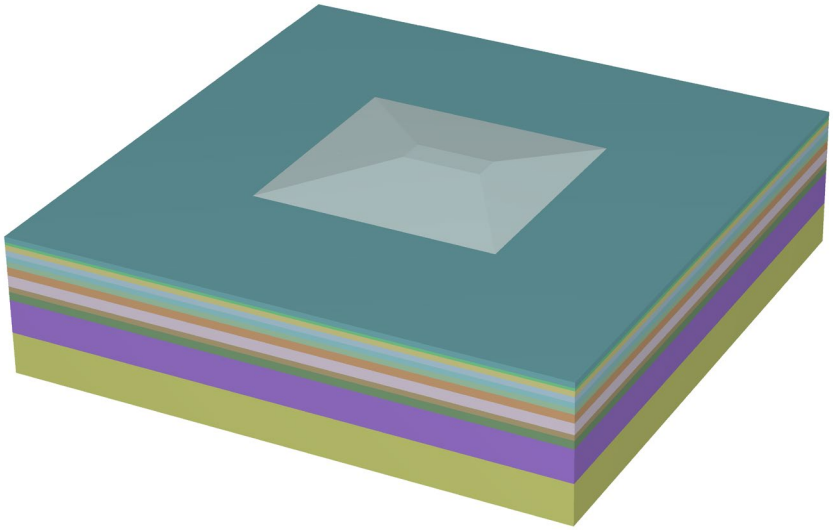

Figure 18: 2010 Trial embankment 3D FEM model (embankment, soil domain)

Additionally, as shown in Figure 19, similarly to PLAXIS 2D, the PLAXIS 3D model is able to capture reasonably well the recorded settlements beneath the trial embankment while capturing better the Excess PWP at 60 ft (PE10-I4-60), as shown in Figure 20. PLAXIS 3D dissipates much slower after loading, likely due to the inclusion of the wick drains. The better agreement of PLAXIS 3D with the NorSand model for the Excess PWP time history at depth is related to the stress distribution being different than plane strain conditions, as assumed in the PLAXIS2D model, although PLAXIS 3D shows slower dissipation of Excess PWP, likely due to simplifications made regarding wick drains exclusions. The trial embankment plan dimensions of ~ 450’ × 300’ were then better approximated by the 3D model due to its truly 3D loading nature. As observed in Figure 20, the PLAXIS 3D model shows a much shallower stress distribution with settlements above 1 ft concentrating within the first 120 ft, while PLAXIS 2D suggest a much deeper settlement distribution up to 160 ft for values above 1 ft, likely due to the overprediction of effective stresses at depth.

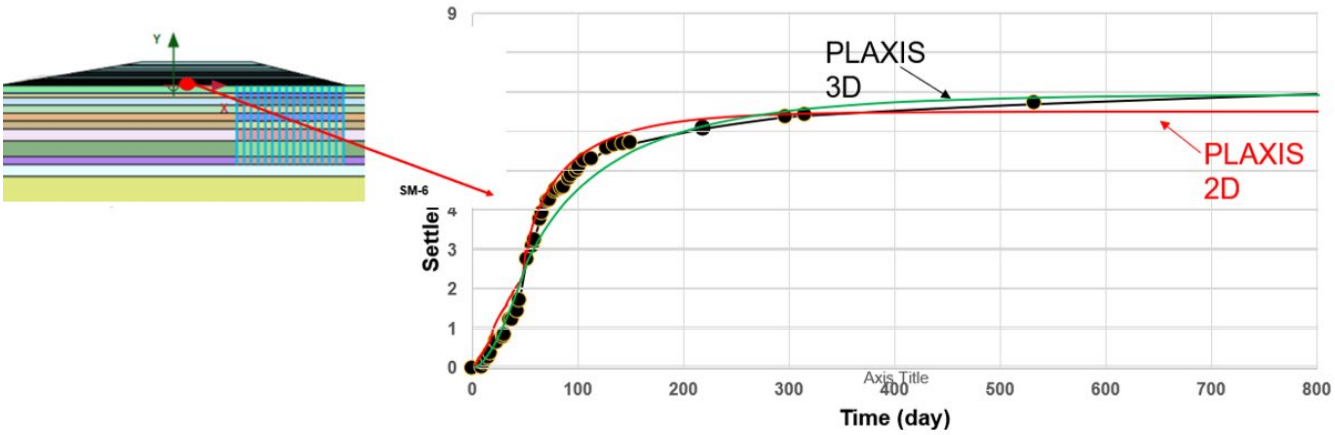

Figure 19: Recorded and computed settlement response from PLAXIS 2D and 3D NorSand models

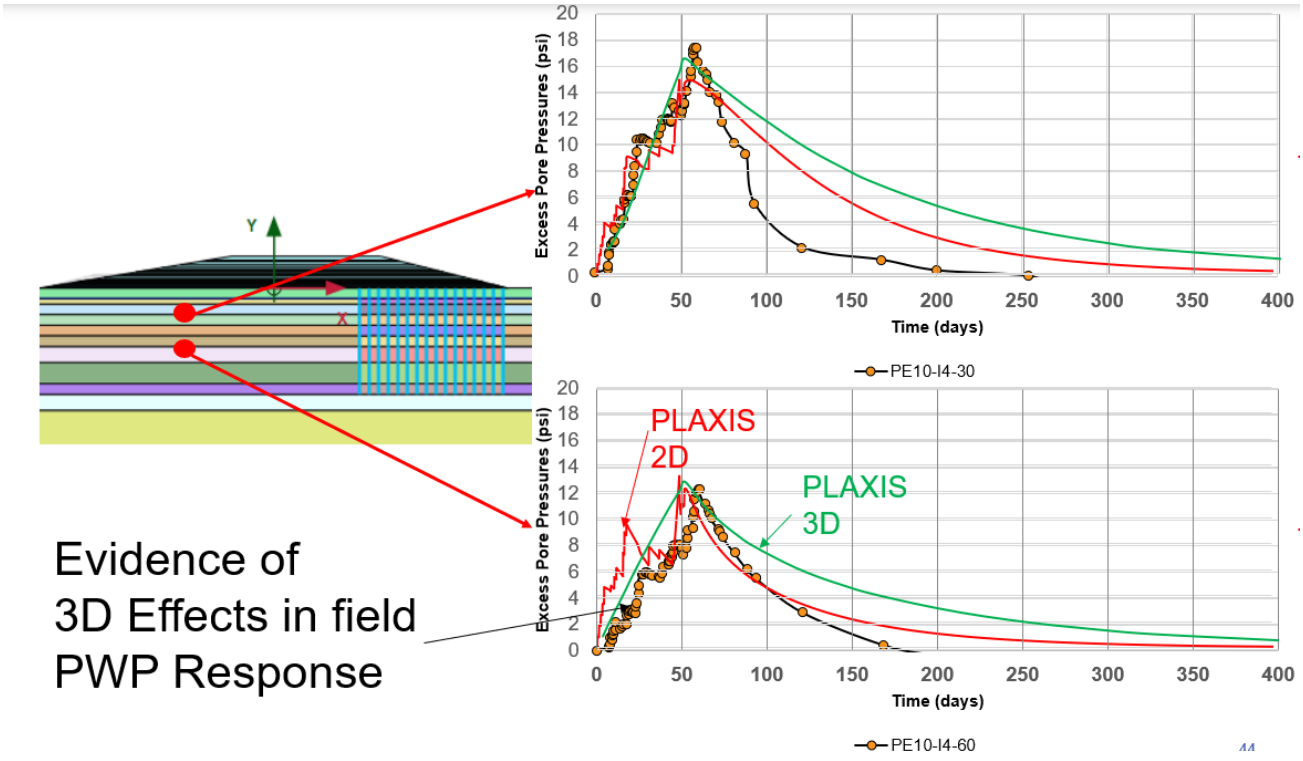

Figure 20: Recorded and computed PWP response from PLAXIS 2D and 3D NorSand models

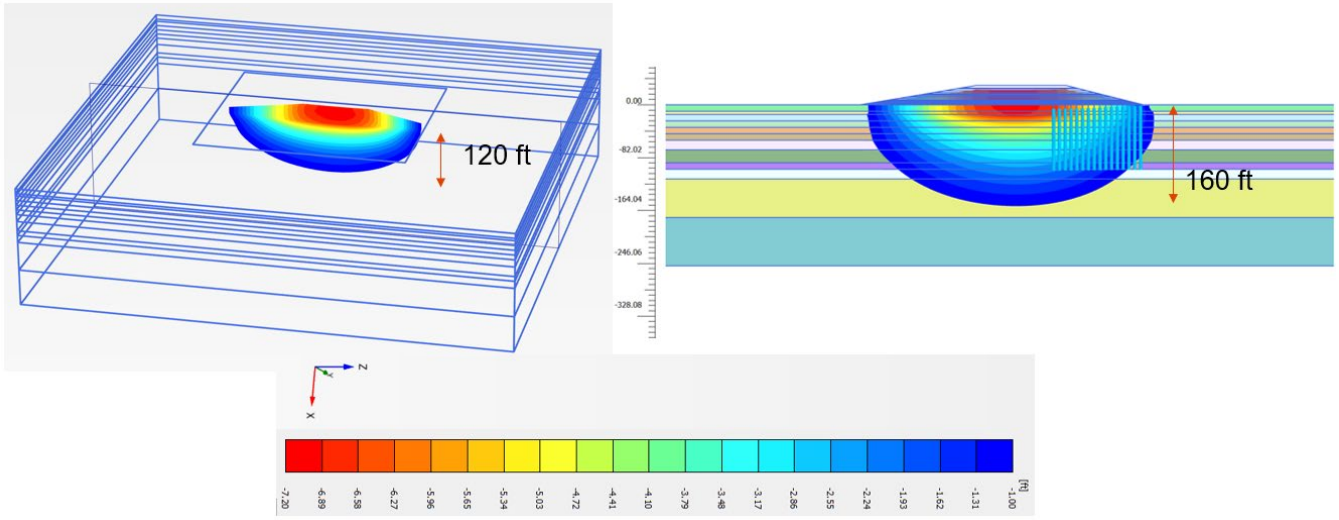

Figure 21: Comparison between computed settlement response from PLAXIS 2D and 3D NorSand models

Summary of 2D and 3D calibrated permeabilities

Figure 22 shows the resultant calibrated vertical permeability (Settle3), and the horizontal and vertical permeabilities from PLAXIS2D and PLAXIS3D that simulated the trial embankment case history. The resultant calibrated permeability distribution between PLAXIS 2D and 3D with depth were found to be compatible in the first 70 ft, while generally the PLAXIS3D model suggesting a half an order of magnitude lower than the vertical permeability derived from PLAXIS2D. The resultant permeability anisotropy values from PLAXIS2D and 3D are consistent with compositional changes that affect the system permeability in interbedded tailings, as suggested by Cerna-Diaz et al. (2024).

The calibrated bounds from PLAXIS3D exhibit better agreement with laboratory Incremental Load (IL) consolidation tests, flexible wall permeability tests performed, and permeability distribution estimates from CPT Ic based correlations (Robertson and Cabal, 2015). This decrease in the calibrated permeability in the vertical direction for PLAXIS3D occurs due to 3D modeling capturing flow in the three directions consistent with realistic flow patterns in the field, while PLAXIS 2D assumes no flow into the page direction and Settle3 assumes only dissipation in the vertical direction.

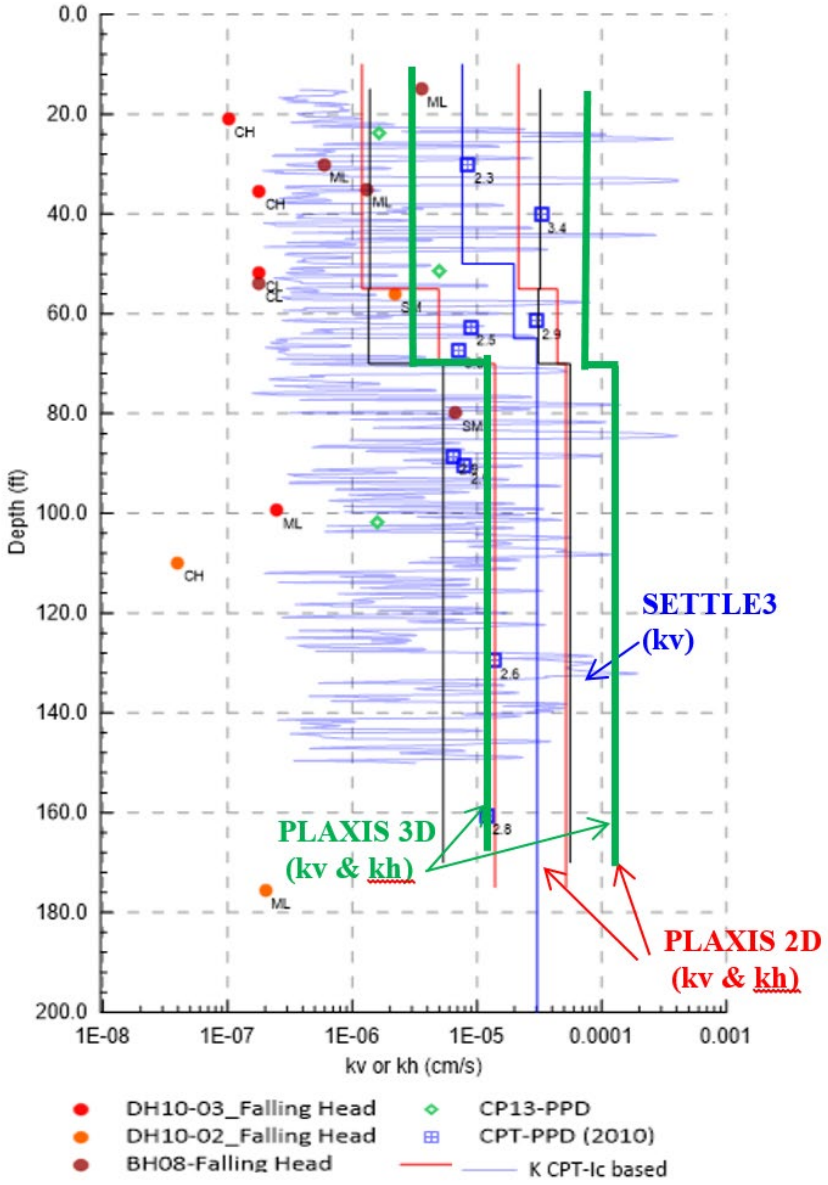

Figure 22: 2010 Trial embankment laboratory, CPT, and calibrated Settle3 (black), PLAXIS 2D (red), and PLAXIS 3D (green) permeabilities (kv and kh)

Conclusion and recommendations

Using a well-documented consolidation of a trial embankment construction over an existing TSF, this paper evaluated the role of 2D and 3D numerical analyses on the back-analyses of settlements and Excess PWP using a simple bilinear FDM consolidation model (Settle3) and a NorSand critical state-based constitutive plasticity model in PLAXIS2D and PLAXIS3D. For all modeling approaches, the results show generally good agreement in the computed settlements among the three modeling techniques used here, while a closer computed PWP response was obtained with NorSand as it captures shear-induced PWP. The NorSand 3D

model was able to best capture the PWP distribution at depth as it captured the dimensionality of trial embankment more realistically. The computed responses also show distinct state parameters, illustrating how drainage conditions can affect consolidation (e.g., consolidation stresses) and shear behavior during the partially drained loading exerted by the trial embankment. In addition, the extracted "system-level" state and permeability that produced computed results in reasonable agreement with the recorded response used an initial-state parameter profile compatible with the 80th percentile, a NorSand G_{ref} between $G_{max}/3$ and $G_{max}/5$, and a combination of permeabilities (kv and kh) consistent with CPT dissipation tests and laboratory testing, and a somewhat improved extracted permeability distribution with 3D FEM analysis using NorSand. Lasty, these analyses highlight the importance of integrating TSF performance monitoring program with large-scale testing to aid recommendations stemming from GISTM performance-based evaluations.

Fabric Effects on the Onset of Static Liquefaction under Drained Conditions – Implications for Mine Tailings

Srinivas Vivek Bokkisa, Georgia Institute of Technology, USA
Jorge Macedo, Georgia Institute of Technology, USA

Abstract

This study investigates the onset of static liquefaction under constant shear drained (CSD) stress paths, considering fabric anisotropy and loading characteristics. The SANISAND-F constitutive model based on the Anisotropic Critical State Theory (ACST) is utilized for the analysis. An analytical criterion is derived to assess the onset of static liquefaction in the CSD stress path, accounting for constitutive parameters, loading-induced anisotropy, and fabric. Numerical results reveal the significant influence of fabric anisotropy on the stress ratio at the point of instability. It is observed that the stress ratio decreases with an increase in Lode angle and major principal stress deviation from the vertical, while increasing with higher initial fabric intensity. These findings are consistent with existing experimental evidence obtained under typical experimental setups. However, we also found that the interaction between Lode angle and loading/fabric directions could potentially alter these trends. The implications of these findings for assessing static liquefaction in mine tailings under generalized loading conditions are discussed.

Introduction

Static liquefaction has led to catastrophic failures in slope systems such as tailings storage facilities (TSFs) and water dams in the past decade (Embankments and Committee, 2021; Jefferies et al., 2019; Morgenstern et al., 2016; Robertson et al., 2019). It is well established that loose particulate materials can experience static liquefaction under undrained shear loading conditions (Ishihara, 1996; Kramer, 1996), but case history failures have shown that it can also be triggered under completely drained loading conditions. Examples include the Wachusett Dam failure in 1907 (Olson, 2000), Fundão in 2015 (Morgenstern et al., 2016), Cadia in 2018 (Jefferies et al., 2019), and the Edenville-Sanford dam failure in 2020 (Embankments, Dams and Slopes Committee, 2021).

Figure 1a illustrates the schematic failure mechanism of the 1907 Wachusett dam failure. Under drained conditions, a rise in the water table caused a significant decrease in effective vertical stresses, while shear stress remained relatively unchanged (Olson, 2000). This stress change can be simulated through a

constant shear drained (CSD) test, as shown in Figure 1b, which involves two stages: initial triaxial loading to reach the desired deviatoric loading (q), followed by releasing the vertical and confining stresses while maintaining a constant q. The response of a loose material in a CSD test, depicted in Figure 1(b, c), exhibits instability characterized by the stress ratio ($\eta = q/p'$) on the instability line. Instability is triggered when the mobilized stress ratio η exceeds the critical stress ratio $\eta_f = \left(\frac{q}{p'}\right)_f$ (Lade, 1992). Later in the paper, we provide more detailed discussions on the conditions for instability triggering and the definition of the instability stress ratio (η_f).

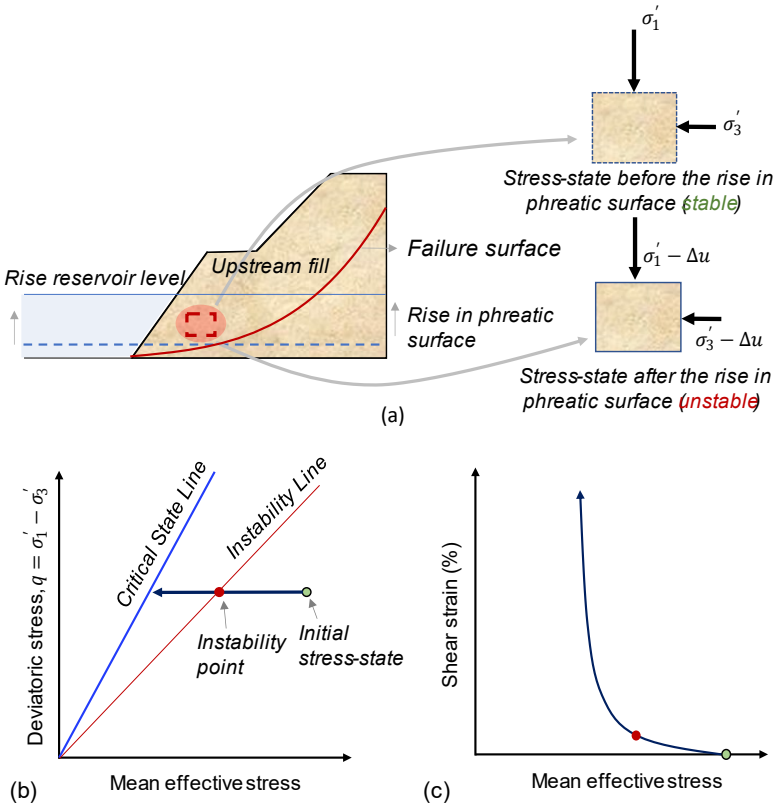

Figure 1: (a) Illustration of the cross-section through the failed portion of the North Dike of Wachusett Dam (b, c) Schematic of the behavior of loose granular material subjected to CSD loading

Prior experimental studies have extensively investigated instability onset under CSD loading, primarily focusing on triaxial conditions and varying densities and stresses (Chu et al., 2003; Dong et al., 2016; Fotovvat et al., 2022; Sasitharan et al., 1993). However, research examining non-triaxial conditions is limited. For instance, Wanatowski et al. (2010) and Wanatowski and Chu (2012) explored sand instability in plane-strain conditions under CSD stress paths, discovering a lower η_f compared to triaxial conditions. Recently, Fanni et al. (2022) conducted experiments using a hollow cylinder setup to investigate the influence of induced and inherent fabric on instability onset under CSD stress path. Their findings indicated

that fabric anisotropy significantly influence η_f, with lower values observed for higher Lode angles and stress orientations further from the vertical. However, the number of loading conditions was limited due to experimental limitations.

Previous numerical studies have examined instability onset under CSD stress paths, primarily focusing on triaxial conditions with different constitutive models (Alipour and Lashkari, 2018; Ramos et al., 2012; Sibille et al., 2007). However, fabric anisotropy effects on CSD stress paths have been rarely explored in these studies. In this context, one of the main contributions of this study is to assess the effect of induced and inherent fabric anisotropic on the instability onset under CSD stress paths comprehensively. Importantly, our simulations also provide insights for scenarios that are difficult to represent experimentally and have not been assessed in previous efforts due to the inherent. Towards this end, we derive an analytical instability criterion for granular materials under CSD loading using ACST and use it to numerically investigate fabric anisotropy's effects on triggering instability. Specifically, we explore the effect of rotation of principal stress direction, intermediate stress ratio, and initial fabric intensity on η_f.

ACST model, instability criteria and performance

The SANISAND-F model

The SANISAND-F model, proposed by Petalas et al. (2020), is an extension of the Dafalias and Manzari (2004) model and is formulated within the ACST framework (Li and Dafalias, 2012). It introduces a fabric tensor $\boldsymbol{F}$ as a state variable to measure the relative orientation between the loading and fabric directions. The model enhances critical state conditions and incorporates a scalar Fabric Anisotropy Variable ($A = \boldsymbol{F}:\boldsymbol{n}'$). The isotropic state parameter ψ (Been and Jefferies, 1985) is further influenced by fabric through the dilatancy state parameter ζ. This new state parameter determines the estimated dilatancy, which varies with fabric anisotropy. For more details, readers are referred to Li and Dafalias (2012) and Petalas et al. (2020).

Instability criteria for CSD stress path

Hill (1958) defined the stability of particulate materials based on positive second-order work, $d^2W = d\,\boldsymbol{\sigma}' d\boldsymbol{\varepsilon} > 0$. Instability occurs when $d^2W = d\,\boldsymbol{\sigma}' d\boldsymbol{\varepsilon} = 0$, where $\boldsymbol{\sigma}'$ and $\boldsymbol{\varepsilon}$ are stress and strain tensors. The instability condition can be expressed as $d\boldsymbol{s}:d\boldsymbol{e} + \frac{1}{3}dp'd\varepsilon_v = 0$, where $\boldsymbol{s}$ is the deviatoric stress, $\boldsymbol{e}$ is the deviatoric strain, p' is the mean effective stress, and ε_v is the volumetric strain. For a constant deviatoric stress ($d\boldsymbol{s} = \boldsymbol{0}$) under a CSD stress path, the instability condition simplifies to $dp'd\varepsilon_v = 0$, yielding two potential instability types: Type 1 ($d\varepsilon_v = 0, dp' \neq 0$) and Type 2 ($dp' = 0, d\varepsilon_v \neq 0$).

Applying constraints for Type-1 instability ($d\varepsilon_v = 0$, $d\boldsymbol{s} = \mathbf{0}$ and $dp' \neq 0$) to the SANISAND-F constitutive equations, the instability criterion $H^1 = K_p - K_{p,f} = 0$ is derived, where K_p is the current plastic modulus and $K_{p,f} = KD\boldsymbol{n}:\boldsymbol{r}$ is the estimated plastic modulus at the instability. K is the bulk modulus, D is the dilatancy, $\boldsymbol{n}$ is loading direction and $\boldsymbol{r}$ is deviatoric stress ratio tensor. Similarly, for Type-2 instability ($dp' = 0$, $d\boldsymbol{s} = \mathbf{0}$ and $d\varepsilon_v \neq 0$), the instability criterion is $H^2 = K_p - K_{p,f} = 0$, where $K_{p,f} = 0$. The instability criteria H^1 and H^2 depend on fabric anisotropy through the dilatancy state parameter ζ and the fabric anisotropic variable A. These dependencies allow for the consideration of fabric anisotropy effects on instability in the CSD loading path. Detailed step-by-step procedures for deriving the instability criteria for each instability type can be found in Bokkisa et al. (2023).

Table 1: Material parameters of the SANISAND-F model

Description	Symbol	Firoozkuh sand	Silica fine sand

Performance of SANISAND-F in simulating CSD stress paths

Bokkisa et al. (2023) assessed SANISAND-F's ability to simulate CSD stress paths for Firoozkuh sand and Silica Fine Sand. Table 1 provides the calibrated material parameters for these sands. The satisfactory

performance of SANISAND-F is demonstrated in Figure 2, even when considering complex stress paths with varying levels of anisotropy in loading (α_σ and b) for Silica Fine Sand. For a comprehensive understanding of the calibration procedure and performance of the model under CSD stress paths, readers are advised to refer to Bokkisa et al. (2023).

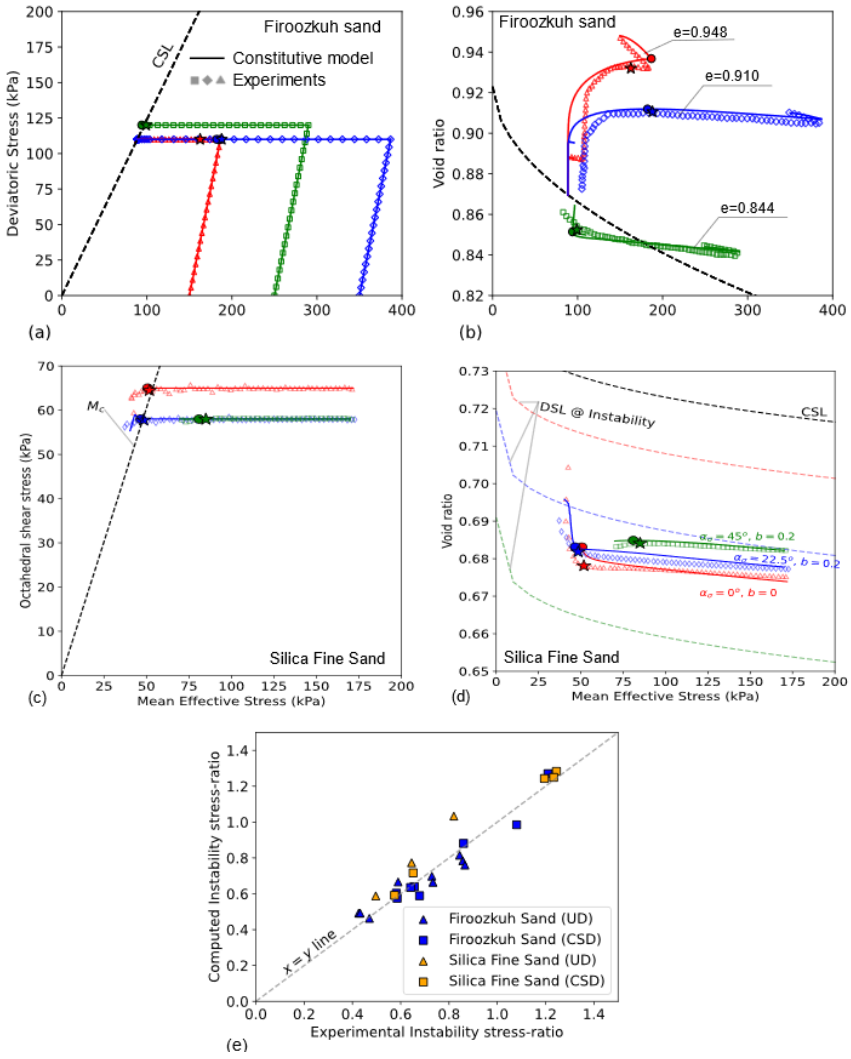

Figure 2: Performance of SANDISAND-F model for CSD stress paths (from Bokkisa et al., 2023)

Fabric effects on the instability onset under CSD stress paths

In this section, numerical simulations are conducted to examine the impact of stress principal axis rotations (α_σ), Lode angle (θ), and initial fabric intensity (F_{in}) on the initiation of instability under a CSD stress path. The stress principal axis rotation (α_σ) represents the constant rotation between the principal stresses and the deposition axis during drained shearing. The simulations are compared against experimental observations where available, with a focus on exploring general trends. The analysis utilizes calibrated

parameters for Firoozkuh sand. The shear stresses and shear strains are expressed in the octahedral form as q_{oct} and γ_{oct}, respectively.

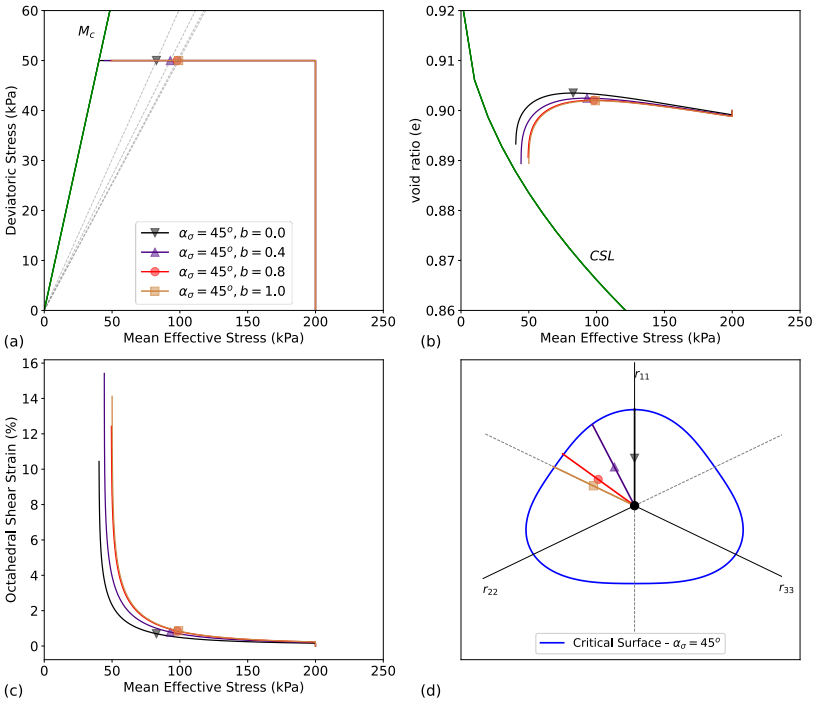

Figure 3: SANISAND-F model responses exploring Lode angle effect on instability

Effect of Lode angle (θ)

Figure 3 shows the simulations of CSD paths considering $\alpha_\sigma = 45^o$, $e_{in} = 0.9$, $p'_{in} = 200$ kPa, a targeted q_{oct} of 50 kPa, and different Lode angles, θ =[$0^o, 23.4^o, 49.1^o, 60^o$] (corresponding to b=[0,0.4,0.8,1.0]). η_f is estimated using the H^1 criterion and highlighted with different markers on each loading path. Figure 3 also shows the M_c line representing the critical state stress ratio for $b = 0$ for reference. Note that, in general, the critical state stress ratio is Lode angle dependent. It can be observed in Figure 3a that as b increases, η_f decreases. Figure 3b shows that instability occurs at the transition between volume increase and decrease responses, consistently with the loose initial state. After the instability onset, the octahedral shear strains also start to increase significantly, as illustrated by Figure 3c. Last, Figure 3d shows the stress paths in the π −plane, where differences in the loading path that cannot be appreciated in the $p' - q$ space are now evident. As b is constant, the stress paths in the π -plane are straight lines. In terms of previous efforts assessing the role of b on η_f under CSD stress paths, we are only aware of the experimental study of Wanatowski et al. (2010), who compared η_f for triaxial paths (i.e., α_σ=0^o, $b = 0$) and plane strain conditions, observing larger η_f in triaxial conditions. Even though b was not estimated by Wanatowski et

al. (2010), previous studies have suggested b varying in the range between 0.25 and 0.5 (Yoshimine et al., 1999) for plane strain conditions. Thus, the experimental observations by Wanatowski et al. (2010) are, in general, consistent with the trends in Figure 3.

To illustrate the assessment of a broader range of b values, we conducted additional simulations considering $\alpha_\sigma = 45^o$ and varying θ from 0^o to 360^o. The η_f estimated at instability for these simulations can be plotted in the π −plane of the principal deviatoric stress-ratio space to construct an instability surface. Figure 4 shows such a surface, where the axes in the π-plane are adjusted to have the distance from the origin to the instability surface also representing η_f in the $p' - q$ space. Figure 4 also highlights the instability points corresponding to $b = [0,0.4,0.8,1.0]$. The interpretation of the instability surface in Figure 4 is that it separates stable from unstable states for any Lode angle; hence, it provides a full assessment of η_f in multiaxial space.

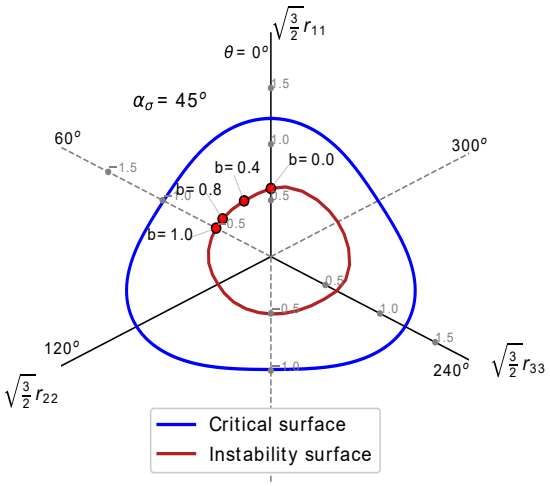

Figure 4: Instability surface obtained for whole range of Lode angels, $0^o - 360^o$

Effect of principal stress axis rotation (α_σ)

Figure 5 shows the simulations of CSD paths considering $\theta = 0^o$ ($b = 0.0$), $e_{in} = 0.9$, $p'_{in} = 200$ kPa, a targeted q_{oct} of 50 kPa, and α_σ =$[0^o, 30^o, 60^o, 90^o]$. The η_f estimated using the H^1 criterion are also highlighted. It can be observed that α_σ significantly affects the instability triggering and η_f. Indeed, η_f decreases as α_σ increases (see Figure 5a). Figure 5b shows that the increase in volume before the instability is less as α_σ increases, and Figure 5c shows that strains increase significantly as the CSD loading progresses after the instability, consistent with previous observations. The difference in the stress paths with respect to α_σ can be better distinguished in Figure 5d where the stress paths are plotted in the global deviatoric stress-ratio space, i.e., $r_z - r_r - r_\theta$ and viewed along the r_r axis. It can be observed that as the α_σ increases, the stress paths rotate more with respect to the vertical (i.e., r_z axis). In terms of previous

studies exploring the effects of α_σ under CSD loading, we are only aware of the experimental study by Fanni et al. (2022), who considered α_σ values of 22.5^o and 45^o. The aforementioned trends are consistent with the observations by Fanni et al. (2022) (i.e., η_f decreases as α_σ increases).

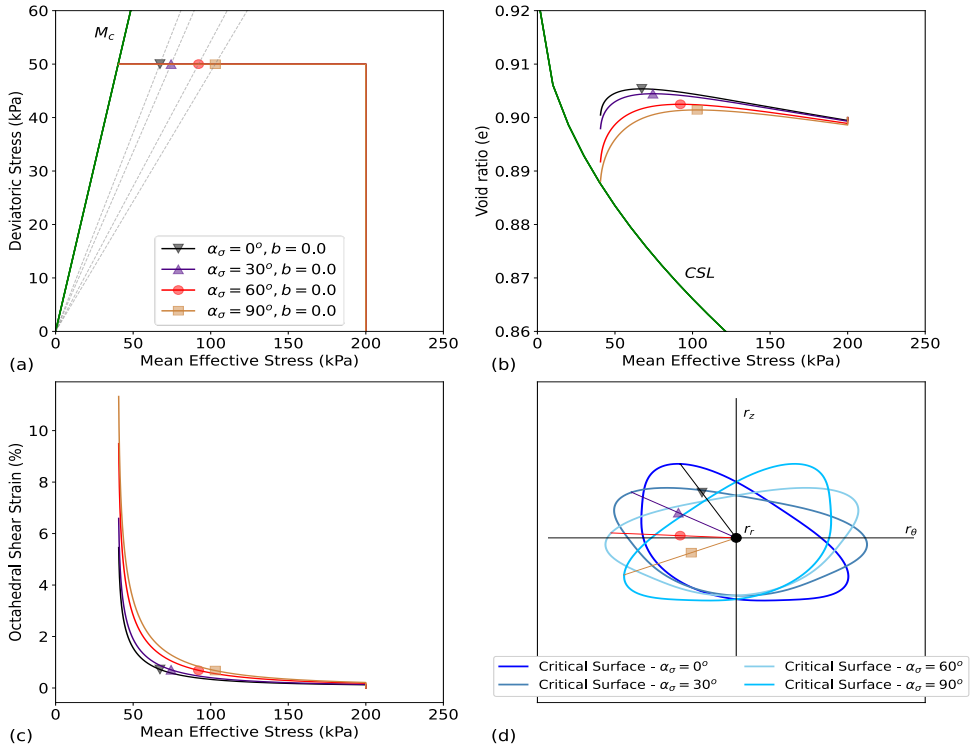

Figure 5: SANISAND-F model responses exploring effect of α_σ on instability

Figure 6 shows the instability surfaces for different α_σ values, considering the full range of θ values. It is interesting to see how the shapes of instability surfaces change as $\alpha_\sigma$varies, affecting interactions with different Lode angles. For example, for low Lode angles, i.e., $\theta = 0^o$ to 60^o, η_f decreases as α_σ increases; however, this trend is reversed for large Lode angles, i.e., $\theta = 120^o$ to 240^o. These trends are associated with the coupling between the Lode angle, α_σ, and the initial fabric direction (represented by the fabric tensor in Table 1). The trend of η_f decreasing as α_σ increases has been observed experimentally for Lode angles and initial fabric directions that are expected to be consistent with those in our simulations (i.e., the Fanni et al. [2022] study previously discussed). However, experimental studies considering interactions of α_σ, initial fabric, and a wide range of Lode angles, as considered in this study, are unavailable. Future experimental studies should inspect this further.

Effect of initial fabric intensity (F_{in})

In this section, numerical simulations are conducted to examine the influence of initial fabric intensity on instability triggering and η_f under CSD loading. The simulations vary the fabric intensity (F_{in}), while

keeping other parameters constant. Figure 7 illustrates the results for simulations with $\alpha_\sigma = 0°$, $\theta = 0°$, $e_{in} = 0.9$, $p'_{in} = 200$ kPa, a targeted q_{oct} of 50 kPa, and different fabric intensities (F_{in}=[0.01,0.5,1.0]) representing nearly isotropic to highly anisotropic fabrics. As F_{in} increases, the initial volume increase during stress relief under CSD loading becomes more pronounced, resulting in higher η_f values (see Figure 7a and 7b). This behavior is linked to the evolution of the fabric anisotropic variable ($A = FN$), which controls dilatancy. For the considered cross-anisotropic fabric with $b = 0$, where the loading direction aligns with the fabric direction ($N = 1$), A equals F. Larger F_{in} values correspond to greater A, leading to a smaller dilatancy state parameter (ζ) and an intensified dilative response. The evolution of shear strains follows the patterns observed in previous simulations, and the stress paths in the π-plane exhibit vertical upward movements ($\theta = 0°$), with instability points occurring at different distances from the critical surface due to varying initial fabric intensities (see Figure 7d).

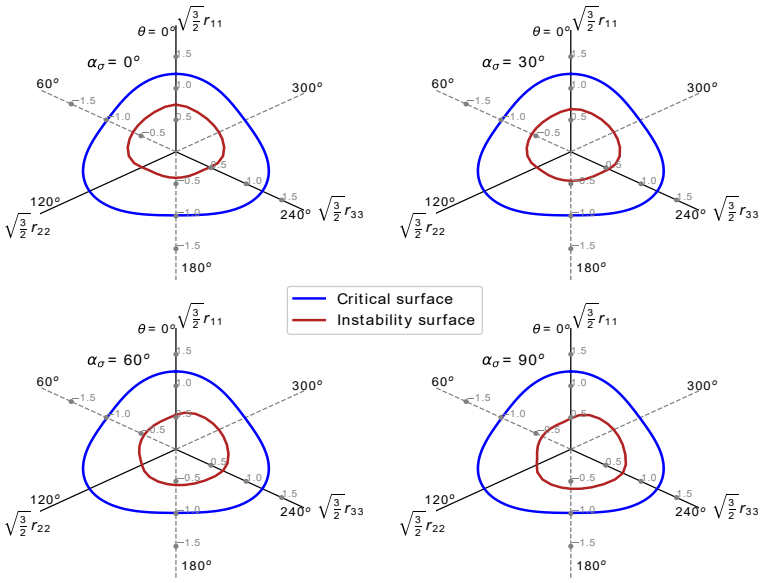

Figure 6: Instability surfaces obtained for various α_σ values

Figure 8 shows instability surfaces estimated for different F_{in}, α_σ of 0^o and 45^o, for the full range of Lode angles. Considering $\alpha_\sigma = 0^o$, it can be observed that for the isotropic fabric ($F_{in} = 0.01$), the instability surface is almost symmetric with respect to the origin. In contrast, the instability surface estimated for the anisotropic fabric ($F_{in} = 1.0$) is not symmetric and particularly distorted for $\theta = 0^o$ and $\theta = 180^o$, where η_f has its maximum and minimum values and also changes more significantly relative to the $F_{in} = 0.01$ instability surface. In the case of $\alpha_\sigma = 45^o$, a significant change in the instability surfaces and η_f relative to the $\alpha_\sigma = 0^o$ cases can be observed. For instance, there is a significant decrease in η_f for cases with a high fabric intensity ($F_{in} = 1.0$) and Lode angles between 0^o and 60^o. Again, these changes

are influenced by the coupling between the Lode angle, α_σ, and the initial fabric direction. As previously discussed, the only study we know of exploring α_σ effects under CSD loading is the Fanni et al. (2022) study, where the authors also considered different reconstitution procedures to represent different fabrics. They observed that dry-pluviated specimens showed a greater reduction in η_f when α_σ is increased for b values in the order of 0.2. Moreover, Yang et al. (2008) highlighted that both dry pluviation and moist tamping produce cross-anisotropic fabrics; however, the fabric anisotropy is higher for dry pluviation. Thus, our results (i.e., Figures 8 and 9) are in qualitative agreement with the experimental observations by Fanni et al. (2022) and Yang et al. (2008).

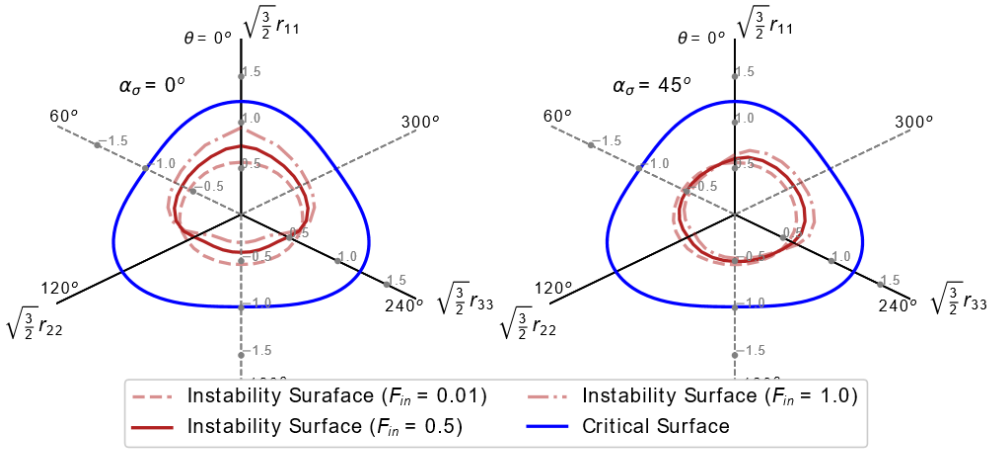

Figure 8: Effect of F_{in} on the instability surfaces obtained for $\alpha_\sigma = 0^o$ and $\alpha_\sigma = 45^o$

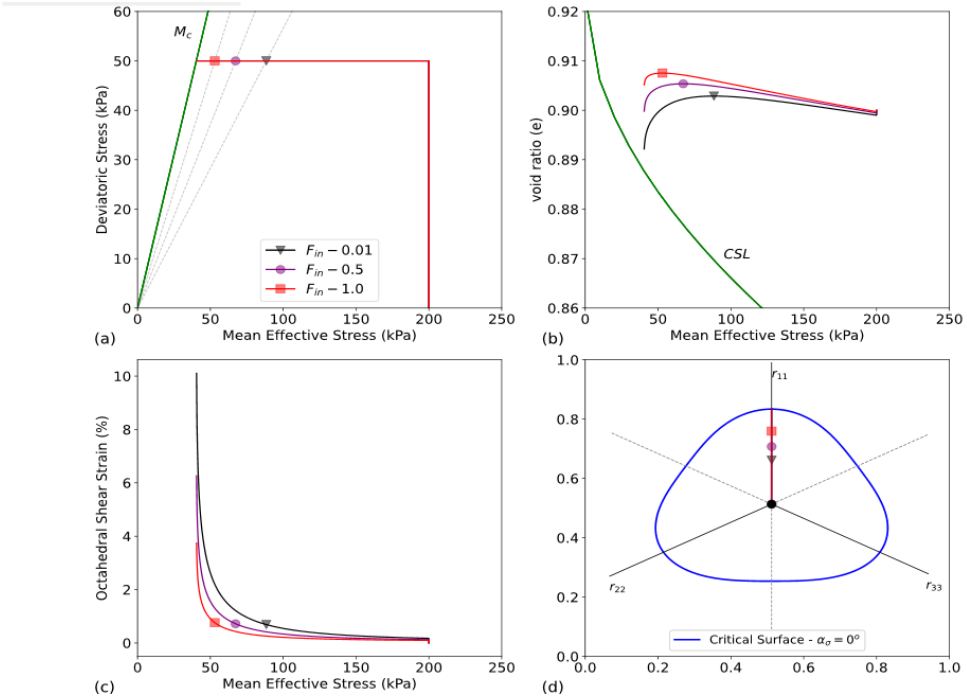

Figure 9: SANISAND-F model responses exploring effect of F_{in} on instability

Implications for mine tailing deposits

Previous sections assessed the effects of inherent and induced fabric on mechanical properties using Firoozkuh sand as an example. However, it is important to note that the constitutive models developed within the ACST framework can be applied to any particulate material, including mine tailings, by accounting for the appropriate mechanical properties (Macedo and Vergaray, 2022). Therefore, the qualitative observations discussed earlier are expected to apply to mine tailings as well. To quantify the responses of mine tailings with fabric anisotropy, it is necessary to have well-calibrated SANISAND-F material parameters for different gradations of mine tailings. In the design or assessment of TSFs, geotechnical engineers typically evaluate the TSF's response to static liquefaction, an important engineering consideration. However, fabric effects, which are expected to be significant, are often overlooked in engineering practice due to their challenging incorporation. Nevertheless, the ACST framework, coupled with well-calibrated models, provides an opportunity to incorporate fabric effects in engineering assessments. Along the slope, various stress states such as triaxial compression, rotated principal stresses, simple shear, and triaxial extension are evident. Considering the findings discussed earlier in this paper, it is anticipated that the inherent fabric of the tailings, combined with different loading paths and initial consolidation states, play a crucial role in triggering the static liquefaction instability. The proposed criteria in this study represent a step forward in incorporating inherent and induced fabric effects once the mechanical properties are quantified.

Conclusion

In this study, we have used the ACST framework to investigate the instability conditions under CSD stress paths, considering the role of fabric anisotropy, multiaxial loading, and state in a comprehensive manner, something that has not been addressed in previous efforts. The performance of the ACST-based SANISAND-F constitutive model under CSD stress paths was found to be satisfactory. Fabric effects were incorporated into defining different instability criteria, resulting in fabric-dependent and loading condition-dependent instability surfaces. The ACST framework with the SANISAND-F model provided valuable insights into assessing the relative effects of fabric (inherent and induced), α_σ, and Lode angle on instability under CSD stress paths. Our numerical findings were consistent with experimental results for conditions representative of the limited experimental information available regarding anisotropic effects. η_f decreased with increasing Lode angle and α_σ within typical experimental ranges.

Additionally, η_f increased with higher initial fabric intensity (F_{in}), and the decrease in η_f with increasing α_σ was more significant for higher F_{in} values, consistent with the experimental study by Fanni et al. (2022). Our findings emphasize the interplay among the Lode angle, α_σ, and F_{in}. In scenarios not

previously examined, the onset of instability can either be promoted or hindered for a given Lode angle and increasing α_σ, depending on the interactions between loading and fabric directions. Further experimental investigations encompassing wider ranges of Lode angle, α_σ, and F_{in} would yield additional insights in this regard.

Numerical Modeling Evaluation of Consolidation Behavior of Saturated/Unsaturated Fluid Fine Tailings Consolidated Using the Applied Suction Method

Bereket Fisseha, Tetra Tech Canada, Canada
G. Ward Wilson, University of Alberta, Canada
Delwyn G. Fredlund, University of Alberta, Canada

Abstract

This paper explores the consolidation behavior of treated fluid fine tailings (FFT) using an applied suction method, incorporating both experimental studies and numerical modeling to enhance dewaterability and management of mine tailings. The study utilized a meso-scale column apparatus to apply negative pore-water pressure, simulating field conditions that impact FFT consolidation, including environmental effects like evaporation and desiccation in arid and semi-arid climates.

Key experimental findings demonstrated that varying atmospheric fluxes significantly influence the drying and consolidation rates of FFT, affecting the soil's transition from fully saturated to partially saturated states. Numerical models, specifically the SVFLUX-SVSOLID and UNSATCON modules, were employed to validate these experimental results and further refine our understanding of FFT behavior under applied suction conditions. The models adjusted for soil properties based on empirical data from laboratory tests, providing insights into the dynamics of self-weight and suction-induced consolidation.

Overall, the integrated approach of experimental validation and numerical modeling presented in this study offers potential strategies for improving the handling and reclamation of tailings, particularly in challenging environmental conditions. Future work will focus on refining these models to enhance their predictive capabilities and practical application in tailings management.

Introduction

The global mining industry faces significant challenges in managing the waste generated by mining activities, particularly tailings, a by-product of mining and mineral processing. Tailings consist of sand, fines (silt and clay-sized materials), and, in the case of oil sand operations, bitumen. These tailings are characterized by slow settling rates and low hydraulic conductivity due to their fines-dominated composition. The high fines content is further amplified during extraction processes by additives such as

dispersing agents (Beier et al., 2009). Upon deposition, tailings segregate, with coarser particles forming beaches and dykes, while the finer particles are stored in ponds. In oil sand operations, these fine particles in ponds are referred to as fluid fine tailings (FFT). The sedimentation process in these ponds, which is influenced by the composition of fine particles, typically results in the solids content reaching 30–35% within two to three years. However, these deposits are slow to consolidate, and once sedimentation ends, the process of self-weight compression determines the final solids content. Mine operators generally use containment structures to store FFTs, which create a large surface footprint and pose ongoing engineering challenges for reclamation.

Several operators are conducting research to improve the dewaterability of tailings and enhance their post-deposition trafficability. Techniques being explored include composite tailings, conventional thickening, centrifugation, inline flocculation and thickening, as well as various combinations of these methods. Additionally, thin-lift deposition and rim-ditching are under consideration. These initiatives focus on increasing tailings dewatering through desiccation via evaporation, drainage, or freeze-thaw and consolidation (Morgenstern and Scott, 1995).

It is well established that geotechnical engineering challenges, such as high-volume change deposits (consolidation), stability of earth-fill structures, and reclamation of tailings impoundments, are best analyzed using the fundamental principles of saturated and unsaturated soil mechanics. For instance, unsaturated flow behavior has been employed to predict the dewaterability of thin or multilayer tailings deposits, including high-density hard rock tailings, as well as to model evaporation and drainage processes (Fisseha et al., 2010; Simms et al., 2007; Simms et al., 2010; Sulfate et al., 2010).

An experimental study on the consolidation behavior of fluid fine tailings (FFT) was conducted using a meso-scale column apparatus, applying negative pore-water pressure (suction) techniques (Fisseha et al., 2017b). This study highlighted the critical role of negative pore-water pressure, an unsaturated soil principle, in the consolidation, drying, and desiccation of deposited tailings, particularly in arid and semi-arid environments with high atmospheric fluxes (Fisseha, 2020).

This paper presents a consolidation model exercise aimed at calibrating experimental results on self-weight consolidation and the applied suction method for treated FFT. The numerical analysis will enhance the understanding of tailings consolidation properties, including self-weight consolidation and suction effects due to evaporation.

Background

This section briefly reviews the objectives of the experimental study, focusing particularly on the need for the consolidation process using applied negative pore-water pressure (suction technique) and its interactions with the saturated, transition, and unsaturated zones.

The study aimed to consolidate soft tailings using the suction technique to better understand and characterize these tailings in relation to saturated and unsaturated zones. This was performed under controlled stress conditions in a laboratory setting using a column apparatus. The fundamentals and advantages of this method are detailed in Fisseha et al. (2017b) and Fisseha (2020).

In the field, desaturation, drying, and desiccation processes occur at the surface of fully saturated tailings due to atmospheric conditions, including evaporation and evapotranspiration. These processes lead to the formation of a transition or interlayer zone, influenced by changes in the water table within the soil profile from rainfall and evaporation cycles.

Figure 1 illustrates a generic transition or interlayer zone between unsaturated and saturated conditions. In the experiment, fully saturated tailings were placed in the column, and water was periodically withdrawn using an incremental applied suction method from the bottom boundary. This apparatus allowed for the investigation and characterization of the transition zone under controlled conditions, simulating field conditions of drying and desiccation. The experiments demonstrated similar development of the transition zone to what was observed in conceptual field trials, although the direction of flux differed. Consolidation and desiccation processes progressed in the column and field, regardless of the direction of flux – whether from applied suction at the bottom or from evaporation and rainfall at the surface.

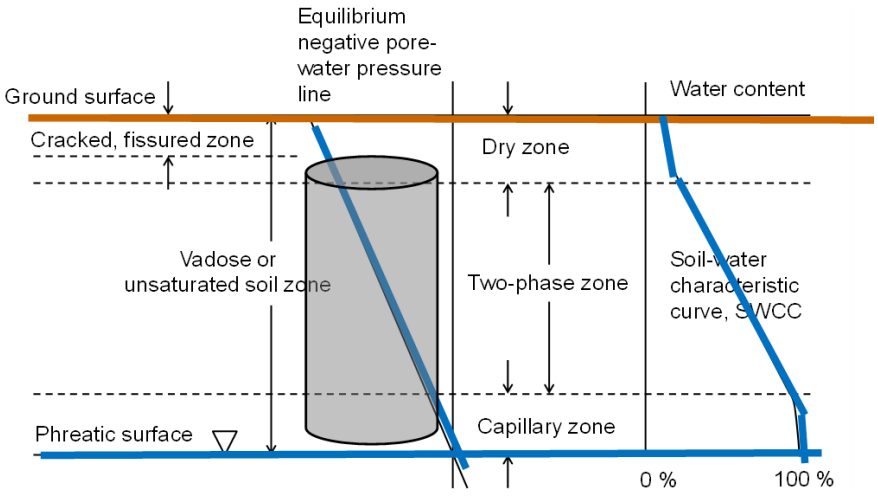

Figure 1: Column used to characterize the consolidation of tailings using applied suction in relation to conceptual unsaturated zones

Materials and methods

Materials

The study utilized flocculated FFT and flocculated centrifuged tailings cake (FCTC), with FFT prepared at 38% solids content and FCTC at 55%. Geotechnical index properties were tested to establish baseline

characteristics, using an anionic polymer A3338 as the flocculant. The preparation methods align with those reported in previous studies (Mizani et al., 2013; Fisseha, 2020). The FCTC materials were prepared off-site and are not discussed in this paper.

Table 1: Summary of geotechnical index properties of FFT and FCTC

Properties	Flocculated FFT	FCTC
MBI (meq/100 g)	3.75	–
Bitumen Content (%)**	2.57	0.37
D50, D60 (μm)	3.2, 6.3	1.4, 2.4

Note: MBI – Methyl blue index; SFR – sand to fine ratio; ** Bitumen content – calculated using total bitumen divided by dry tailings. Major ions in pore fluid were not measured

Testing methods

A number of standard laboratory tests was carried out to characterize and obtain the engineering properties of flocculated FFT and FCTC materials. Detail descriptions of testing procedures for settling test, soil-water characteristic curve (SWCC), shrinkage curve (SC), and large-strain consolidation tests (LSC) to obtain compressibility and hydraulic conductivity curves are presented in Fisseha et al. (2017a) and Fisseha (2020). A brief description of the methodology for consolidation using the applied suction technique (Fisseha et al. 2017b) during the experimental study is presented herein.

Consolidation using applied suction test

LSC testing of flocculated FFT was conducted using a meso-scale column apparatus, constructed from Plexiglas with a PVC base and a high air-entry value ceramic disc. The column had dimensions of 300 mm in diameter and 500 mm in height. This apparatus employed an applied negative water pressure technique to consolidate the materials placed within it.

Initially, flocculated FFT in Column 1 and FCTC in Column 2 underwent self-weight consolidation. This phase was complete when changes in height became infinitesimal. Following this, the accumulated bleed water resulting from settlement was decanted. It is crucial to remove this bleed water before applying negative pore-water pressure at the base of the column, to preserve the natural sedimentation process.

During the settlement/self-weight consolidation phase, the water flow was upward. This direction reversed to downward when negative water pressure was applied at the column's base. After decanting the

bleed water, sufficient time was allowed for the materials to reach equilibrium from the loading and unloading processes. The consolidation using applied negative water pressure was then continued by applying incremental vacuum pressure.

Further details on the new column apparatus can be found in Fisseha et al. (2017b).

Modeling approach

Numerical analyses were conducted to validate the experimental results from this study on the consolidation of FFTs. These analyses primarily focused on the behavior of tailing consolidation coupled with unsaturated flow properties. The literature underscores the significant role of evaporation in dewatering slurry tailings and facilitating tailings management and mine reclamation. It highlights how soil-atmosphere interactions can influence consolidation rates due to notable changes in soil suction. The study builds on these findings by providing detailed insights into how these processes interact under varied conditions, thereby offering potential improvements in tailings management and reclamation strategies.

Literature review

Models such as PLEXIS 2D (formerly known as 1D consolidation from SOILVISION), FSCONSOL, and CONSOL employ large-strain consolidation formulations. Additional models like CONDES, MinTaCo, and UNSATCON specifically integrate unsaturated flow or desiccation processes to account for dynamic soil conditions near tailings surfaces. These models are crucial for understanding the varying degrees of saturation and their impact on tailings behavior, particularly when the soil transitions from fully to partially saturated.

Numerical analysis in the experimental study utilized two stages of modeling to replicate the experimental tests as detailed in Fisseha (2020) and Fisseha et al. (2022). These stages are self-weight consolidation and consolidation using applied suction.

Stage 1: Self-weight consolidation

PLEXIS 2D (formerly known as 1D consolidation from SOILVISION SYSTEMS) was used to model the self-weight consolidation phase of flocculated FFT. This stage involved adjusting material properties based on laboratory results to align model predictions with empirical data, focusing specifically on the self-weight consolidation of FFT, not FCTC.

Model setting

The initial stage of self-weight consolidation analysis was performed using the SVFLUX-SVSOLID (consolidation) GT module from SoilVision®, chosen for its availability and compatibility with our data.

The material properties, alongside initial and boundary conditions for Stage 1, were derived from engineering properties obtained through laboratory testing, and are summarized in Table 2.

Table 2: Summary of geometry, material properties, initial and boundary conditions used during the self-weight consolidation modeling exercise for the flocculated FFT

Geometry				
Description	unit	Base reference (y-axis)	Thickness of material	
Deposited tailings	m	0	0.505	
Material property				
Model type and description	Used functions	Fitting method	Parameters	
SVSOLID	Compressibility function	Weibull function under Elasto-plastic category	*A*	0.585
			B	-0.821
			E	-0.688
			F	-0.269
		Elastic parameters	Poisson's ratio	0.3
			Minimum stress limit (*kPa*)	0.15
SVFLUX	Saturated hydraulic conductivity	Single power function	*C* (*m*/*day*)	1.750E-07
			D	8.71
Initial condition				
Model type and description	Assigned parameters	unit	Type	Value
SVFLUX	Initial head	m	calculated	–
SVSOLID	initial void ratio	–	constant	4.07
Boundary condition				
Model type and description	Boundary regions	Assigned parameters	Y– direction	Value (kPa)
SVSOLID	Top	Displacement	Free	–
	Bottom		Fixed	–
SVFLUX	Top	No boundary condition (No BC)	Excess pore pressure constant	0
	Bottom	No boundary condition (No BC)	Zero flux	–
Stage setting				
Stage name	Description	Duration (days)	Total duration (days)	Increments
1st Stage	initiation	0.1	0.1	1
2nd Stage	construction	99.9	100	1

Key parameters used include:

- Poisson's ratio: assumed within an acceptable range based on standard engineering practices.
- Hydraulic conductivity: adjusted from a measured value of 8.64E-07 m/day to 1.75E-07 m/day. This modification was necessary to align simulation results with the observed total settlement.
- Compressibility curves: modeled using the Weibull function to accurately represent the significant volumetric changes observed in flocculated FFT.

These adjustments ensured the convergence of the model and improved the agreement between the simulated results and the empirical data.

Stage 2: Consolidation using increments of applied suction

Current commercial software generally lacks the capability to model consolidation processes that involve applying increments of suction. UNSATCON, a developmental model, was employed to simulate these conditions and to validate the experimental results from incrementally applied suction. Model parameters were carefully adjusted to reflect observed behaviors, such as changes in hydraulic conductivity and volume compression, ensuring accuracy in the simulations. This streamlined summary focuses on the critical elements and results of the modeling efforts, omitting redundant details and emphasizing the outcomes and adjustments made during the modeling stages.

Model setting

The UNSATCON model was used to validate the measured results during stage 2. As an example, only results for the flocculated FFT were modeled and compared with the measured results. The results displayed the change in suction distribution over time with profile.

Table 3: Summary of fitting parameters for the tailings used during the testing program

Modified State Surface Model (SSM)								
Volume change behavior								
Fitting parameters	a – controls initial e	b – related to average slope of compression line and SWCC	c – curva-ture of compres sion curve	d – curva-ture of SWCC	f – curva-ture of compres sion curve	g – curvature of SWCC	κ	K_s
Flocculated FFT	5.3	0.85	0.06	0.006	1620	1000	0.015	0.0015
Water retention behavior								
Parameters	$C_{drying\ –\ postion\ SWCC}$		$C_{wetting}$	$\lambda_{se\ -dependence\ SWCC\ on\ e}$		$\lambda_{sr\ -\ slope\ SWCC}$	λ_{ss}	
Flocculated FFT	2.5		1.5	0.15		0.4145	0.115	

The required parameters were determined by fitting with the empirical formula described in the UNSATCON model (Qi et al., 2017, 2018). The parameters used from the state surface model (SSM) and the hydraulic conductivity functions are summarized in Table 3 and Table 4, respectively.

Table 4: Summary of parameters obtained using the power and exponential functions for the flocculated FFT

Permeability function parameter	Flocculated FFT	
	Power function	Exponential function
k1	1.0E-11	8E-12
k2	8.7089	3.1541
k3	0.75	0.5

The initial and boundary conditions assigned during the modeling exercise are presented in Table 3 and Table 4, respectively. The initial conditions were the thickness of the deposited tailings, number of depositions, initial void ratio, specific gravity, and duration of time for the model to run.

Table 5 and Table 6 summarize the initial condition and boundary conditions used during the modeling exercise for the flocculated FFT, respectively. The boundary condition given for the first 100 days described self-weight consolidation at the top that includes decantation. The bottom boundary condition describing incrementally applied negative water pressure (suction) was given the following day 100 until the end of the experimental test (i.e., 450 days).

Table 5: Initial conditions used during the modeling exercise

Description	Symbol	Units	Flocculated FFT
Total tailings height	*h*	*m*	0.5
Number of depositions	1	*unitless*	1
Initial void ratio	e	*unitless*	4.01
Specific gravity	G_s	*unitless*	2.22
Total run time	*t*	*days*	450

Table 6: Boundary conditions used during the modeling exercise

Description	Stage 2	Flocculated FFT
Top boundary	No boundary condition	Decantation
Bottom boundary	Consolidation using applied suction	Incremental suction with time

Results

The modeling exercise output with the laboratory measured results for the flocculated FFT. These results are presented in this section. The results are organized under stage 1 (self-weight consolidation) and stage 2 (consolidation using applied suction).

Stage 1: Self-weight consolidation

The output results obtained from the model are presented in this section. Figure 2 presents the final output results showing the final change in height and void ratio distribution for the self-weight consolidation process of the flocculated FFT. A comparison of measured results with modeled outputs is presented in the discussion below.

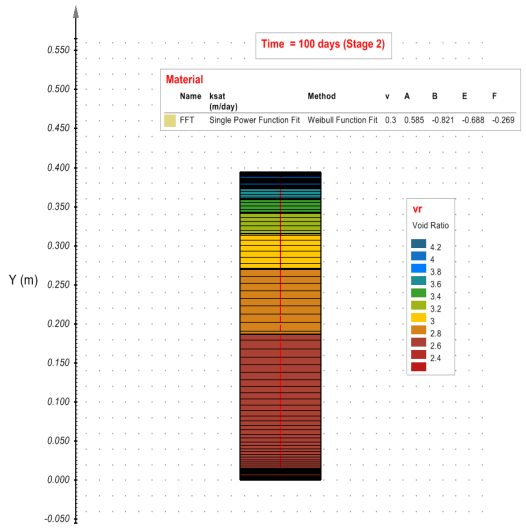

Figure 2: Model output results from SVSOLID coupled SVFLUX

Void ratio

The void ratio distribution within the flocculated FFT profile varies with depth, as expected. The initial void ratio assigned was 4.07 and was uniform for the entire profile. Figure 2 shows an output results

comparison between the model output and average void ratio measured. The modeled output results are presented as "Day 1" and the measured values are presented as "e-avg_Day 1." The output from the self-weight model results shows a smaller void ratio near the bottom of the column with variations along the entire material thickness, as shown in Figure 3.

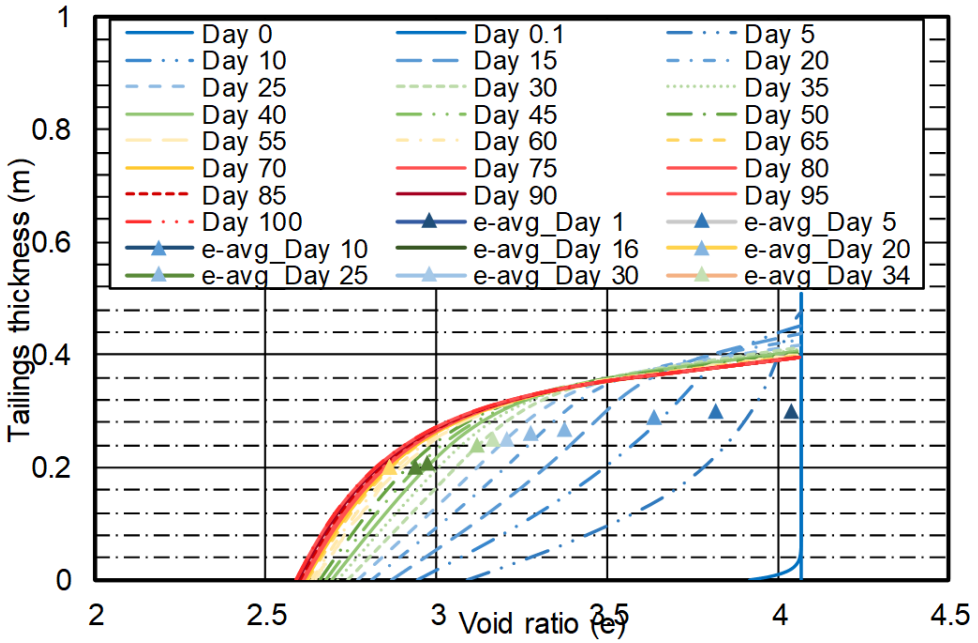

Figure 3: Modeled and measured average void ratio for the FFT during stage 1

For instance, a final void ratio of 2.2 was observed at the column's bottom and 4.07 near the surface at the end of the self-weight consolidation process, as illustrated in Figure 3, which depicts changes in void ratio with depth and time. The model output was assessed against the average void ratio across the entire tailings column, calculated daily and plotted as single data points. The measured and predicted results generally aligned, with discrepancies likely due to averaging the void ratios for the entire column thickness instead of using a more detailed model approach.

Settlement

The modeled settlement results for the flocculated FFT are presented in Figure 4. These results were in reasonable agreement with measured results. The model slightly over-predicted the settlement for the first 30 days and under-predicted the settlement from day 60 until the end of the self-weight consolidation process.

In general, the model output was in agreement with the average measured settlement. It should be noted that the settlement measurements were conducted using three-point measurement and that the averaged methods from the surface since the tailings surface were not flat and smooth.

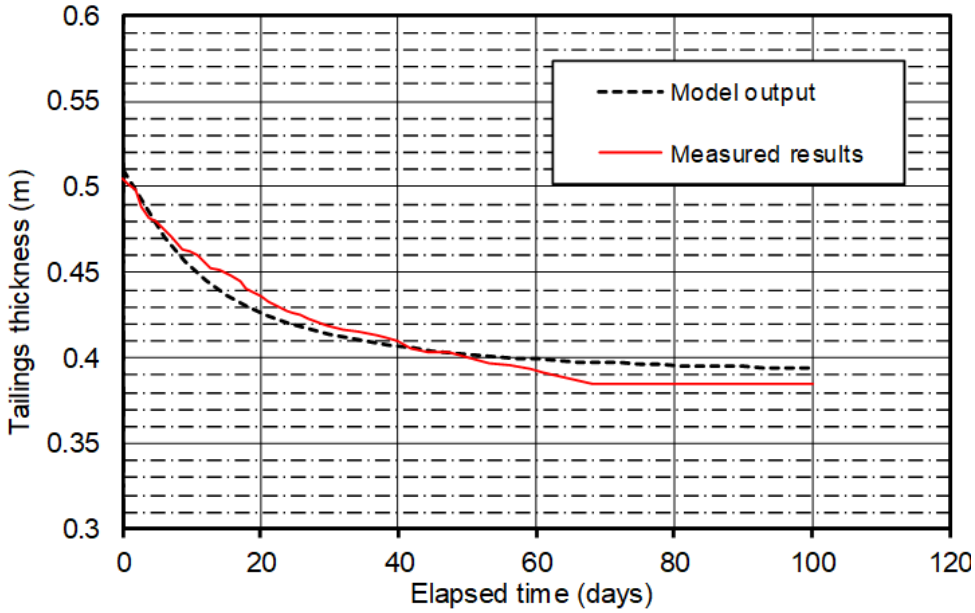

Figure 4: Total vertical settlement for the FFT during Stage 1

Excess pore pressure

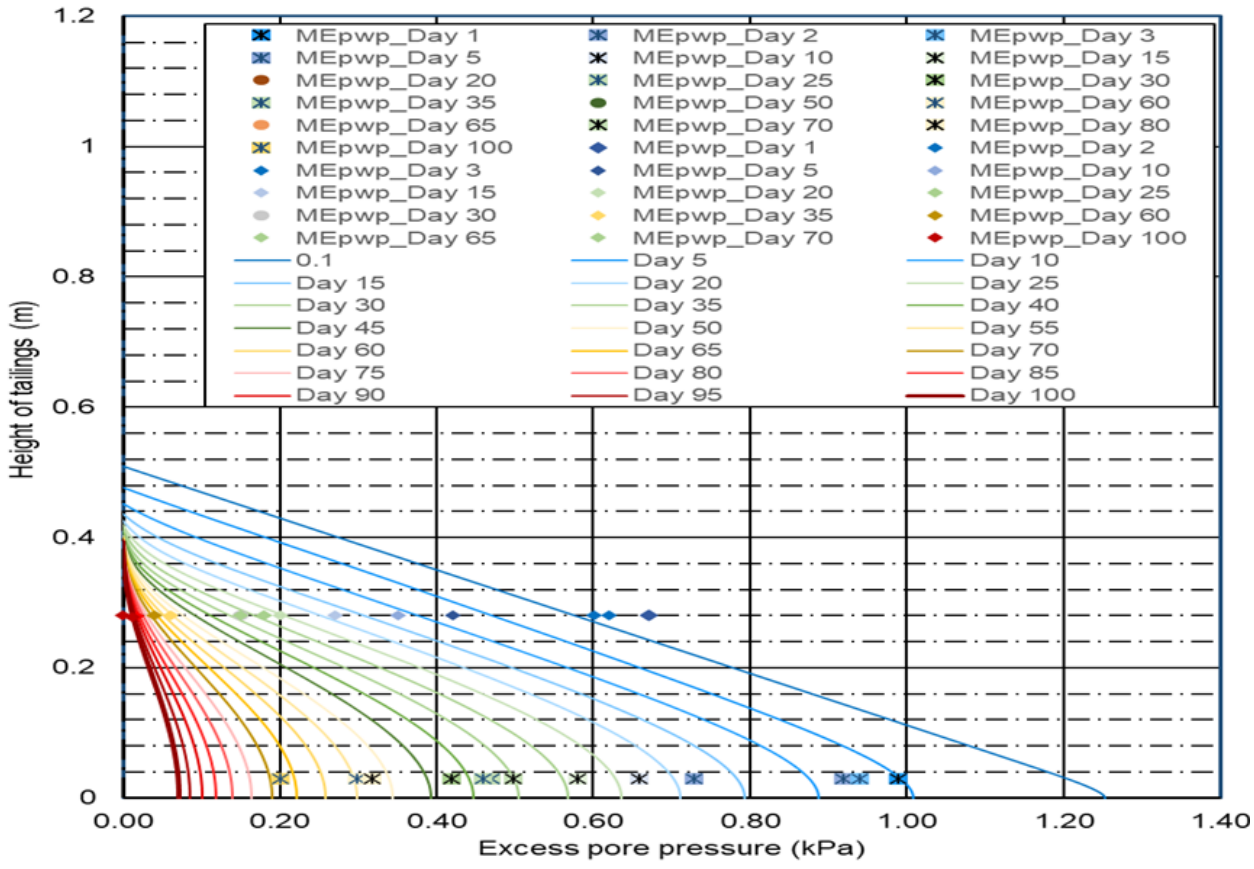

Figure 5: Excess pore pressure dissipation for the flocculated FFT during Stage 1

The results of excess pore pressure dissipation from the model output and measurement are presented in Figure 5. A comparison of the modeled and measured results shows good and reasonable agreement. Pore pressure results are described as "MEpwp_Day 1" for the measured excess pore pressure and "Day 1" for the model output. Possible excitation values were incorporated that can increase the sensitivity values of the sensor. Roughly up to +/- 5% of error can be included due to excitation and other factors.

The measured data points are presented with the same color for the corresponding dissipation time presented by the model. The model and measured results are presented as line and data points in Figure 5 for the corresponding elevation, i.e., sensor located 3 cm and 28 cm above the column base. The same colors are used between measured and modeled excess pore pressure for the same corresponding times. Overall, a good agreement was predicted between the modeled and measured dissipation of excess pore pressure results.

Effective stress

The effective stress results calculated using the model are presented in Figure 6. The model output was compared with the calculated effective stress results using the change in total density calculated.

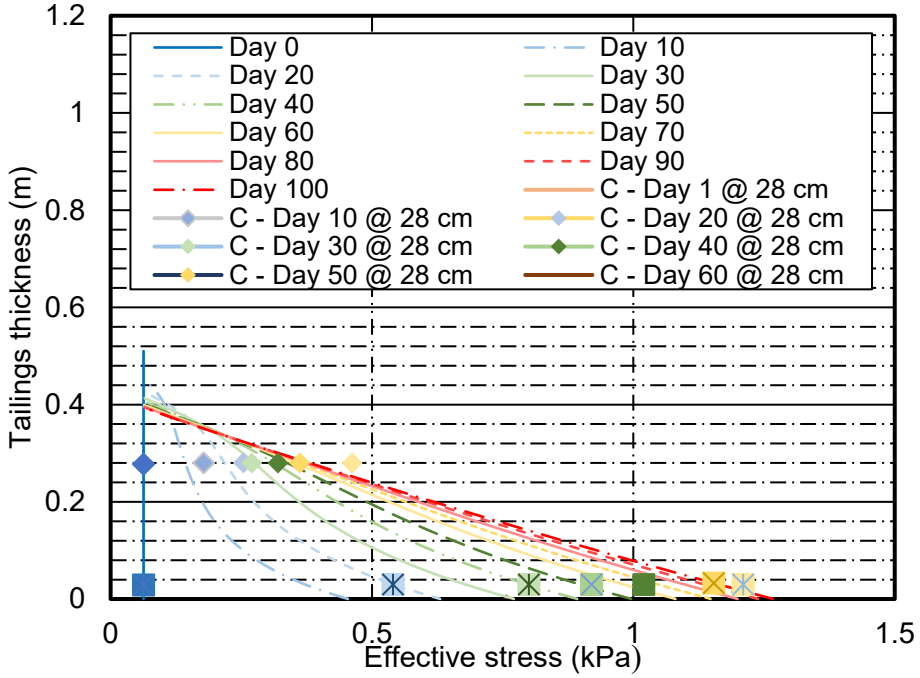

Figure 6: Effective stress computed from model output for the FFT during Stage 1

The calculated effective stress values are presented as individual data points for a given time and described in the legend as "C – Day 10 @ 28 cm" to indicate the calculated, day 10 located at 28 cm from the base of the column. The model results are given as a line in the plot. The calculated effective stress results were higher than the effective stress predicted using the model. For example, the calculated effective

stress was 2.6 kPa near the base of the column by the end of the self-weight consolidation period, in comparison to 1.2 kPa predicted by the model. The calculated effective stress values were reasonable in agreement assuming error values of 0.4 – 1.3 kPa over time.

Stage 2: Consolidation using applied suction modeling

The results from the UNSATCON model were changed in total height, gravimetric water content, solids content, void ratio, and distribution of suction with deposited tailings thickness, and are discussed in the following section.

The model requires additional calibration and refinement to achieve reasonable agreement with the measured results. The scope of this thesis does not include development of the software, refinement, and calibration.

Change in total height

The measured and modeled change in total height (vertical strain) for the applied suction test are presented in Figure 7. The final height was 0.23 m and 0.25 m for the measured and model, respectively. Overall, reasonable and acceptable agreement was obtained between the measured and modeled results.

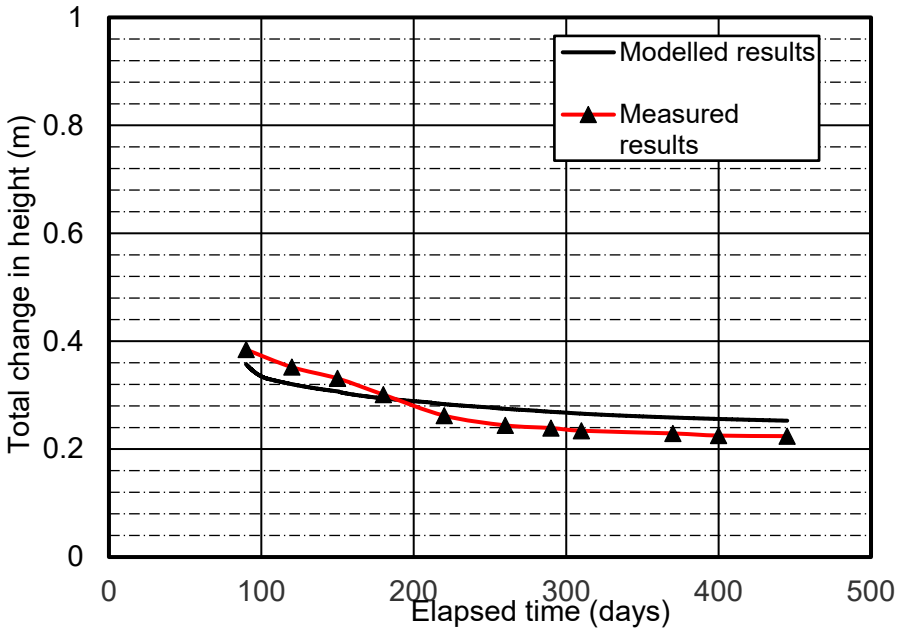

Figure 7: Comparison of measured and modeled vertical strain results

Solids content

The solids content, calculated from the gravimetric water content, averaged 72%. Figure 8 shows an overall acceptable agreement, with unsaturated soil properties slightly underpredicting the results at 68%. Three

months after the mesoscale test, the solids content increased, likely due to evaporation, as no additional suction was applied following completion of the test.

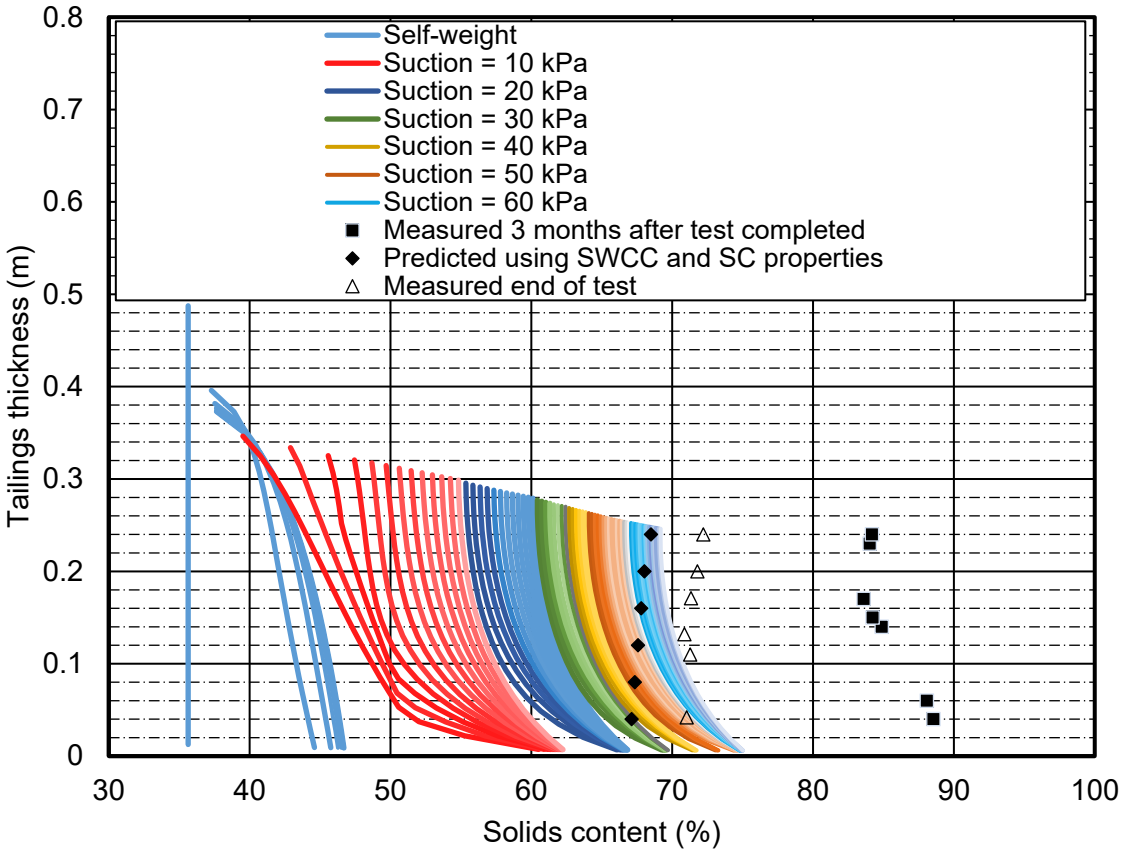

Figure 8: Comparison of measured and modeled solids content results

Void ratio

Figure 9 shows the measured and modeled void ratios, with the measured values accounting for lateral deformation. The average measured void ratio across the tailings thickness is represented by a colored diamond, corresponding to the suction line colors in the figure. Averaging the void ratios affected the values, especially when there was a significant difference between the surface and bottom of the tailings. The final average measured void ratio was 1.07, while the modeled ratio was 1.35. Reasonable agreement was observed at lower suction values, but as suction increased, significant differences emerged between the measured and modeled void ratios. Further model refinement is recommended for further accurate results.

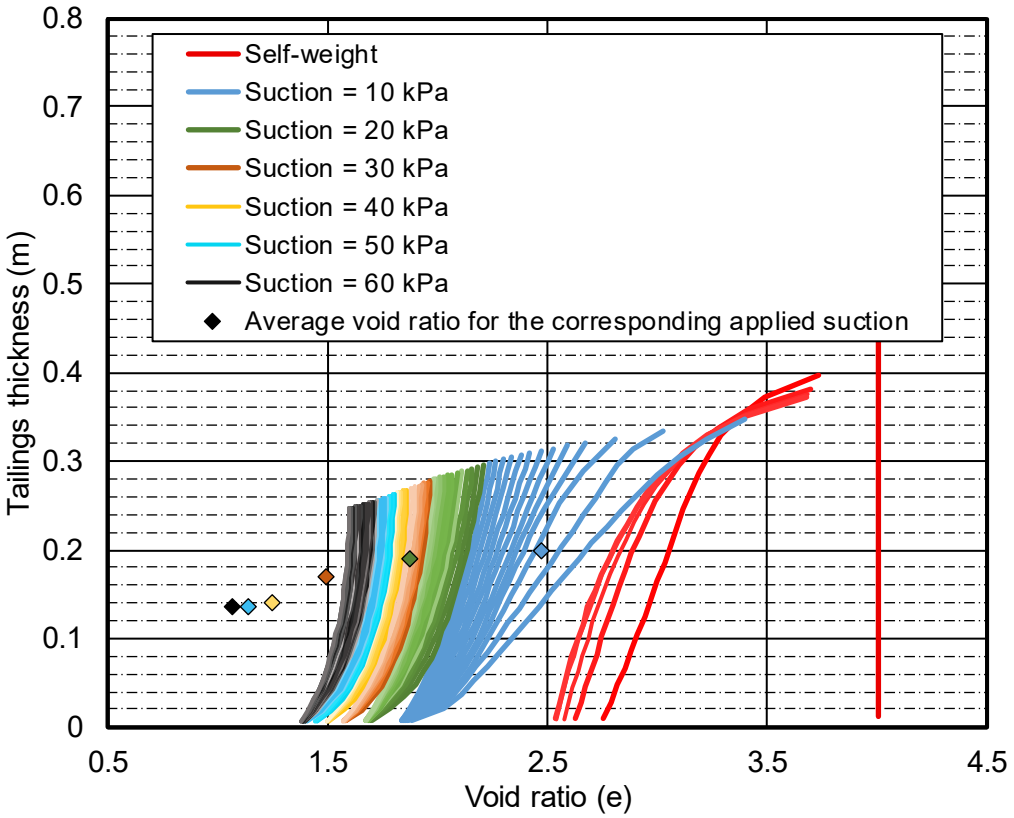

Figure 9: Comparison of measured average void ratio and modeled void ratio results

Conclusion

In conclusion, the SVFLUX_SVSOLID model closely aligns with experimental results for self-weight consolidation, as seen in Figures 2 to 5, covering void ratio, total settlement, excess pore pressure dissipation, and effective stress distribution. The UNSATCON model provided a good match for surface settlement compared to mesoscale testing. While solids content showed reasonable overall agreement, the trends varied with depth between measured and modeled results. However, the suction results showed no agreement between the model and measurements.

The UNSATCON model offers significant capabilities in simulating the consolidation behavior of unsaturated soils, making it a valuable tool in engineering design and analysis. By accurately modeling the complex interactions between soil structure, moisture content, and suction, UNSATCON allows for a more reasonable prediction of settlement and consolidation in unsaturated soils, which are often challenging to assess with traditional methods. This enhanced understanding facilitates more reliable designs, particularly in geotechnical applications where soil behavior under varying moisture conditions is critical, such as subject to various drying and wetting cycle. The model's ability to incorporate unsaturated soil mechanics

into consolidation analysis provides engineers with a more comprehensive framework, ultimately leading to safer and more efficient design solutions in civil engineering projects.

Abstract

In recent decades, there has been a significant increase in the demand for mineral resources, driving advancements in mining technologies and processes. This has led to the rapid expansion of mining complexes and associated geotechnical structures such as slopes, waste piles, and dams. Consequently, there is a growing need for geotechnical studies, analysis, and projects. In some mining complexes such as the Itabira Mining Complex in Brazil, geotechnical parameters for fragmented waste rock used in projects are often qualitatively inferred or based on relationships proposed in literature, due to limitations in quantitatively defining these parameters from large-scale samplings. This qualitative approach introduces uncertainties in safety factors and geotechnical design criteria confidence.

To address this, the Itabira Mining Complex has developed a method to quantitatively characterize waste rock for more precise use in geotechnical projects. Studies on friable samples have shown more conservative parameters compared to those for rocky samples, serving as an initial step in understanding these materials and evaluating whether parameters derived from literature are suitable references for design studies on waste rock piles. Laboratory testing campaigns, particularly triaxial tests, have been conducted on various lithologies within the Itabira complex to primarily determine strength parameters such as friction angle and cohesion. These tests, supplemented by characterization tests, enhance our understanding of the lithologies and their behavior. The test results presented in this study outline the approach used in the Itabira Mining Complex to quantitatively characterize waste rock for more accurate and informed utilization in geotechnical projects, particularly in waste rock piles and shared tailings and waste rock piles.

Introduction

The Itabira mining complex is situated in the extreme northeast of the Iron Quadrilateral, within the central region of Minas Gerais state, Brazil. It comprises the Conceição, Minas do Meio, Periquito, Dois Córregos, Onça, Camarinha, Chacrinha, and Cauê mines, encircled by their respective geotechnical structures. Open-pit iron ore extraction is a primary economic pursuit in Itabira, a municipality in Minas Gerais state. Established in 1942 in Itabira city, Vale S.A. presently holds the distinction of being one of the world's largest iron ore producers. The Itabira mining complex presently yields approximately 25 million tons of iron ore annually. The cessation of mine operations is projected to happen around 2042.

Nearly 80 years of operational history have engendered vast, deep, open-pit excavations and significantly elevated heaps of waste rock, some of which exceed 300 meters in height. Given its adjacency and constraints relative to urban locales, the ensuing two decades will witness an augmentation in extant geotechnical structures, encompassing waste rock heaps, alongside the initiation of novel structures. Moreover, alterations in long-term mine planning over the years and shifts in the acceptance of geotechnical design criteria necessitate the reinforcement of certain extant waste structures.

In all instances, fragmented rock waste is integrated as an elemental constituent within projects. The term "fragmented" denotes materials subjected to detonation. Principal applications encompass its utilization within drainage systems, safeguarding the slope facets of waste piles constituted of altered material, and, notably, serving as a geotechnical reinforcement material (buttress). Diverse designers and consultants undertake project execution. The variability in quality and geotechnical proficiency of waste rock stems from constraints in quantitatively delineating geotechnical parameters from fragmented waste rock. These parameters are qualitatively inferred or established via relationships posited in literature, leveraging fundamental parameters of friable materials, which have undergone extensive scrutiny.

Regional and local geology

The Iron Quadrilateral is located at the southern extremity of the São Francisco Craton (Almeida, 1977). It is the result of various tectonic and deformational activities involving two major orogeneses: the Trans-Amazonian, which occurred over approximately 2,000 to 2,200 million years and the Brasiliano, which occurred over 650 to 500 million years (Alkmim and Marshak, 1998; Dorr, 1969). These two orogenic events at different times led to the formation of high-grade ores (Rosière et al., 2001; Rosière and Chemale, 2000). The rocks of this formation are divided into three lithologies: the Metamorphic Complex, consisting of gneisses, migmatites, and granitoids; the Rio das Velhas Supergroup, a metavolcanic sedimentary sequence of the greenstone belt type; and the Minas Supergroup, composed of clastic and chemical metasedimentary rocks (Castro et al., 2020; Dorr, 1969). The combination of hypogene and supergene

processes explains the formation of high-grade iron ores in the iron quadrilateral (Rosière et al., 2008). In the geological formation process, high-grade iron ores replaced itabirites in locations where faults occurred in the rocks due to tectonic activities (Rosière et al., 2008).

In the Itabira mining complex, the formation of marine metasedimentary rocks is observed (Dorr, 1969). These consist of itabirites, dolomitic itabirites, amphibolitic itabirites, and, subordinately, phyllites, quartzites, schists, and marbles of the Cauê Formation. Rossi et al. (2019) demonstrate that within this mining complex, depicted in Figure 1, four geological units are identified, constituting the Itabira synclinorium: basement gneisses, volcano-sedimentary sequence of the Rio das Velhas Supergroup, metasedimentary units corresponding to the Minas Supergroup, and granitoid bodies. All of these sequences are intruded by intrusive rocks. Additionally, there are recent sedimentary coverings throughout the region.

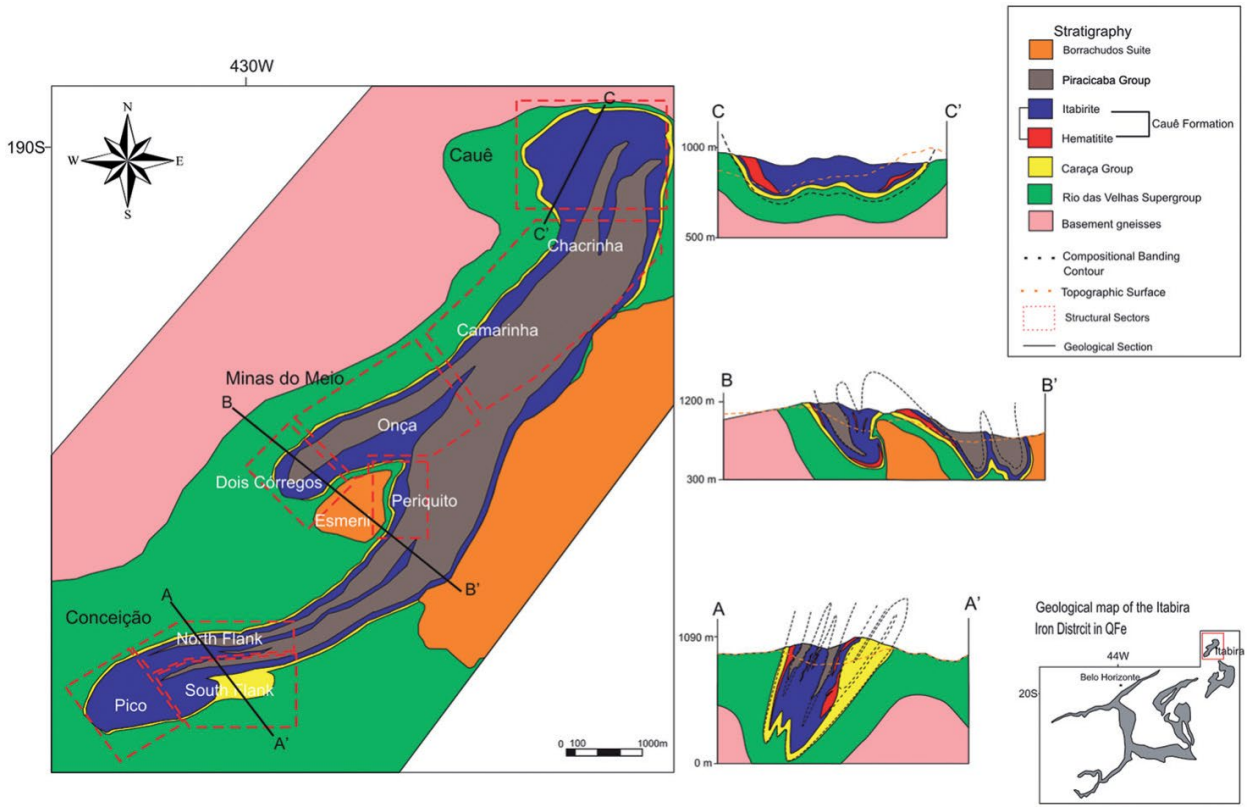

Figure 1: Geological map of the Itabira Mining Complex, location of the mines, structural sectors, and vertical geological section of the mines (extracted from Endo et al., 2019)

Geotechnical characterization of the Itabira complex waste materials

The imperatives of sustainability and economic efficiency are fundamental realities in the mining sector, driving the imperative to innovate and modernize operational processes while optimizing the utilization of available materials in mineral extraction endeavors. Alongside the persistent aim of maximizing metal retrieval from ores, ensuring continued access to mining sites and safeguarding the stability of waste rocks

and tailings management infrastructure such as piles and dams create a critical necessity for comprehensive studies and analyses of the geotechnical properties of these materials. However, the assessment of such properties for waste materials within areas of ancient rock formations, subject to diverse weathering processes as observed in Itabira, poses challenges due to the inherent complexity and variability of these materials. Consequently, geotechnical parameters are often qualitatively inferred or derived from established relationships found in the literature. The comprehensive characterization of fragmented waste materials on a large scale to accurately quantify geotechnical parameters remains a significant challenge in the mining industry, prompting reliance on characterizations primarily based on easily disaggregated rocks in locations such as Itabira. The presence of cavities in the Itabira massifs signals a prevalent occurrence of waste materials derived from easily weathered and fragmented rocks, predominantly composed of quartzites and schists. Therefore, a testing campaign on these materials was conducted to determine their strength and characterization parameters for waste pile projects.

Friable quartzites

Two primary types of quartzite material exist in the Itabira Complex, categorized as Micaceous Quartzite and Ferruginous Quartzite. These materials were classified using the Bieniawski method as completely weathered rock (W5) and highly weathered rock (W4) (ISRM, 1981). Subsequently, the strength varied from very weak rock (R1) to weak rock (R2) (ISRM, 1981). Characterization tests were conducted on various samples to determine the particle size distribution, demonstrated in Figure 2; the Atterberg limits to determine the plasticity of these materials, presented in Figure 3; and specific mass. All tests are executed by the Brazilian Association of Technical Standards (ABNT).

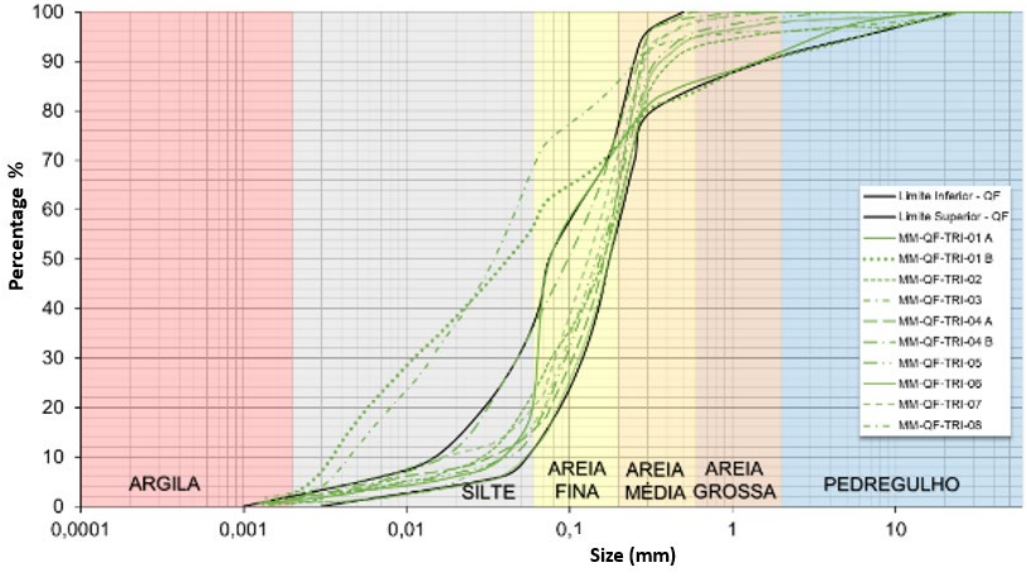

Figure 2: Particle size curves of friable quartzite

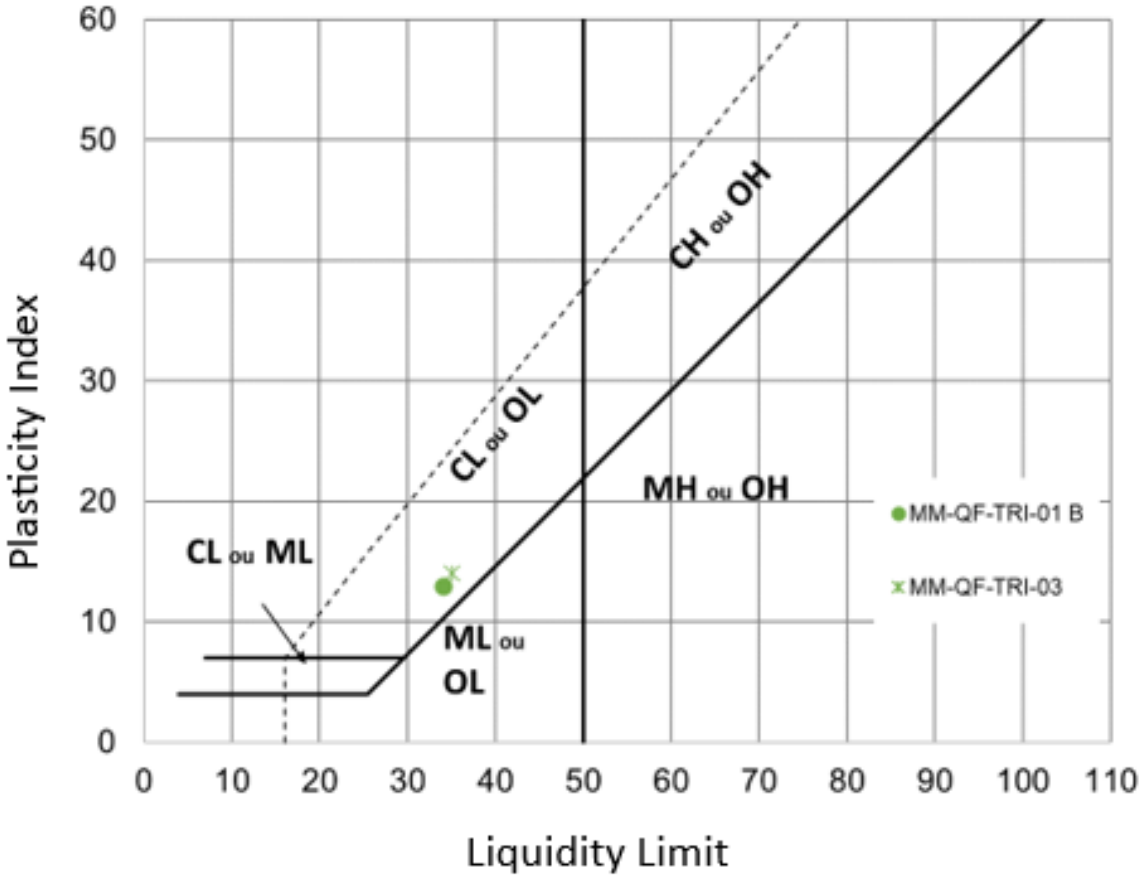

Figure 3: Plasticity chart of friable quartzite

Based on the particle size curves, the friable quartzite was categorized by ABTN as poorly graded silty sand with fines, comprising approximately 20% of materials passing through the sieve with an aperture of 0.075 mm. The fine fraction of the materials predominantly exhibits low plasticity or non-plastic characteristics. The specific mass ranged from 2.70 g/cm³ to 3.51 g/cm³, with higher values attributed to elevated concentrations of ferrous oxides.

Drained and undrained triaxial compression tests were conducted on samples reconstituted to a dry density of approximately 85% of the maximum dry unit weight, determined through standard compaction tests, under confining stresses of 200, 400, 800, 1,600, and 3,200 kPa.

The drained test results are illustrated in Figure 4, revealing dilative behavior under the three lowest confining pressures (200, 400, and 800 kPa) and contractive behavior under the two highest confining pressures (1,600 and 3,200 kPa).

The results of the undrained tests are depicted in Figure 5, indicating an increase in pore pressure due to shear for all 5 confining pressures. This behavior suggests a contractive material and aligns with the drained test outcomes discussed earlier.

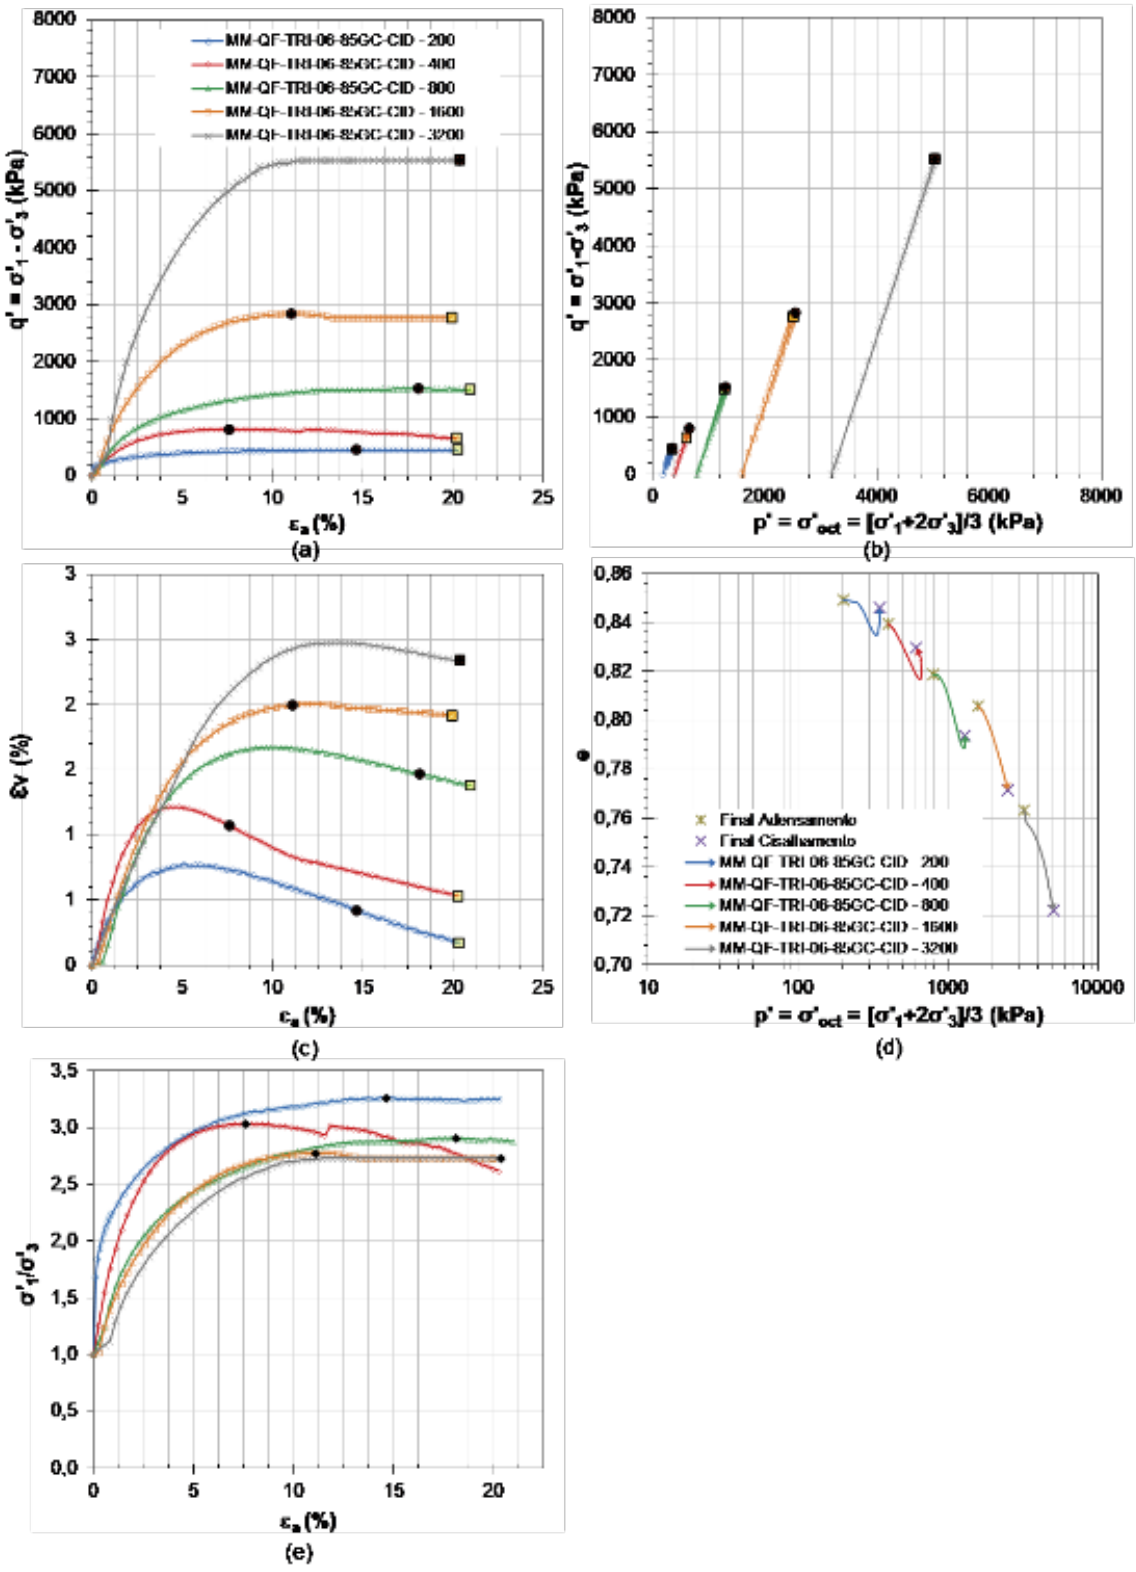

Figure 4: Drainage tests on friable quartzite

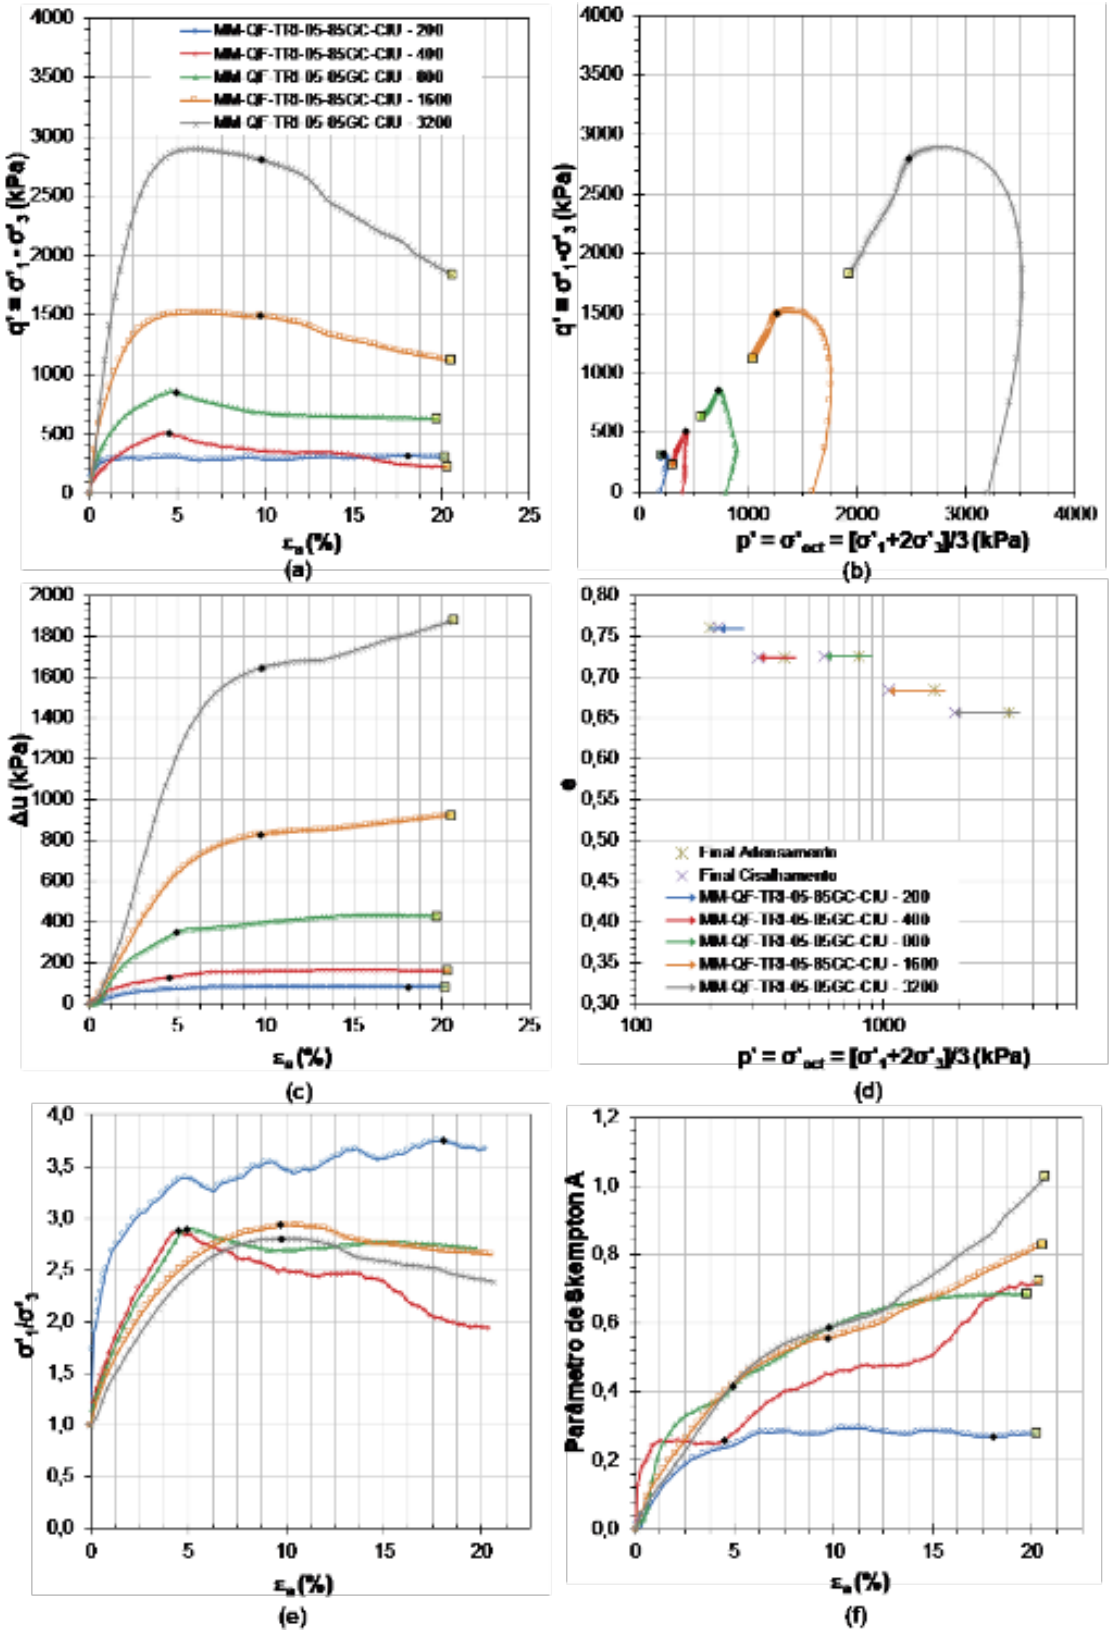

Figure 5: Undrained friable quartzite tests

Friable schist

The friable schist material is characterized as saprolitic schist with intercalations of phyllite. The material's weathering degree was determined as completely weathered (W5), and its resistance level was classified as very weak (R1), in accordance with ISRM (1981) standards. Various samples underwent characterization tests to acquire the particle size curve, depicted in Figure 6, the Atterberg limits, shown in Figure 7, and specific mass measurements of the friable quartzites. All tests were executed by the Brazilian Association of Technical Standards (ABNT).

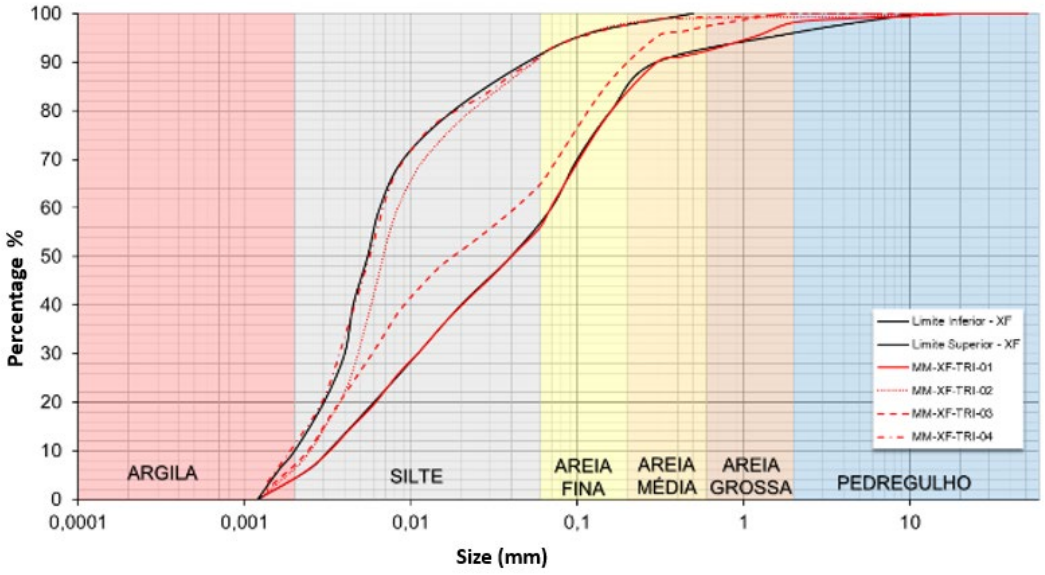

Figure 6: Particle size curves of friable schist

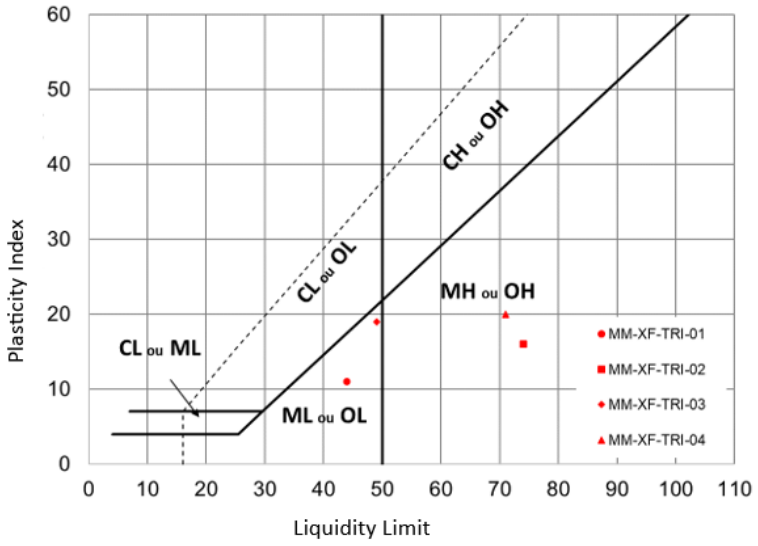

Figure 7: Plasticity chart of friable schist

The results of the particle size characterization tests classified the friable schist as a fine-grained material, with 52% to 85% of the total mass passing through the sieve with openings of 0.075 mm. The fines were categorized as low to high plasticity silt based on the results of the Atterberg limits. The specific mass of the materials averaged 2.86 g/cm³. Triaxial tests show that friable schist tends to generate positive pore pressures in undrained conditions and undergoes contraction, reducing the void ratio, in drained conditions. Figures 8 and 9 illustrate the results obtained in the drained and undrained tests for stresses ranging from 200 to 3,200 kPa. The materials showed contractive behavior in both cases.

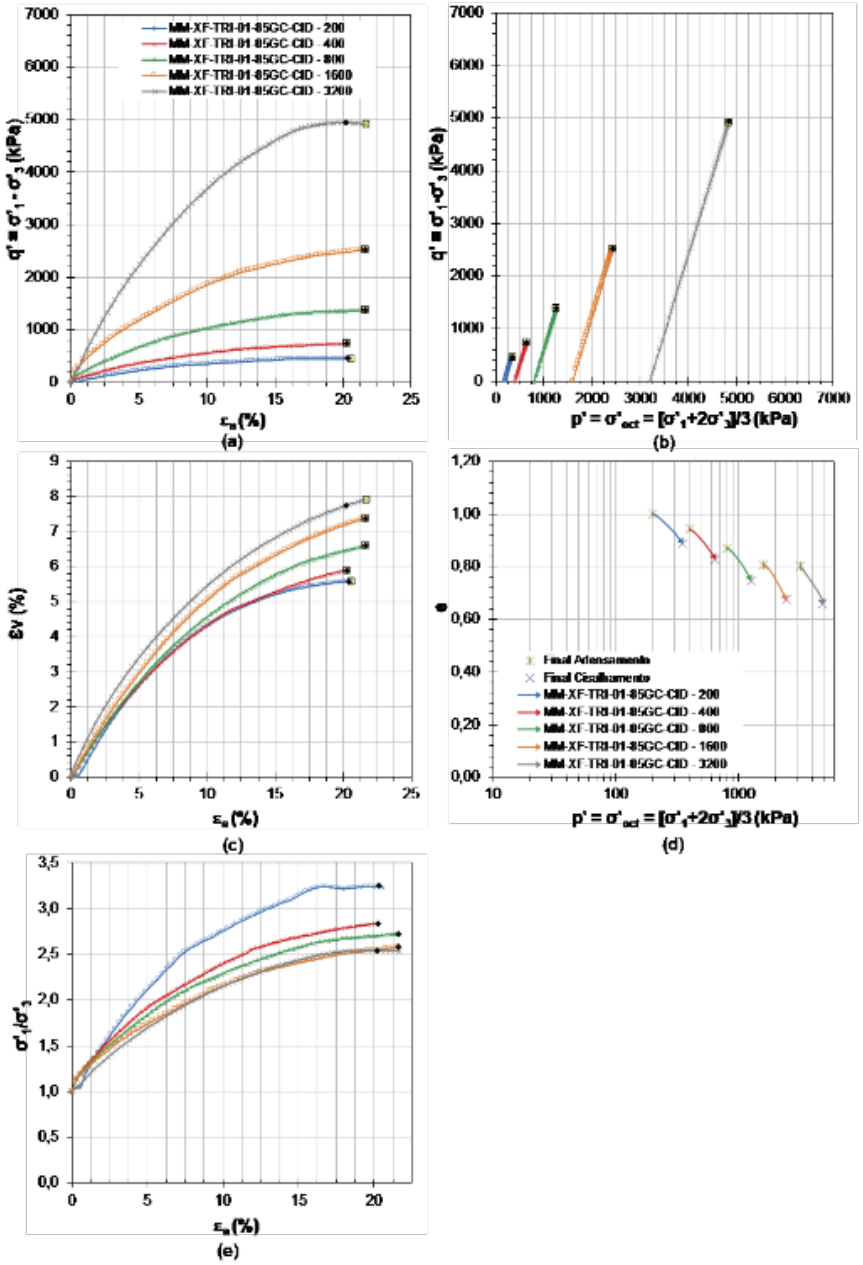

Figure 8: Drained tests friable schist

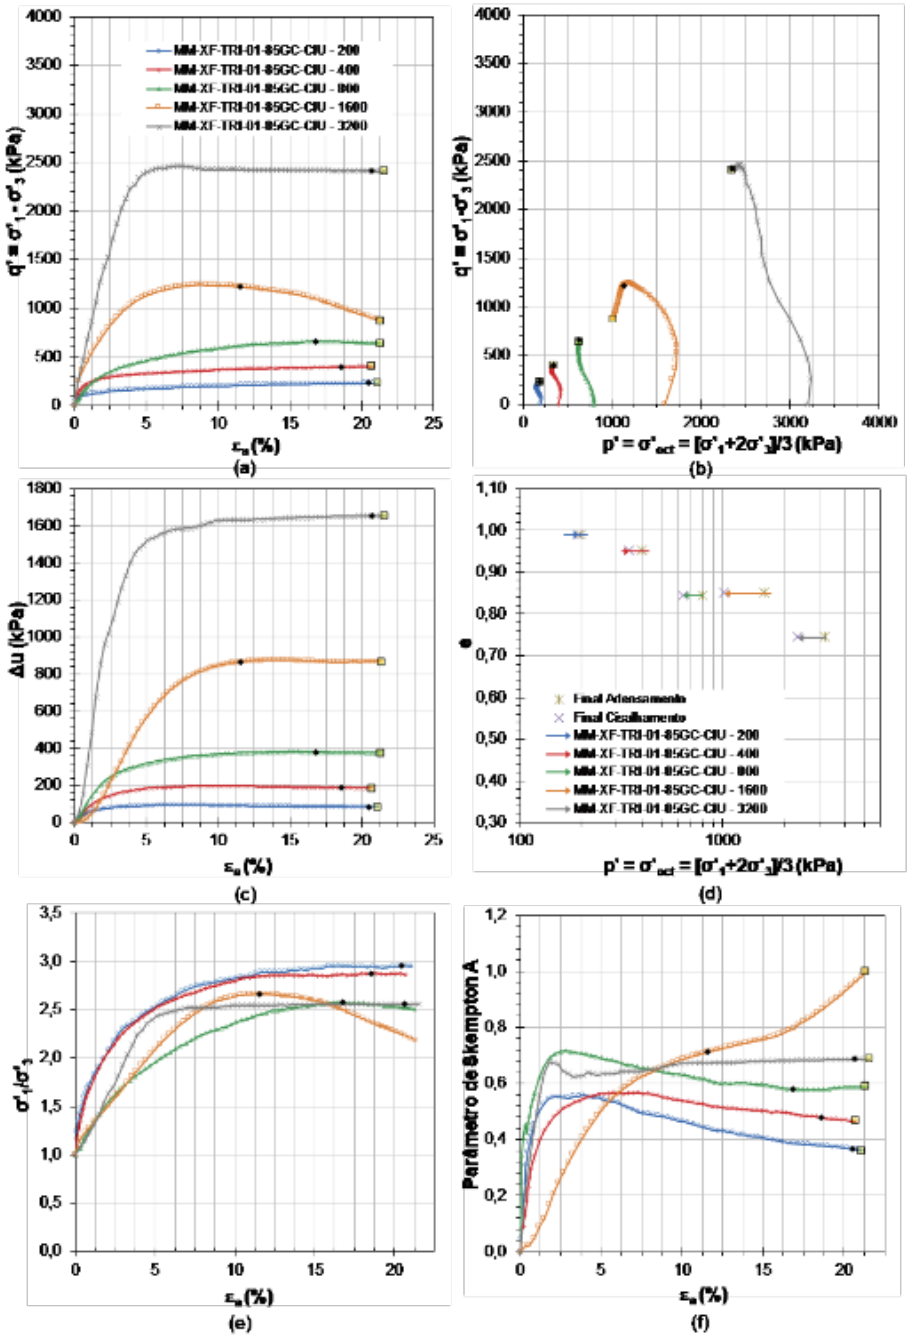

Figure 9: Undrained friable schist tests

Conclusion

Due to the depth of the mines in the Itabira complex, the waste materials consist of friable and rocky materials from blasting. The results of this study classified the behavior of friable materials, demonstrating that at low (200 kPa) and high (3,200 kPa) stresses, these materials tend to behave preferentially in a contractive manner. However, as observed in the test on sample MM-QF-TRI-06, the friable quartzite

exhibited dilative behavior at low stresses when compacted to 85% of standard Proctor density. These findings prompted a revision of the designs to enhance the geotechnical parameters of the waste rock piles, given that friable materials contribute to increased structural fragility. Despite this behavior, none of the samples underwent static liquefaction in any of the tests, indicating that pore pressures did not exceed effective stresses. Although there were discrepancies in the behavior of quartzites and schists, it is assumed as a design premise in the Itabira Complex that the most critical condition of these materials, in each evaluated parameter, should be adopted to ensure greater accuracy in the safety factors of the structures.

Studies focused on the parameters of rocky materials should be conducted to potentially enable the segregation of materials in pile structures, aiming to identify areas where friable materials can be disposed of in a confined manner, in case the geotechnical parameters of rocky materials exhibit characteristics that increase safety factors.

Feijão Dam I 3D Numerical Simulation: A Comprehensive Approach, from Triggering to Dam Breach

Alfredo Arenas, ATC Williams, Australia
Nicolas Pereira, Red Earth Engineering a Geosyntec Company, Australia

Abstract

The failure of Dam I at Vale's Córrego do Feijão iron ore mine on 25 January 2019 resulted in significant human, environmental, and economic losses. Efforts have focused on understanding the triggering mechanisms behind the failure, traditionally modeled using commercial software based on continuum mechanics and small strain theory. However, these approaches are limited to capturing only the initiation of events.

This study employs the Material Point Method (MPM), a robust numerical technique capable of modeling large deformations, to bridge the gap between small and large strain theories. Unlike conventional methods like FLAC3D, MPM offers a more comprehensive analysis of the complex triggering mechanisms and initial stages of dam breach events.

The paper summarizes liquefaction triggering analyses of the tailings storage facility (TSF) and details the integration of post-triggering states from FLAC3D into the MPM framework. This approach avoids the arbitrary assignment of residual strengths typical in traditional dam breach analyses. The study outlines the iterative propagation process of failure using MPM-PUCRio and presents detailed results from the dam breach analysis conducted with this method.

Introduction

The failure of Dam I at Vale's Córrego do Feijão Iron Ore Mine on 25 January 2019 resulted in tragic consequences, including over 270 fatalities and significant economic and environmental damage. This event, along with other recent catastrophic failures of tailings storage facilities (TSFs), have prompted extensive efforts to enhance TSF safety (ICOLD, 2022; Morrison 2022).

Despite the clear visual evidence of flow liquefaction captured in video footage of the failure, there remains substantial debate regarding its triggering event. Two primary investigations have been conducted. First, the Expert Panel (EP) released a report in December 2019 (Robertson et al., 2019). This group

attributed the failure to a combination of reduced surficial suction due to increased rainfall and drained creep. They explicitly dismissed drilling activities conducted at the time as a plausible cause. Second, CIMNE published a report in August 2021 (Arroyo and Gens, 2021). They identified drilling-induced liquefaction as the primary trigger, while discounting creep and suction reduction as potential causes.

The work herein summarizes the methodology and findings of the triggering mechanism that led Dam I to failure. The FLAC3D triggering mechanism assessment is part of an undergoing work, with an already finished set of analyses, which is an extension of the work presented at NUMGE 2023 (Arenas et al., 2023) from plain strain analysis (2D) to a full 3D model.

Specifically for the work presented herein, a series of FISH codes were implemented in FLAC3D to export mesh state into MPM-PUCRio. The mesh analyzed in FLAC3D is exactly the same mesh used in MPM-PUCRio. Among the exported data from FLAC3D are the grid points, the material groups, stress tensor, strains, liquefaction state, and the pore water pressure.

MPM-PUCRio was run iteratively to simulate the propagation of the failure under large strain deformation. The triggering mechanism framework is imported as defined in FLAC3D. Through a C# code the progression of the solution is iteratively carried out in MPM-PUCRio, where a solution is saved as time in the model advances.

FLAC3D numerical modeling

Geometry

The numerical model geometry was derived from publicly available information, notably the EP report on Feijão dam. This information consists mainly of plain images and tables, lacking digital data such as UTM coordinates or elevations.

To address this challenge, Geo Meshing v4.3.2 software was employed to convert this information into a detailed 3D numerical model. Geo Meshing utilizes parametric inputs, such as crest width, to generate 2D/3D meshes without requiring 3D surfaces or volumes. It was also utilized for interpolating Ψ values within tailings elements, inferred from Cone Penetration Testing (CPTu) data.

A discretization size of 3.5 × 3.5 × 3.5 meters was used, resulting in a model with approximately 1 million elements. Figure 1 provides insights into the 3D model details. Note the model's cutting plane is located at section "SM13," named after the borehole position, being drilled at the failure moment (BH SM13). The model was created using tetrahedra elements, to make it 1:1 compatible with the MPM solver.

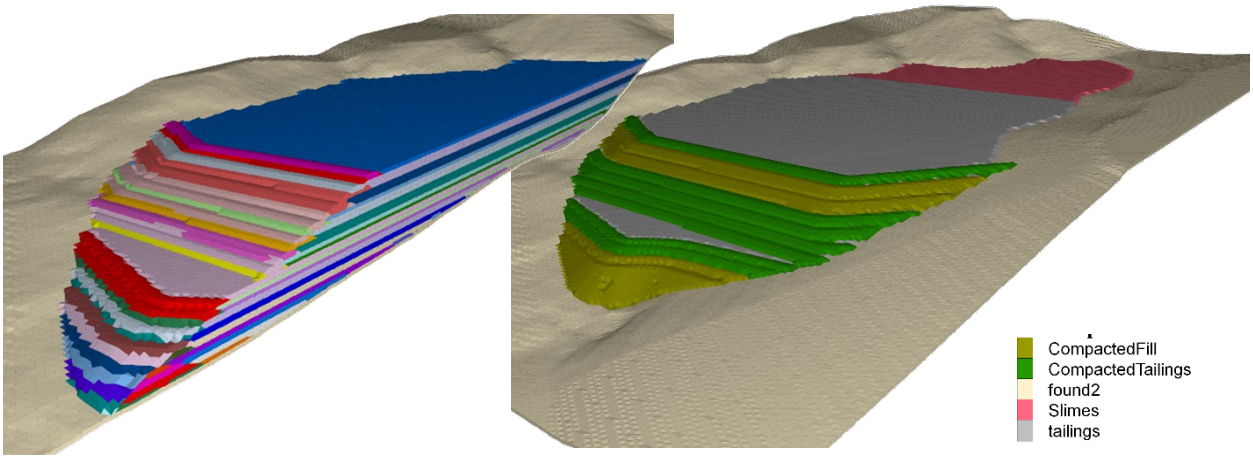

Figure 1: FLAC3D model. Left: FLAC3D model cut at section SM13, showing construction stage layers. Right: full 3D model describing main geotechnical units

Constitutive models

Each material during the Dam I construction sequence was simulated using the Mohr-Coulomb (MC) constitutive model (Itasca, 2022), with parameters detailed in Table 1. In addition, and during the triggering process, the NorSand model was used to capture the excess pore pressure generation that loose and brittle tailings generate before crossing the instability line in Table 2.

While the use of MC for stiff foundations or compacted embankments is common, even in advanced modeling, its application to saturated, contractive, and brittle tailings necessitates further discussion.

The decision to employ a modified form of the MC model, for those tailings element crossing the instability line, is supported by several factors:

(i) no constitutive model, to the best of the authors' knowledge, reliably captures behavior along the critical state line (constant shear drained stress path) in boundary value problems for loose, contractive, brittle soils; and

(ii) the use of any constitutive model, regardless of its sophistication, inherently assumes or explicitly defines in-situ values of parameters like the lateral earth coefficient at rest (K_0), the principal stress ratio (Kc), and the Lode Angle, which are crucial for identifying instability initiation when verifying if the stress ratio η (the ratio of deviatoric stress, q, to mean effective stress, p') is higher than the stress ratio at the instability line (ηIL).

To address these challenges, the MC model was adapted during the construction sequence with a Poisson's ratio selected to target a specific K_0 below ground level, set at 0.7 in this instance. This approach enables a reasonable estimation of in-situ K_0, which is not always feasible with more complex models. In addition, this value avoids setting off the proposed triggering scheme at the end of construction.

Table 1: Mohr Coulomb material properties. Drained properties. Construction only

Material	Shear Modulus Reference[1] (kPa)	Friction (°)	Cohesion (kPa)
Foundation	1,472,000[2]	N/A[3]	N/A[2]
Slimes	1,285	0	$0.22(\sigma'_v)$
Compacted Tailings	3,496	40	0
Compacted Fill	2,525	35	10
Ultra fine Ore	2,525	35	10
Fine Tailings	1,028	33.2	5
Coarse Tailings	1,028	34.6	5

Note[1] $G = G_0 P_a \left(\frac{p\prime}{P_a}\right)^n$, where G_0 is the Shear reference modulus

Note[2] Constant Value

Note[3] Elastic constitutive model adopted

Table 2: NorSand material properties

Material	CSL			N	Xtc	H_0	Gref	n	Mtc	H_Y	Pois-on
	a	b	c								
Fine Tailings	1.04	0.037	0.0	0.15	6.0	60	24,800	0.62	1.4	300	0.2
Coarse Tailings	1,31	0.145	0.235	0.136	3.0	35	25,000	0.55	1.34	218	0.2

Pa = 101.3 kPa

Instability initiation is identified by monitoring η across all saturated tailings elements using routines developed by the authors. Elements where η exceeds ηIL are then assigned liquefied strengths as cohesion inputs, effectively transitioning the failure criterion from MC to Tresca.

It is important to note that during static construction phases, the MC strength criterion is utilized as a review of material plastic states within the model, consequently indicating that elastic input parameters control the in-situ stress state. During triggering analyses, modifications implemented by the authors, along with the NorSand constitutive model, govern instability and liquefied strength, a process detailed subsequently in this study.

Construction sequence, in-situ state and tailing types

The construction sequence simulation of the Feijão TSF was organized into 13 stages, with each stage further divided into approximately 3.5-meter layers. This division resulted in 33 lifts for the embankment and 27 lifts for the tailings, activated sequentially and alternately to simulate TSF construction. A K_0 value of 0.7 was applied during the construction of the 3D model, chosen initially to ensure numerical stability before triggering testing. Figure 2 guided the selection of K_0 to closely approach the instability line while keeping in-situ stresses for the most contractive materials below it.

At the end of each construction stage, the phreatic level was updated based on seepage analysis conducted by the EP.

Regarding tailings in-situ state at the end of the construction sequence simulation, both ηIL and su(LIQ)/σ'vc values utilized in the modeling are functions of Ψ, highlighting the critical importance of Ψ interpretation and its assumed in-situ distribution for analysis outcomes.

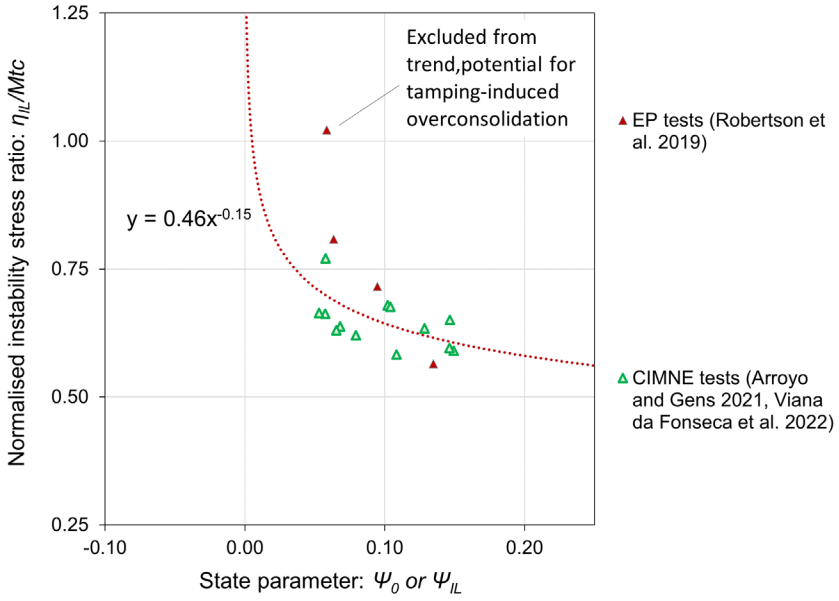

Figure 2: Normalized instability stress ratio versus state parameter (Arenas et al., 2023)

Using Geo Meshing v4.3.2, Ψ values were interpolated from CPTu using the built-in data feature. The interpolation scheme utilized a bin height of 1.75 meters (half of the numerical element height) and 50th percentile Ψ values, chosen after testing various bin sizes to minimize mesh bias. The 50th percentile was found to offer a balanced representation of field conditions for Ψ, avoiding excessive conservatism. While Jefferies and Been (2015) recommend using 80% Ψ for domain-wide representation, such an approach would be overly conservative for this detailed numerical analysis at the element level. Ψ values were estimated from CPTu data using the inversion method (Plewes et al., 1992), with Figure 3 illustrating the interpreted Ψ distribution.

Residual strength

The liquefied strength ratios for the tailings were determined following the "best practice trends" outlined by Jefferies and Been (2015). In this approach, su(liq)/σ'vc is treated as a function of Ψ, informed by both the back analysis of flow liquefaction case histories and Continuous Surface Subsidence Monitoring (CSSM). This method is preferred over the "steady state approach" due to compelling evidence of flow liquefaction occurrences in deposits with Ψ ranging from -0.05 to +0.05.

Triggering

A critical component of the triggering analysis conducted in this study is the adoption of the ηIL value specific to in-situ tailings, particularly the relationship between ηIL and Ψ (e.g., Yang 2002). To establish this relationship for Feijão tailings, the triaxial compression test data from both investigative groups were synthesized, as depicted in Figure 2. While electronic data from CIMNE tests were accessible (Viana da Fonseca et al., 2022), data from the EP tests was unavailable to the authors, necessitating the use of previously digitized data (Reid et al., 2022).

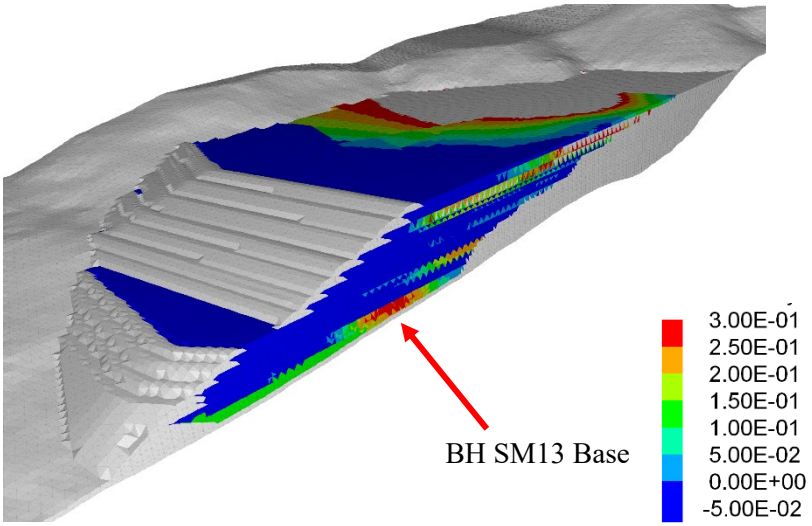

Figure 3: Tailings interpolated state parameter over the FLAC3D model

The data presented in Figure 2 and the selected trend are normalized by Mtc, with Mtc being the normalization factor for the triaxial compression tests shown. This normalization allows the triaxial compression data to be reasonably extrapolated to the in-situ conditions of the 3D numerical model. It should be noted that one of the EP tests was excluded from the synthesis in Figure 3 (as indicated) due to concerns that tamping-induced overconsolidation may have influenced the resulting peak strength/ηIL (Reid et al., 2022).

It is important to highlight the absence of suitable strength tests for the Feijão slimes within the framework of Figure 3, which is a significant limitation given the potential presence of slimes at the base of BH SM13. Consequently, the same trend observed for fine/coarse tailings was applied to the slimes, with adjustments based on the inferred lower Mtc/M for the slimes, as was indicated in Table 2.

Once the model reached equilibrium under the aforementioned conditions, an assessment of potential instability triggering around borehole SM13 during drilling was conducted. This process involved two primary stages: (i) establishing a pore pressure regime around the borehole; and (ii) checking for triggering. This approach represents a modified version of that adopted by Reid et al. (2021). Specifically, this

simplified procedure systematically evaluates all elements of saturated tailings within a numerical model. The procedure involves assessing whether the in-situ η exceeds a critical instability value ηIL at any location. If ηIL is exceeded, liquefied strengths are assigned to triggered elements, stability is reassessed, and the process is iteratively repeated to determine whether the model converges. This approach was chosen for its suitability in analyzing a constant shear drained (CSD) stress path, typical around boreholes where increased pore pressures can occur, particularly in brittle, loose tailings.

Results

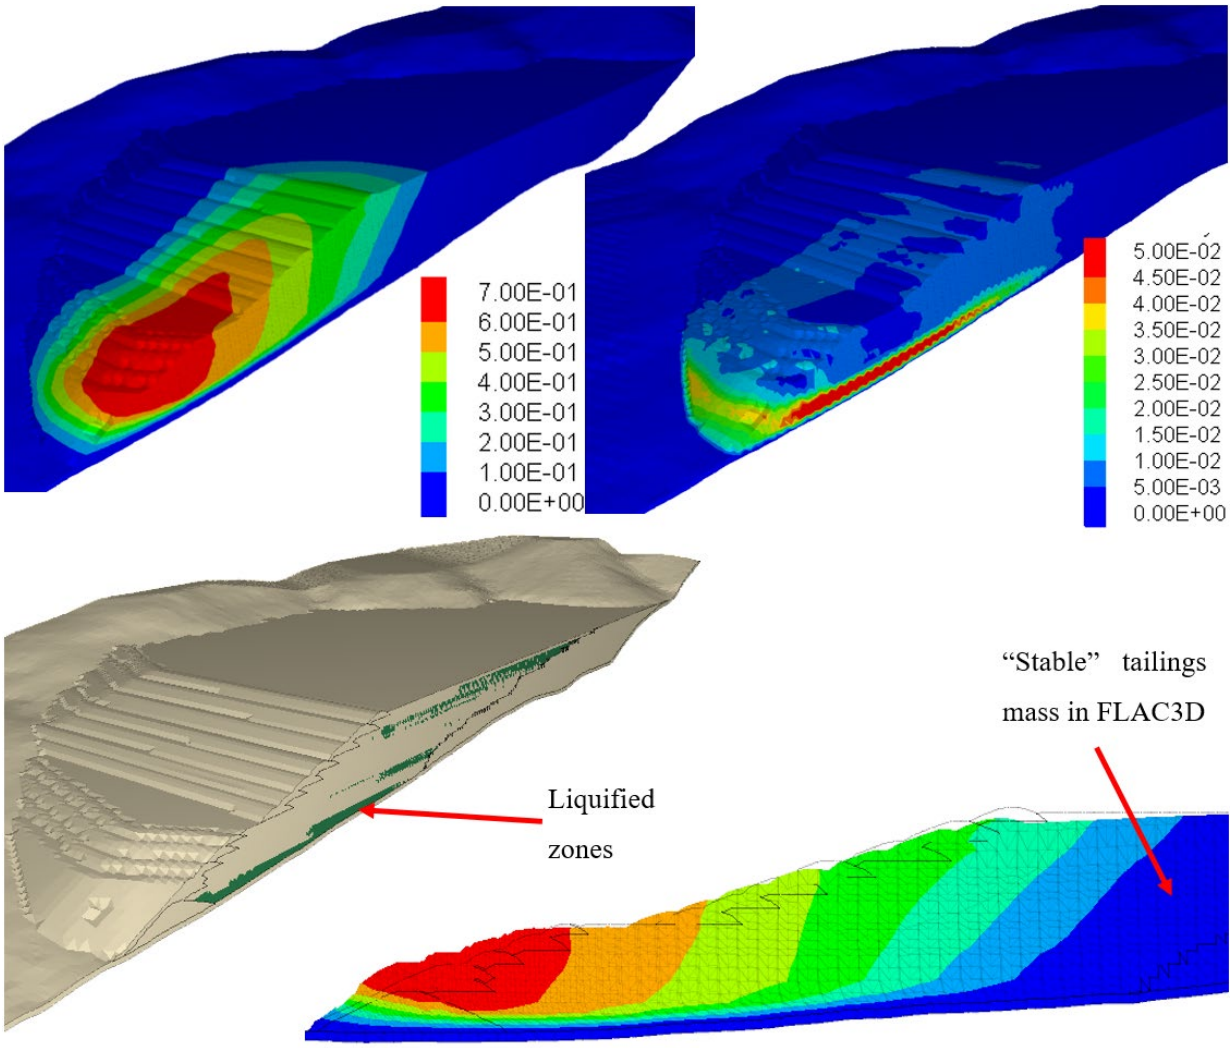

Figure 4: FLAC3D triggering results. All figures have a cutting plane at SM13. Upper left: displacement magnitude. Upper right: maximum shear strain. Lower left: liquified zones in Green. Lower right: displacement magnitude at SM13. Contours deformed and delineated original configuration

It is important to clarify that the FLAC3D model developed to run MPM analysis was run only long enough to establish the triggering mechanism. Therefore, displacement and shear strain magnitudes are small when

compared to the detailed FLAC3D model (not presented herein). The detailed model presents displacements that reach over 10 m and shear strain above 30%. This was also noted in the 2D model presented by Arenas et al. (2023).

Figure 4 shows partial results of the FLAC3D comprehensive stability assessment. The upper left figure illustrates the magnitude of displacements in meters. The upper right figure depicts shear strain, capped at a maximum value of 5%. The lower left figure identifies liquefied zones (areas where $\eta > \eta IL$, in green). Finally, the lower right figure replicates the same information as the first figure, but with the mesh deformation exaggerated and the original position of the slope delineated with a black line. Notice the bulged area below the setback resembling the first movement observed in the Feijão failure footage.

Limitations

Even though FLAC3D is a very robust platform, its continuous mesh nature prevents assessing analysis with extremely large deformations, even when the "large strain" option is active. This characteristic precludes the shear stress shifting that happens when a mass of soil moves and unconfines the soil right behind the moving front. In essence, shear stresses and pore water pressure will not increase in the "stable" soil mass, and the cascading failure effect will not be reproduced.

Figure 4 shows the "stable" mass. At these zones shear stresses are not transferred from the liquefied zones, as was happening during the expansion of the failure surface during the triggering assessment. Therefore, those zones beyond the failure surface will not generate excess pore pressure and/or increment in shear stresses, precluding activating the triggering mechanism in a software such as FLAC3D. In order to mobilize those zones, large strains are needed to produce the necessary reduction of lateral stress, with the consequent increment in shear stress and triggering.

MPM analysis

MPM is a computational technique employed to simulate large deformation processes in various scenarios. Rather than representing individual soil grains, MPM discretizes the continuum into material points, each embodying a volume of the solid.

The methodology involves two computational meshes, one serving as a background grid, and a second one representing the material points. This hybrid approach, described by Soga et al. (2016) and Yerro et al. (2022), mitigates distortion issues commonly encountered in traditional methods like finite element or finite difference approaches. By transferring data between grid and material points at each step, MPM can capture large deformation processes such as those seen in dam failures.

Similar approaches have been considered in the past for Tailings Dam Breach Analyses (TDBA): Zabala and Alonso (2011) presented the first application of MPM to model tailings dam failure; Robertson

et al. (2019) presented a 2D MPM dam breach model of Dam 1; and Pierce (2021) used MPM to identify the key factors controlling the runout of the Cadia tailings dam failure of 2018 in Australia.

The runoff modeling was conducted using MPM-PUCRio software. It includes various constitutive models and incorporates memory parallelization techniques, allowing for simulations with a large number of material points (Pierce, 2021).

Geometry

The MPM mesh was exported from FLAC3D, allowing for the integration of materials and their distribution. Figure 5 presents an isometric view of the resulting MPM mesh geometry and material distribution.

Given the size of the elements in the FLAC3D mesh, a regular structured cubic background grid of 3.5 meters was used for the material point simulation.

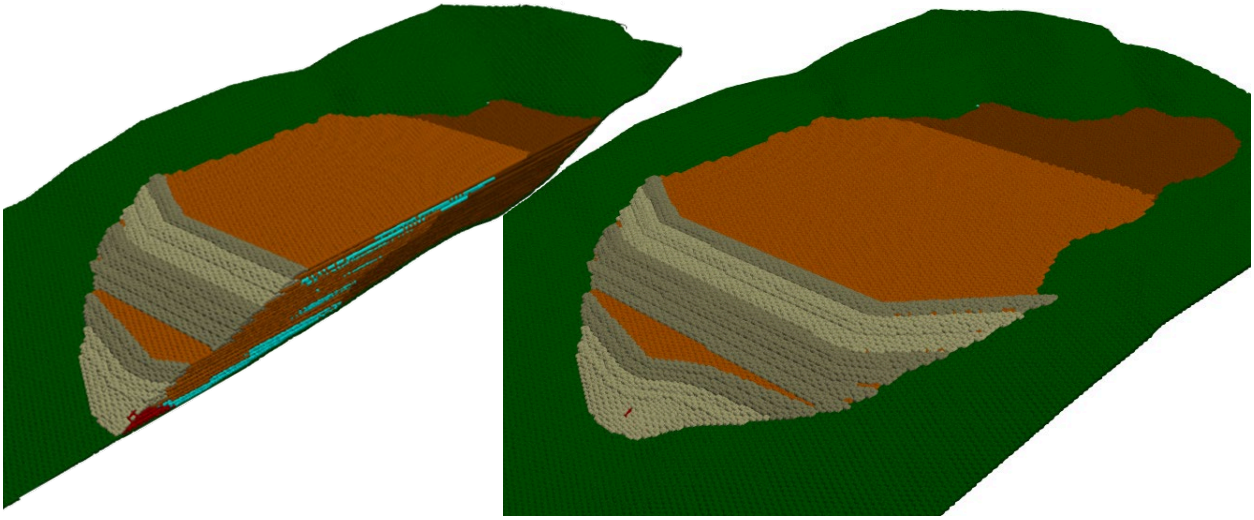

Figure 5: MPM model. Left: MPM model cut at SM13. Liquefied zones shown in light blue as imported from FLAC3D. Right: full 3D MPM model

State from FLAC3D

After analyzing the triggering in FLAC3D, the mesh and material configuration was imported into MPM-PUCRio. Along with this information, the strain and stress tensor as well as the pore water pressure was preserved for each zone/material point. Finally, the liquefied condition reached in the FLAC3D analysis was also transferred into MPM-PUCRio; thus, it constitutes the initial condition for triggering the failure.

The major advantages of using this approach are: first, the stresses generated with the detailed construction sequence replicated in FLAC3D are preserved, which in turn preserves K_0 conditions. This last feature is key when analyzing CSD triggering mechanisms. This is a mayor advancement since MPM software packages usually define a single stage for initial conditions, gravity loading, which provides an inconsistent K_0 distribution across the model. Second, it eliminates the guess work related to the initial

triggering. Most of the time, standard practice using MPM methodology assigns residual properties to an arbitrary area of the facility to initiate the simulation.

Constitutive models

Differing from FLAC3D analysis, the response of the embankment and tailings materials were modeled with MC. This model does not explicitly consider the effects and evolution of pore water pressure as NorSand does, and therefore it is expected that fewer zones would potentially liquefy during the analysis. It is important to note that once the material point reaches liquefied conditions, it was modeled with the MC using residual strength properties, as was done in FLAC3D.

The foundation materials were considered linearly elastic, and the inherent MPM contact algorithm controlled the interaction of all materials.

Triggering in MPM

As previously mentioned, the triggering mechanism used in the MPM analysis is the same as is used in the FLAC3D analysis. Given the large strain capabilities of the MPM solution, it allows for a significant change in the deviatoric stresses in the mass immediately behind the moving front (which after a few seconds in the simulation becomes the new front). Therefore, the effectiveness of the triggering mechanism to expand across the impoundment is much greater.

Results

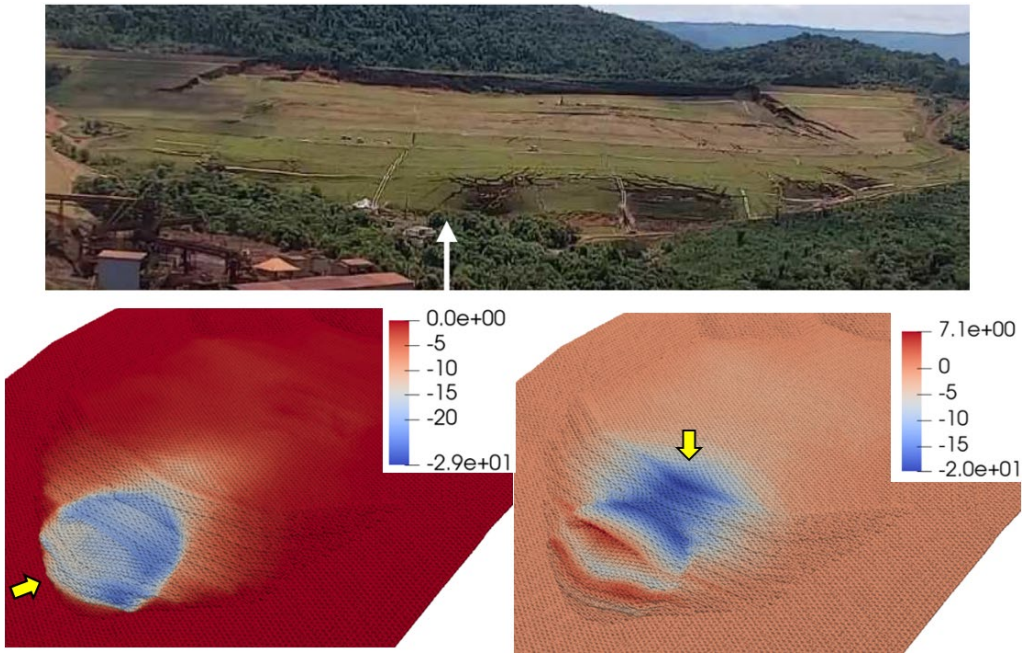

Figure 6: Above: video footage captured at 5.5 s after the initiation of the failure. Below: MPM runout simulation at 5.5 s. Left: horizontal displacements. Right: vertical displacements

The upper portion of Figure 6 shows the Feijão Dam I capture at 5.5 s since the initiation of the failure (Robertson et al., 2019). Similarly, the lower part of Figure 6 shows the runout analysis at 5.5 seconds after initiating the analysis. The bulging below the TSF step back and the crest settlement can be clearly observed.

Figure 7 shows the displacement magnitude of the MPM runout simulation. The left- and right-hand figures show the displacement magnitude after 20 seconds and 54 seconds (respectively) after triggering the failure. Note how the mobilized mass has extended into the impoundment.

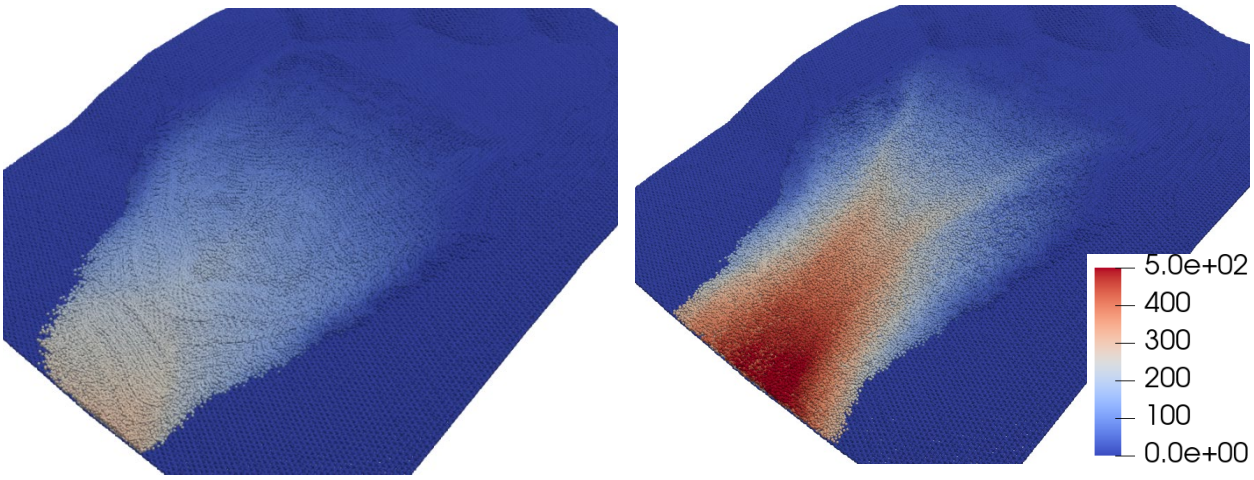

Figure 7: MPM runout simulation. Left: displacement magnitude at 20 seconds. Right: displacement magnitude at 54 seconds

Conclusion

The following conclusions can be drawn from the present work:

- The current analysis and methodology, as per Reid et al. (2021), enhances our understanding of why the TSF could have failed during the drilling of borehole SM13.The authors trust the mechanism of triggering presented herein is plausible and credible, as it has a strong foundation in a robust theoretical framework, and it uses advanced, proven 3D modeling techniques and the reliable NorSand constitutive model. Subsequently, the results observed from either FLAC3D or MPM- PUCRio encompass those observed during the failure.
- The adopted methodology offers a practical framework for analyzing and predicting liquefaction triggering mechanisms. This methodology eliminates the more traditional guess work of where to apply residual conditions to tailings within the impoundment. And therefore, it is applicable to existing facilities with no distress conditions.
- MPM-PUCRio offers large strains solutions that allow the implemented triggering to efficiently propagate throughout the tailings impoundment where liquefaction potential exists.

- The presented runout simulation closely replicates essential features of the failure captured on the video footage, such as the bulging below the TSF setback and the initial crest settlement.

The Use of Programming Language in GISTM Compliance for the Holden Mine

Summer Y. Sun, Stantec, USA
Phillip E. Crouse, Stantec, USA

Abstract

Since the release of the Global Industry Standard on Tailings Management (GISTM) in 2020, Rio Tinto and other ICMM member mining companies have been reassessing the stability of their legacy tailings storage facilities (TSFs). Reassessing the stability of these tailings storage facilities necessitates effective handling and analysis of vast amounts of geotechnical data. The advent of information technology has enabled the collection of this data in digital formats, prompting the utilization of software platforms such as ArcGIS, DAARWIN, EarthSoft, gINT, and Access for data organization and visualization. However, integrating data into these platforms often requires substantial initial efforts.

This paper presents a case study of reassessing the stability of the Holden Mine Tailings Piles using the R programming language. The study showcases the capabilities of programming languages in handling decades-worth of data, organizing it into suitable formats, and integrating it into a comprehensive three-dimensional model. This paper highlighted key advantages of programming, including efficiency in automating repetitive tasks, and its flexibility in designing customized plots tailored to specific geotechnical parameters. The extensive open-source graphics packages foster collaboration and innovation within the geotechnical engineering community, contributing to continuous improvement in data management and analysis practices.

Furthermore, the paper demonstrates the utilization of R's statistical packages to develop site-specific correlations between field and laboratory test results, including the Standard Penetration Testing, Cone Penetration Testing, and Index Testing. These correlations are an important part of assessing legacy tailings piles for GISTM compliance. The paper presents the site-specific correlation between unit weight and cone tip resistance, as well as the observed trend between the degree of saturation and dynamic pore water pressure. This paper presents the process to develop these correlations, which are tailored to the unique conditions of Holden Mine Tailing, and which provide more accurate and precise estimations of geotechnical parameters. The efficiency of programming enabled us to leverage data management, analysis,

and visualization, which enabled stakeholders to make more informed decisions regarding the design, monitoring, and maintenance of TSFs, ultimately advancing safety and sustainability in the mining industry.

Introduction

Rio Tinto reclaimed the Holden Mine between 2010 and 2016 which included reconfiguring the tailings piles that had been operated between 1937 and 1957. The Holden Mine is a former underground copper mine that was developed and operated by the Howe Sound Mining Company (Howe Sound). The mine is in the northwestern U.S. in north central Washington State near Lake Chelan. Rio Tinto never owned or operated the mine; they are managing and funded the reclamation and currently performing operating and maintenance of the closed facility. Since the release of the Global Industry Standard on Tailings Management (GISTM) in 2020, Rio Tinto and other ICMM member mining companies have been reassessing the stability of their legacy tailings storage facilities. Reassessing the stability of these tailings storage facilities (TSFs) necessitates effective handling and analysis of vast amounts of geotechnical data. It is especially difficult to integrate such wide range of data types when they come from various sources and formats. This study proposes an alternative tool for geotechnical data management using R programming language and demonstrated a workflow to use the tool for a tailings storage facility (TSF).

Geographic Information System (GIS) technology is widely used in the industry as an efficient tool to store, organize, analyze, and display this type of data in the form of digital layers and maps (Player, 2006). GIS provides promising outcomes for integrating multiple data types, such as photos, scanned maps, Shapefiles or computer-aided drafting (CAD) files (Singh, 2018). However, GIS is not designed for geotechnical data analysis and is mostly used to visualize the final results of the geotechnical analysis. It lacks the specialized functionalities tailored to the unique characteristics of geotechnical data, such as geospatial analysis and geotechnical calculations, which hinders the real-time visualization of the analysis results.

As a popular programming environment for statistical computing and graphics, R can be the one-stop solution for both powerful data calculations and high-quality plots. It is especially valuable for geotechnical data where visualization data through plots, maps, and charts helps understand patterns, trends, and relationships in the data. R's flexible plotting functionalities allow customization and interactive exploration of the data. R is an open-source software, which means it is freely available to use. Companies can encourage geotechnical engineers to explore the capabilities of R without incurring substantial software licensing expenses. Table 1 shows the comparison between the GIS-based software and the open-source programming code in the application of geotechnical data processing.

Table 1: Comparison between GIS-based software and open-source programming code

	GIS-based software	Open-source programming code
Data integration	Usually requires significant initial efforts to build the model	Relatively less efforts to build the model
Data visualization	Strong at integrating multiple data types and displaying the data in layers, including maps and photos	Not a tool designed to display maps and photos, but the graphics packages can present spatially relationships of data
Data processing	Not a tool tailed for calculations and spatial analysis of geotechnical data	Allows the customization and interactive exploration of data
Learning curve	Steep	Steep with no prior programming experiences
Cost	Usually not free	Usually free of charge

Figure 1 illustrates a simplified process of data management discussed in this work that includes three steps: data acquisition, data integration and data processing. Instead of providing a synthesized manual to data management, this study aims to demonstrate a workflow using R and therefore only the key steps within the workflow are listed in Figure 1. The workflow is flexible to adapt to additional data needs. Section 2 of this paper discusses in more detail each step in the workflow.

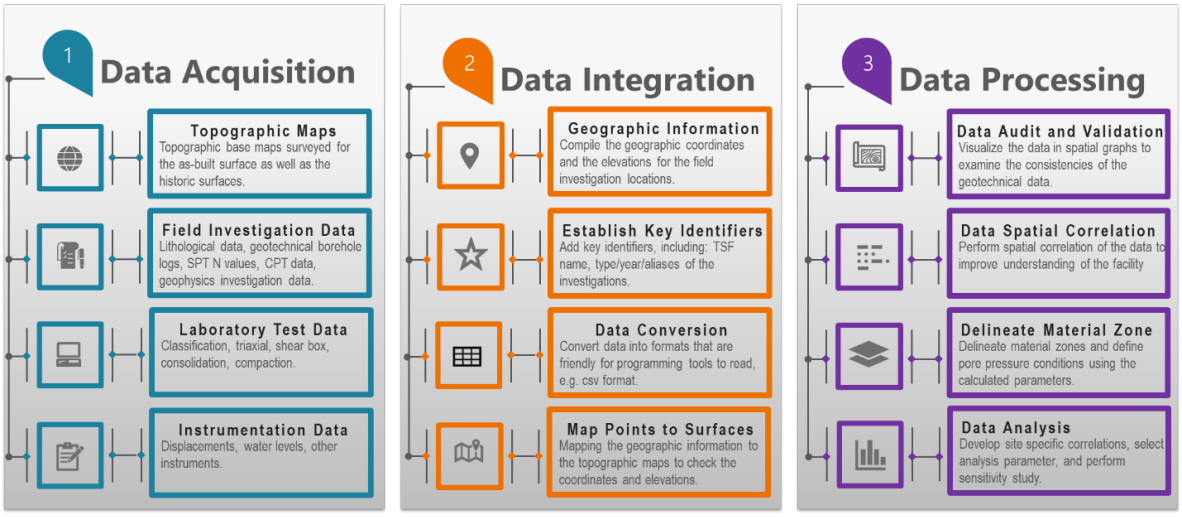

Figure 1: Diagram of the streamlined workflow for data acquisition, integration and processing

Geotechnical data acquisition and integration

Data acquisition

Data acquisition can involve several sources of information including topographic maps, field investigation data, laboratory test results and instrumentation monitoring data. Topographic maps are the basis to develop a three-dimensional (3D) model to incorporate geotechnical information into a spatial database. Topographic maps of the area, not only for the as-built surface but also for the surfaces over the life of the

facility, should be gathered to improve the accuracy and resolution of the 3D model.

Field investigation data, laboratory test results and instrumentation monitoring data can vary in complexity depending on the specific investigation or monitoring instrument. Prior to performing a geotechnical investigation, a desktop study should be conducted to collect existing information about the site. This helps to select the investigation locations and define the objectives of the subsequent investigation. Electronic formats of the collected data should be gathered to minimize manual data entry in the next steps of the analysis.

Data integration

Data integration is a process to map the geotechnical data into a 3D model. The first step is to compile the geographic data of the investigation and to align them spatially with the coordinate system used in the 3D model. This step ensures that the geotechnical data can be accurately referenced within the 3D model. The second step is to identify the key identifiers that can be used to sort, filter, and differentiate the data. Examples of the commonly used identifiers include names of the facilities, types of the investigations, and dates of the investigations. The third step is to convert the data to formats that are computer-friendly. It is crucial to minimize manual data entry, as this will reduce time and cost, and also the potential for human error. R supports integration with various data formats commonly used in geotechnical engineering, such as CSV, Excel, and databases. This enables seamless importing and exporting of data from various sources and tools. Figure 2 shows the steps used to sort the available geotechnical data according to their sources and to utilize geographic coordinates to associate the data to a spatially represented point in the 3D model.

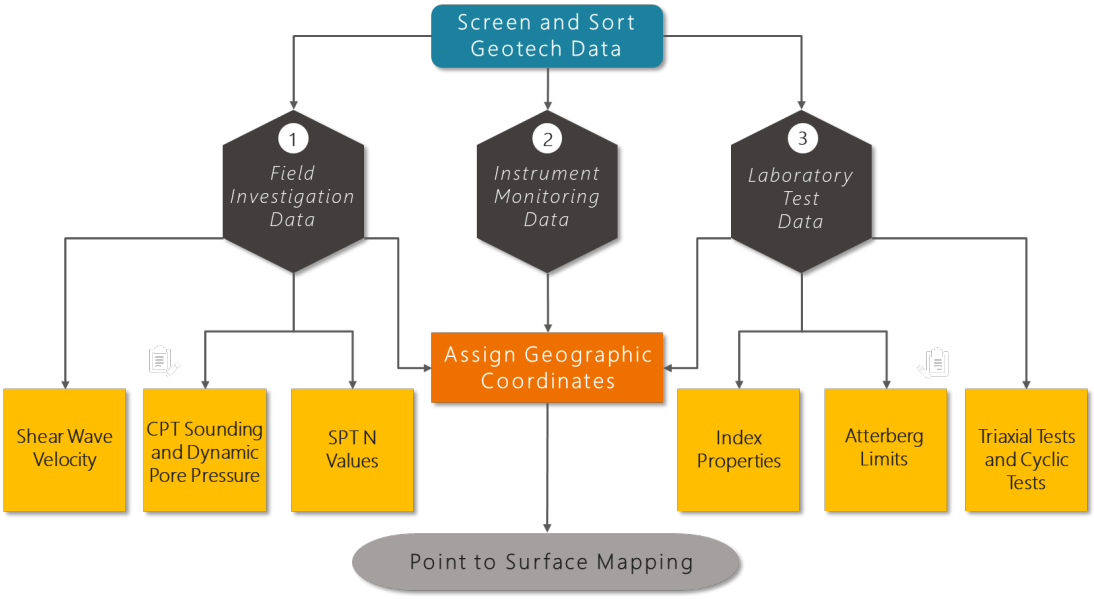

Figure 2: Steps to screen and sort geotechnical data

The most preferred method for data entry is to import data directly from the testing equipment, such as the laboratory apparatus, the monitoring devices, and the CPT rigs. If legacy data are stored in PDF files, internet tools are available to analyze the scanned documents or images and convert the texts into machine-readable data using technologies such as artificial intelligence (Jaksa and Liu, 2021). If the above two mentioned strategies cannot be applied, one can use template-based data entry. This is the least preferred method for data entry and should be used only if handwritten texts are the sole source of information. It is recommended that standardized data entry templates are designed to match specific data requirements and to be readable by computer (Deaton, 2018). Template-based data entry is also useful when migrating data from the legacy reports to the new database.

Geotechnical data processing

Data audit and validation

R can support data validation by assisting with visualizing data in one-dimensional, two-dimensional, and three-dimensional plots. The data validation aims to check the following aspects.

- If major features (e.g., depth of the tailings, thickness of the cover material) indicated by the CPTs or boreholes agree with or contradict the topographic surfaces established.
- If data collected by different methods, including field investigation data, laboratory test results and instrumentation monitoring data, show similar stratigraphic layers.

Figure 3 provides an example of a comparison between the information gathered from a mud rotary drilled borehole (TSF-BH-C10) and a companion CPT (TSF-CPT-B14) that is 45 ft away. The example in Figure 3 includes the field description of the soils, the field blow counts, and the composition of soil types by weight from the borehole investigation, as well as the tip resistance, the dynamic pore water pressure, and the clean sand equivalent normalized tip resistance (Qtncs). The vertical axis is labeled with both the elevations and the depths for the various geotechnical properties, which enables comparison of the data at similar depths. Figure 3 also includes additional annotations to enhance the desired emphasis on important thresholds or reference values.

For example, the Qtncs plot includes Qtncs = 70 as a reference line between the contractive and dilative behaviors, which is defined by Robertson and Wride (1998) and is associated with the state parameter of Jefferies and Been (2006). CPT results show a contractive behavior in the depth between 45 ft and 85 ft as well the bottom 10 ft, where low field blow counts are observed in the collated SPT profile. The comparison between boreholes and CPT data enables geotechnical engineers to find contact surfaces between the stratigraphic layers.

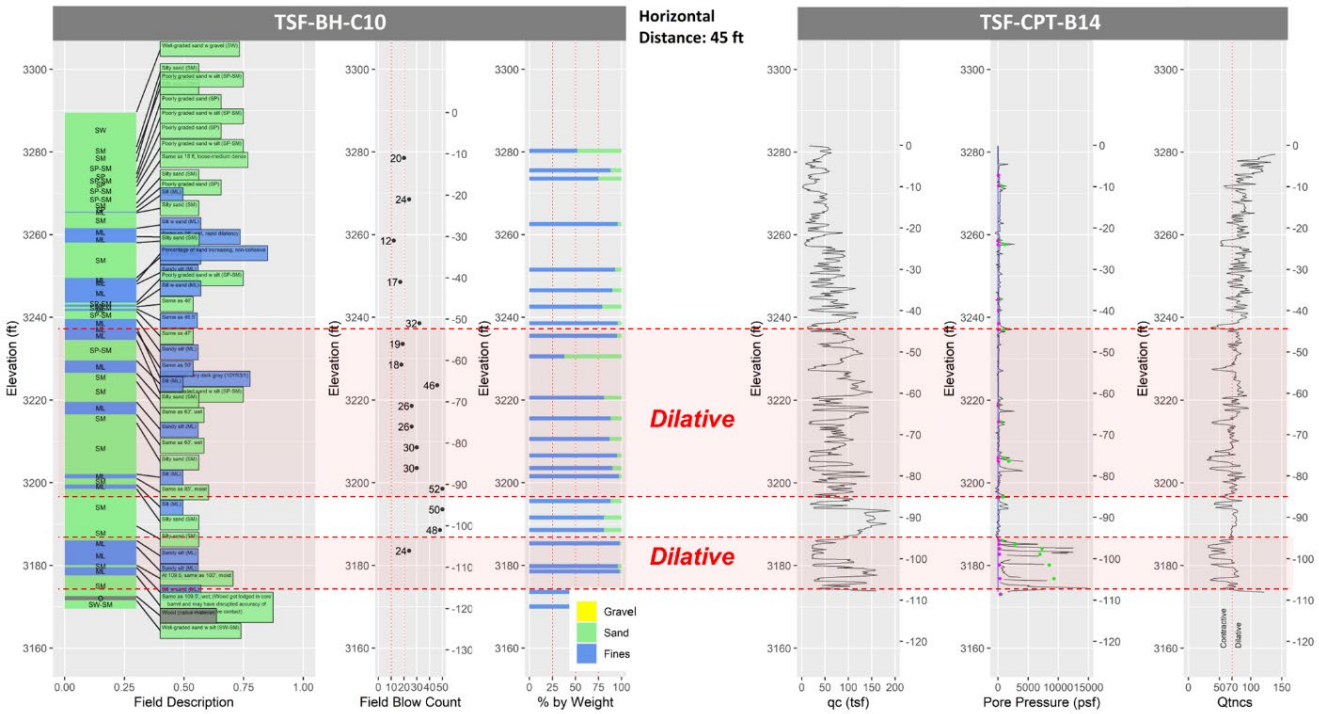

Figure 3: Comparison between CPT and borehole data

Data spatial correlation

Evaluation of mine facilities often requires manipulations and correlations of a large amount of spatial information. The 3D plots produced by R can be customized to show desired parameters of the field and the laboratory data. Figures 4 and 5 provided two examples of the 3D visualization of the information gathered from CPT within the TSF. In Figures 4 and 5, normalized cone tip resistance Qtncs and dynamic pore water pressure u2 are shown as color columns that are associated with their northings, eastings, and elevations. The magnitudes of the geotechnical parameters are coded by colors. It is important that spatial reference points are included in the 3D model so that the positions of the data are readable. In Figures 4 and 5, the locations of the CPT data are vertically projected to the terrain contours to represent their relative positions within the TSF. As shown in Figures 4 and 5, the Qtncs and u2 plots can be compared to examine the subsurface conditions and locate areas with contractive and saturated tailings. The views can be rotated, and zoomed in and out, to provide a comprehensive view of the geotechnical data within the site context.

The 3D model can assist in the process of selecting slope cross-sections for the stability analyses to determine the factors of safety against slope failures. In the next section, a 2D cross-section was generated by R to delineate the tailings profiles within the TSF.

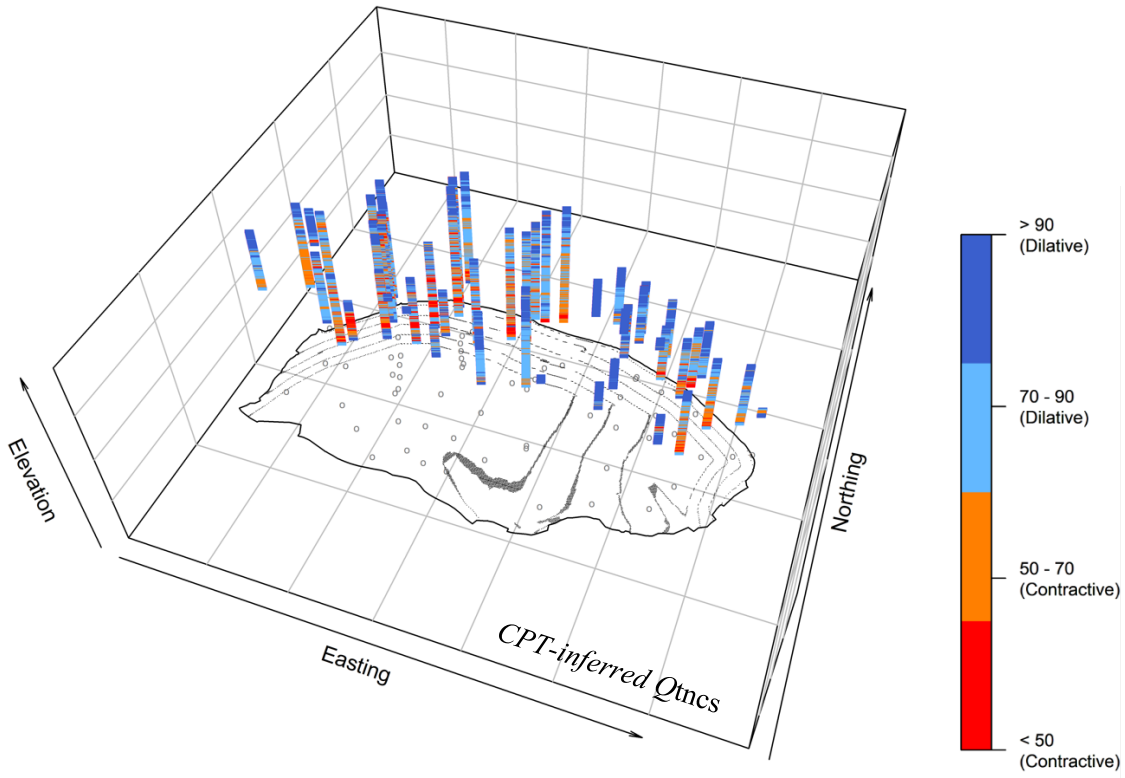

Figure 4: Spatial visualization of CPT-inferred clean sand corrected tip resistance

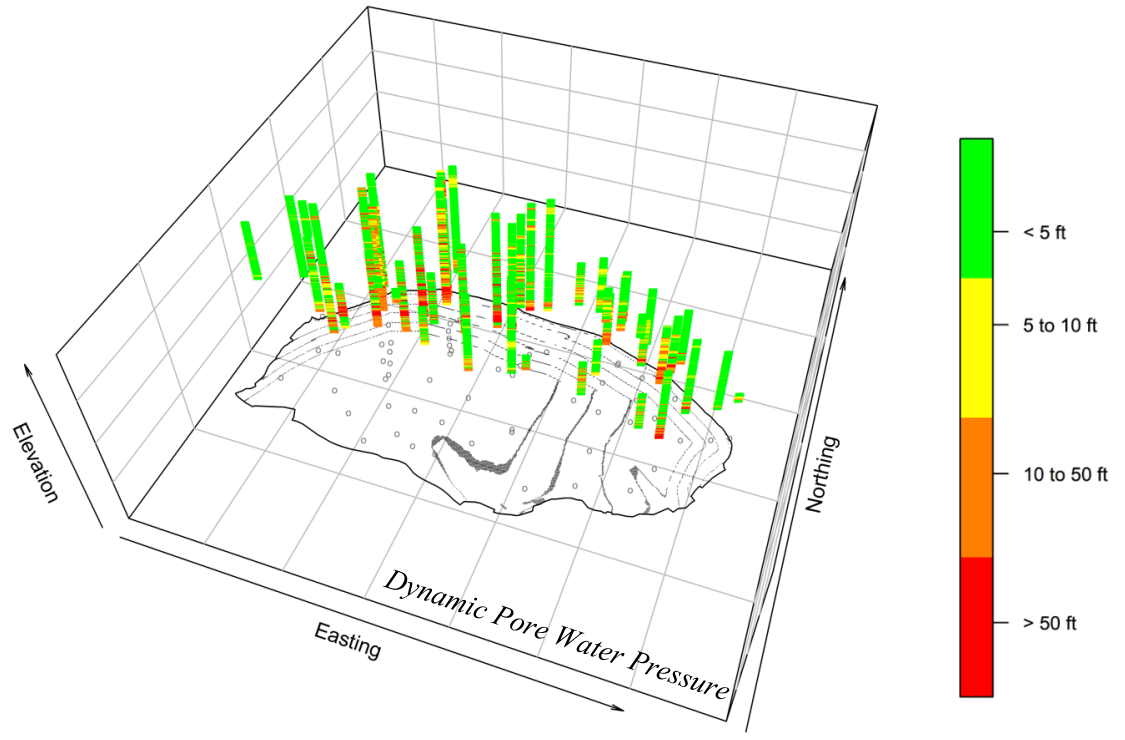

Figure 5: Spatial visualization of dynamic pore water pressure

Delineate material zones

R can produce 2D cross-sections that enable layer delineation by evaluating multiple sources of data. Figures 6 and 7 provided two examples of the 2D cross-sections of a TSF with the information gathered from CPT. Instead of the actual configuration of Holden Tailings Piles, a simplified cross-section is used to demonstrate the process of the data analysis. In Figures 6 and 7, two variables were projected to the cross-sections: dynamic pore water pressure u_2 and normalized tip resistance Qtncs. The foreground black lines combined with the background color bars indicate both the trend and the magnitudes of the parameters.

An essential step to ensure the correct location of the projected data is to interpolate the spatial coordinates along the selected cross-section to calculate the lateral distance, which is shown as the horizontal axis in Figures 6 and 7. Instead of showing multiple geotechnical parameters across the board, we noted that the 2D geotechnical model needs to be focused on one or two parameters in the same plots to maintain readability.

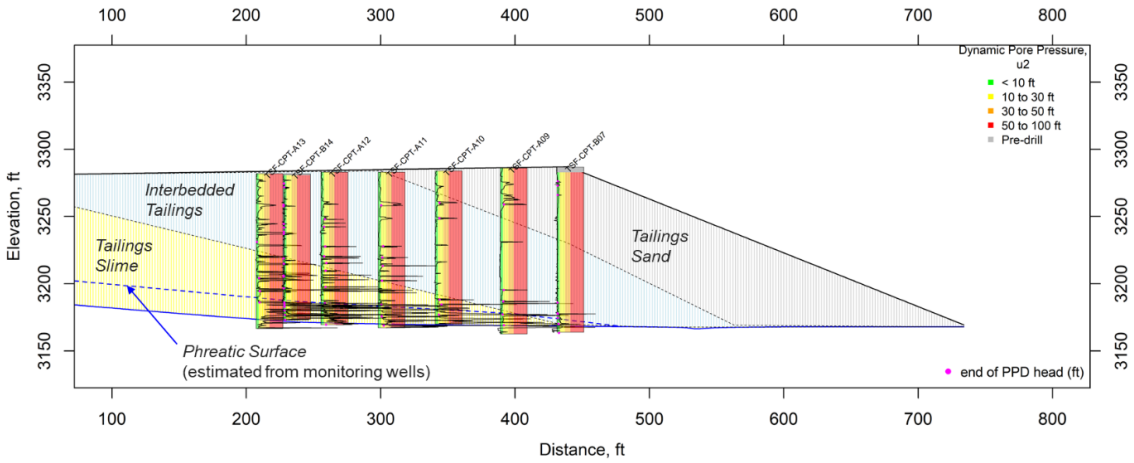

Figure 6: Dynamic pore water pressure and delineated tailings profile

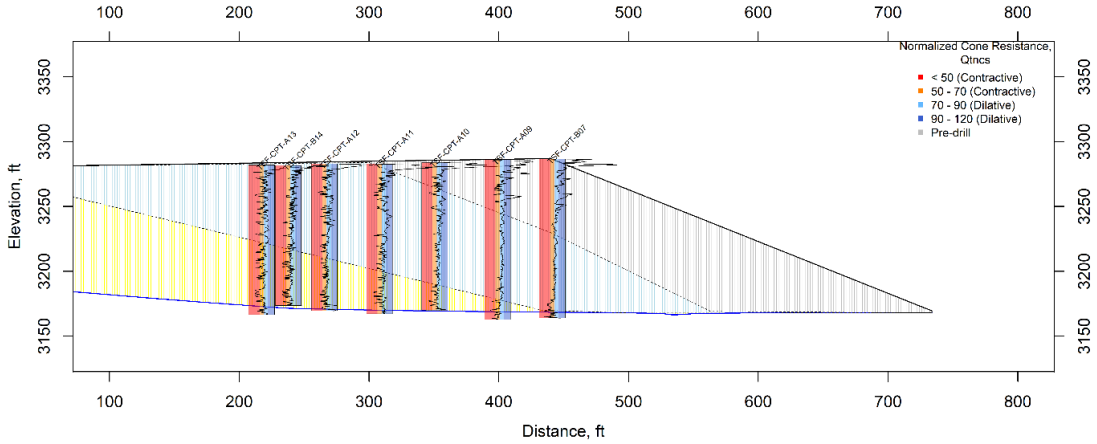

Figure 7: Clean sand tip resistance and delineated tailings profile

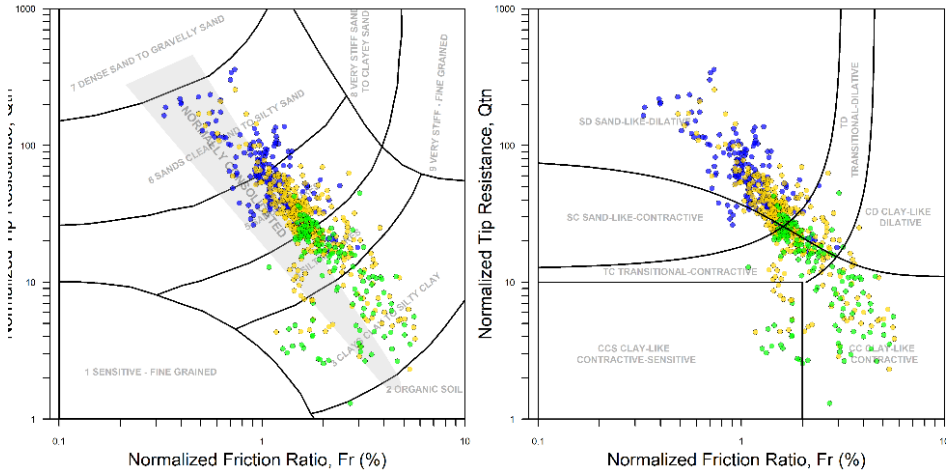

Figure 8: Evaluation of tailings response in the CPT soil behavior charts

The 2D cross-sections can be used for the following purposes:

- Delineate tailings profile. In Figure 6, a total of three tailings groups were identified between the as-built topographic surface and the bottom of the tailings: the contractive tailings slimes, the dilative tailings sand, and the interbedded tailings with intercalated behaviors between the contractive. Also shown in Figure 8, the tailings slime zone is located within the contractive zone in the potential liquefaction chart, which indicates a possible strength loss (flow-liquefaction) and cyclic softening (Robertson, 2010).
- Understand pore water pressure condition. The dynamic pore water pressure within the cross-section and the phreatic surface depicted from the monitoring wells are shown in Figure 7. In Figure 7, the pressure head at the end of pore pressure dissipation tests is shown to assist in evaluating the saturated zones. For this exercise, it is considered that the tailings slime is saturated and is potentially liquefiable, the tailings sand is not saturated, and the interbedded tailings are partially saturated.

The next section will demonstrate sensitivity predictions using R that show how the pore pressure condition changes the liquefaction trigger analysis result.

Data analysis

Once the material zones are delineated, the geotechnical data within each material zone can be extracted for further data analysis. Figure 9 shows the residual strength ratio profiles, and Figure 10 shows the cumulative distribution curves for the residual shear strength ratio calculated for the tailings sand, the interbedded tailings and tailings slimes delineated in the cross-section. The values in Figure 10 can be used to develop the geotechnical parameters that can be used in subsequent stability analyses of this section.

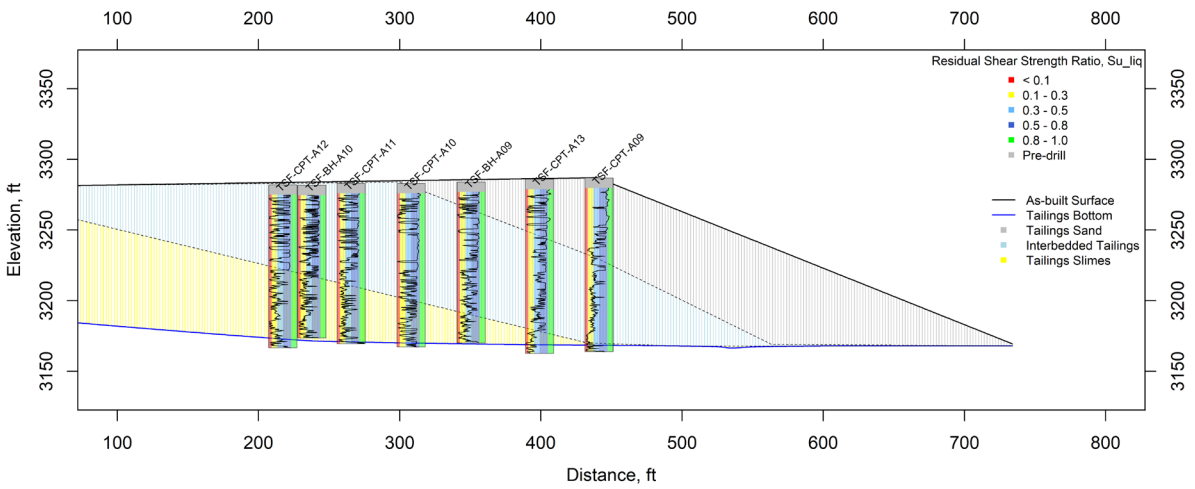

Figure 9: Tailings residual shear strength ratio

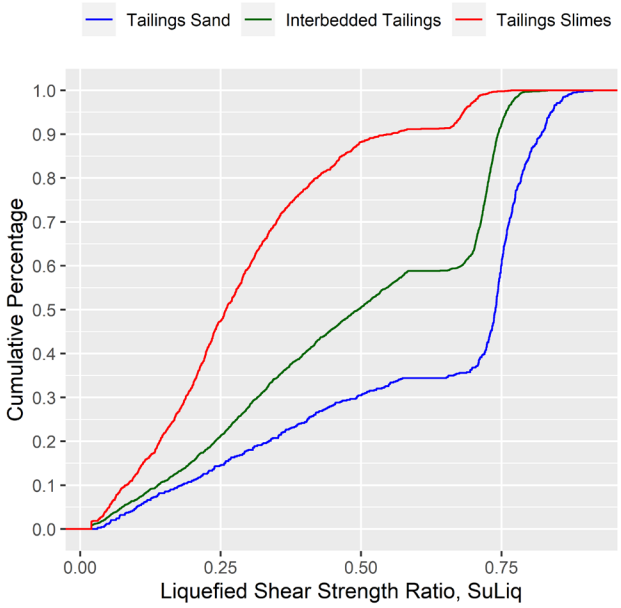

Figure 10: Cumulative distribution curves of liquefied shear strength ratio

After identifying the potentially liquefiable zones, CPT-based empirical correlations were used to calculate the factor of safety against liquefaction (FoS_{Liq}) for the identified saturated zones. In this example, FoS_{Liq} was calculated using the correlation in Boulanger and Idriss (2014). In Figure11, the FoS_{Liq} under various design earthquake return periods are calculated by assuming two scenarios for the saturated zones. In Figure 11 (a) and (b), both the slime and interbedded tailings are considered saturated, while in Figure 11 (c) and (d) only the slime tailings are saturated. Through this exercise, the conclusions were drawn that the assumption of fully saturated slime is reasonable, and that most of the interbedded tailings at the bottom half of the TSF, although partially saturated, are not susceptible to liquefaction.

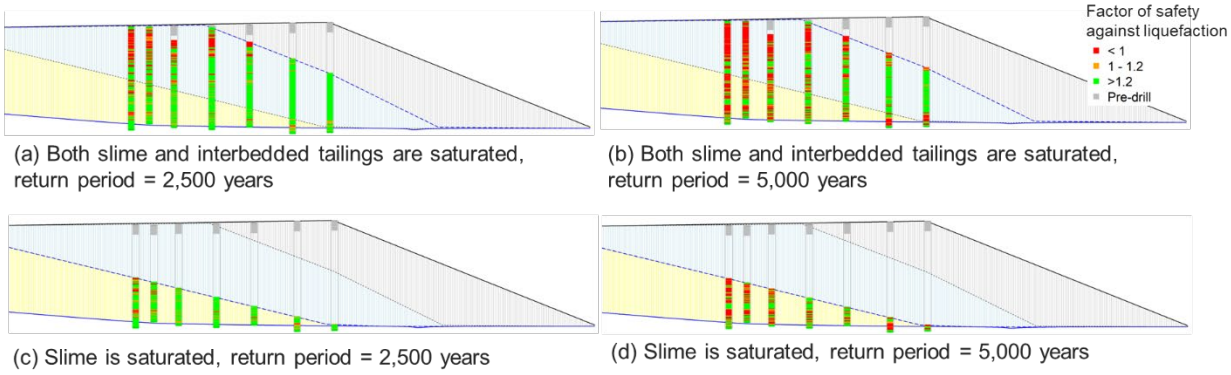

Figure 11: Calculated factors of safety against liquefaction for different saturation assumptions and design earthquake return periods

Discussion and conclusion

This paper presented a workflow to integrate geotechnical data into a database and utilized R to process the geotechnical data. The examples demonstrated the efficiency of R, which enables the automation of repetitive tasks involved in the data processing, as well as the flexibility of R, which designs plots specifically tailored to incorporate desired geotechnical parameters for visualization.

The techniques discussed in this study are demonstrated to be easy to adapt and can be utilized for not only the TSFs but also other mine domains, such as the waste stockpile. It is noted that the complexity of the models will require basic knowledge in programming and, most importantly, the developer's technical expertise in geotechnical engineering, mining, and the related engineering disciplines. The site and engineering knowledge are more important than the programming skills. To adapt to the new needs in the industry and to improve the quality of the solutions, continuous learning for geotechnical engineers in programming and data science should be encouraged by consulting companies.

Acknowledgements

We are grateful to Rio Tinto for their invaluable support and approval to publish the information presented in this study. Their collaboration and willingness to share information have significantly contributed to advancing knowledge in the mining industry. We believe that sharing this approach has the potential to greatly improve our available tools for data management in the mining industry.

Chapter Three

Application of GISTM

TAILINGS AND
MINE WASTE 2024

ALARP: Where are We Going and How Do We Get There?

Malcolm Barker, GHD, Australia
Chris Topham, GHD, Australia
Nick Glover, GHD, Australia
Manuel de Membrillera Ortuño, GHD, Australia

Abstract

The water dam industry has been using the ALARP (As Low as Reasonably Practicable) principle for many years in order to assess the tolerability of public safety risks. Consideration of the ALARP principle is inherently subjective, and it is necessary to develop a repeatable and defendable process. This paper presents the current guidance from experience in Australia and other countries on how to address the primary and secondary considerations in determining an ALARP risk position for tailings facilities, using both the International Council on Mining and Metals (ICMM) publication and the Global Industry Standard on Tailings Management (GISTM), together with the Australian National Committee on Large Dams (ANCOLD) 2022 Risk Assessment Guidelines, as well as other sources where the ALARP principle is considered, in order to propose a process for tailings dams.

The paper then provides a case study using quantitative and qualitative risk analysis in the application of the ALARP principle and reflects on the resulting justification to both pursue and avoid dam safety upgrades to small and large tailings dams.

What is ALARP?

Recent research shows that approximately 20,230 Tailings Storage Facilities (TSFs) have been constructed in the period 1965 to 2020, and that the annual number of constructed TSFs increased three-fold over this period (Rana et al., 2022). The average annual probability of failure of a TSF over that period is approximately 2.7×10^{-2} (1 in 37 years), that is, two orders of magnitude greater than water dams.

Among other issues, that is the reason why the mining and tailings dams industry has been addressing the question of "How do we reduce the risks to As Low as Reasonably Practicable (ALARP)?" in recent years.

In this regard, it is important to note that there is no clear guidance in GISTM or ICMM as to which method of risk assessment should be used for evaluating ALARP. This paper aims to provide a process that can be used for any of the risk assessment approaches, including quantitative, semiquantitative and qualitative methods for facilities that may range from Low to Extreme consequence classification, or using the applicable regulation or guidance in each country.

According to GISTM Requirement 4.7:

*"… the Accountable Executive shall approve and document the implementation of measures to reduce **both** the probability and the consequences of a tailings facility failure in order to reduce the risk to a level as low as reasonably practicable (ALARP). The **basis and timing** for addressing the upgrade of existing tailings facilities shall be **risk-informed** and carried out as soon as reasonably practicable."(Emphases added by author)*

According to the Glossary in GISTM:

ALARP requires that all reasonable measures be taken with respect to 'tolerable' or acceptable risks to reduce them even further until the cost and other impacts of additional risk reduction are grossly disproportionate to the benefit.

According to the *ICMM Tailings Management Good Practice Guide*, factors involved in applying ALARP after a remedial action and/or enhanced operational practices or surveillance have been implemented include:

- Application of relevant good practice. This can be applied to all aspects of the facility including operation, maintenance, surveillance, construction, and emergency planning.
- The level of incremental risk in relation to the established risk guidelines.
- The cost-effectiveness of the risk reduction measures in relation to likelihood and/or consequence.
- Remaining life of the facility and potential alignment with closure planning that may reduce likelihood and/or consequence.
- Societal concerns as revealed by consultation with the community and other stakeholders.
- Other factors such as:
    - consideration of standards-based approaches,
    - benchmarking,
    - direct business impacts,
    - constructability,
    - implementation schedule, and

- environmental consequences.

Each of these factors is considered in the ALARP approach proposed for facilities varying from Low to Extreme risk, as shown in Figure 1.

It should be noted (ANCOLD, 2022) that the additional understanding that comes from the risk assessment process for reducing risks to ALARP may reveal that a less costly solution to a dam safety problem could be justified, but it could just as easily be that a risk assessment shows that a more stringent safety level, and thus a more costly solution, should be implemented.

Risk assessment approaches

Figure 1 presents a risk matrix based on a previous paper (Barker, 2023) and the ANCOLD Guidelines on the Consequence Categories for Dams (ANCOLD, 2012). This shows an indicative way forward for the use of the various risk assessment methods when evaluating ALARP, including ratings for population at risk (PAR), potential life loss (PLL), environment, social effects, infrastructure and economics, and company reputation.

		Potential Life Loss				
		None <0.1	Unlikely 0.1 - 1	Possible 1 - 5	Likely 5 - 50	Many >50
		Population at Risk				
		None	1 - 10	10 - 100	100 - 1000	>1000
		Consequences				
Likelihood Description	**Likelihood AEP Range**	**Low**	**Significant**	**High**	**Very High**	**Extreme**
Very High	1E-2 to 1E-3	Medium SQRA	High Hybrid/ QRA	High Hybrid/ QRA	Extreme QRA	Extreme QRA
High	1E-3 to 1E-4	Medium SQRA	Medium SQRA	High Hybrid/ QRA	Extreme QRA	Extreme QRA
Moderate	1E-4 to 1E-5	Low Qualitative Matrix	Medium SQRA	Matrix to Full QRA	High Hybrid/ QRA	Extreme QRA
Low	1E-5 to 1E-6	Low Qualitative Matrix	Low Qualitative Matrix	Medium SQRA	High Hybrid/ QRA	High Hybrid/ QRA
Remote	1E-6 to 1E-7	Low Qualitative Matrix	Low Qualitative Matrix	Low Qualitative Matrix	Medium SQRA	High Hybrid/ QRA
Environment		Minimal Loss	Not Significant	Significant	Major	Catastrophic
Health Social and Culture (People affected)		Minimal Effects	Significant Disruption	100-1000 People	1000 People affected	5000 people affected
Infrastructure & Economics		<US$1M	<US$10M	<US$100M	<US$1B	>US$1B
Company Reputation		Minor Temporary	Measurable - Limited	Substantial - State	Serious - National	Severe – Global
Severity Factor		10	30	100	300	1000

Figure 1: Risk assessment approaches selected using a risk matrix example (Barker, 2023)

The selection of the risk approaches does not negate the use of more detailed risk analyses for low-risk facilities where data is available and there is a requirement to comply with the tailings storage facility

owner's risk management framework or a Regulator's requirements. The more detailed risk analyses are preferred where there is a population at risk; however, where a tailings facility has little or no PAR or PLL, then the simplified analyses are appropriate, particularly since the cost benefit ratios are limited in value for the ALARP evaluation.

Process for achieving an ALARP solution

The process for achieving an ALARP solution has been further developed, as presented in Figure 2, which shows the bigger picture spiraling into the focal point of the ALARP solution, as discussed below.

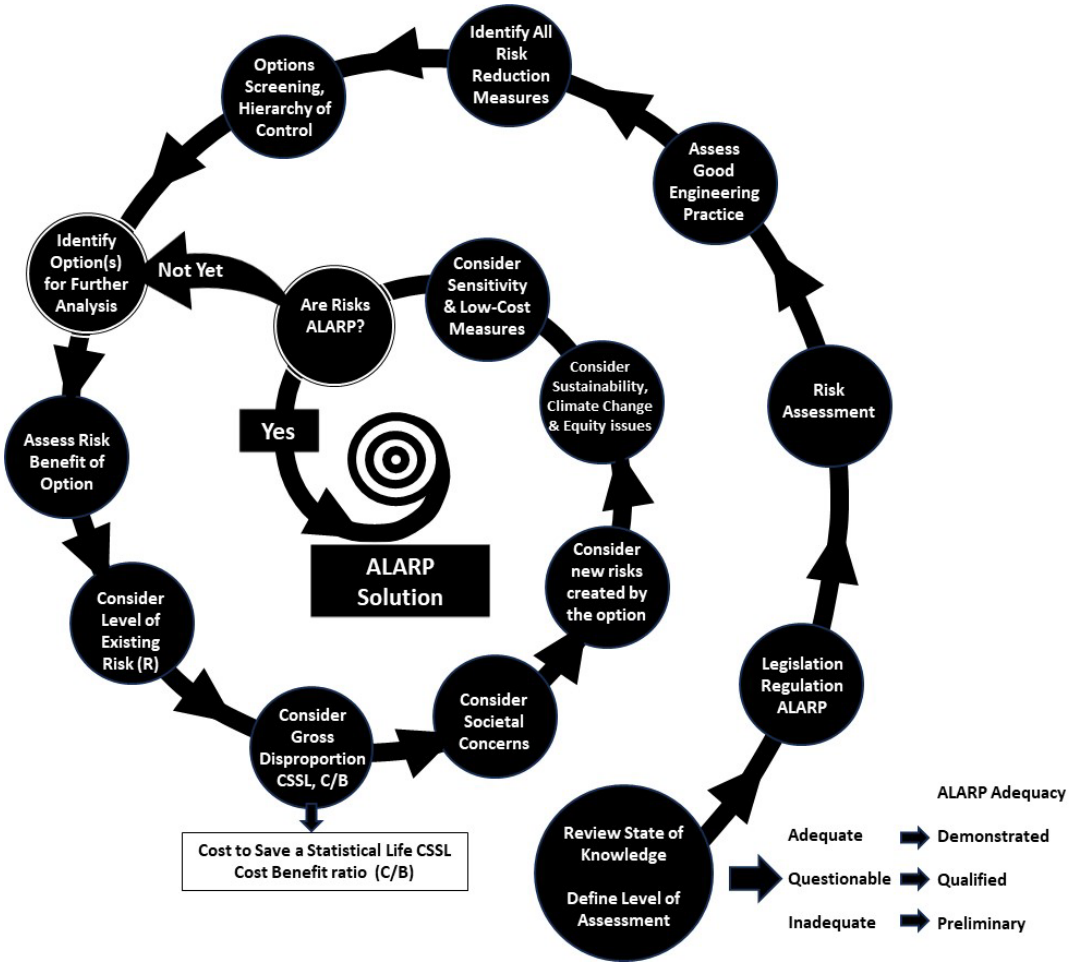

Figure 2: Conceptual representation of the iterative process to circle in on a risk position that is ALARP for a single dam (modified after Topham et al., 2024)

State of knowledge and level of ALARP assessment

A useful approach to a state of knowledge assessment is provided below, based on Pearse et al. (2022). This approach is a screening tool to qualify the outcomes of the assessment. The assessment is subdivided into four categories to assess the adequacy of the information in terms of these points:

- Level of detail and currency of risk assessment.
- Engineering inputs, which are used for the potential failure modes and likelihood assessment.
- Consequence assessment inputs.
- Understanding of risk control measures (existing and additional).

For each of these categories, the assessment team makes a judgement on the degree of adequacy (inadequate, questionable, or adequate) for the dam system. The lowest "adequacy level" will generally dictate whether the ALARP assessment is Preliminary, Qualified, or Demonstrated.

Legislative and regulatory context

The facility owner may have obligations for the ALARP assessment to be compliant with the following:

- GISTM, which "provides a framework for safe tailings facility management while affording Operators flexibility as to how best to achieve this goal."
- Legal duty to reduce risks to ALARP under both statute and common law (in the UK and Australia).
- Any requirements their regulator may have in regard to ALARP.

Risk assessment

The level of knowledge, regulatory requirements and internal company policies, together with the initial evaluation of risk using a failure modes and effects analysis (FMEA) approach are used to determine whether the quantitative or qualitative approach is to be used for the risk assessment, as shown in Figure 3.

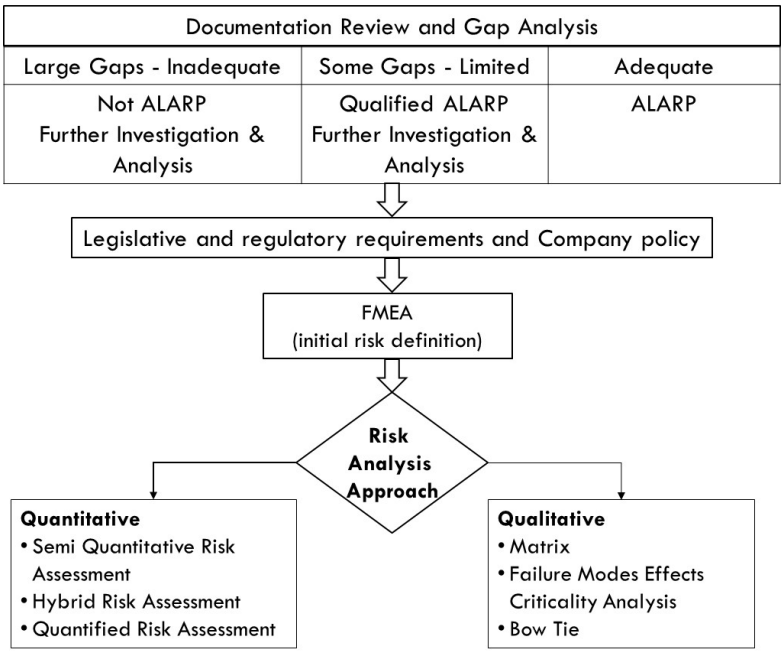

Figure 3: Selection process for risk assessment approach (Barker et al., 2022)

Where a qualitative risk assessment is used, a criticality rating system like the example shown in Table 1 can be used for evaluating the likelihood of failure or a descriptive system based only on the Initiation (I) shown in Table A1 in the Appendix.

Criticality as an alternative for probability in qualitative analysis

In order to evaluate the likelihood or criticality of a failure mode, three numerical ratings are multiplied together to calculate the overall "criticality," as the following example shows:

Table 1: Example criticality rating system (adapted from GHD, 2023)

Symbol	Rating name	Description	Score range
I	Initiation	Likelihood of the initiating mechanism being present or occurring. Includes all events up to and including the point at which the failure mode initiates	Score of 1 (rare) to 5 (almost certain)
P	Progression	Likelihood the failure mode, once initiated, will progress to a catastrophic consequence	Score of 1 (rare) to 5 (almost certain)
E	Control effectiveness	Effectiveness of existing controls that PREVENT and DETECT the failure mode event, and/or INTERVENE to lessen the consequences. This is a measure of the effectiveness of the controls listed in a TSF Bow Tie analysis, FMEA, (and any others) relevant to each failure mode	Score of 1 (highly effective) to 5 (absent)

Note that the "initiation" portion of event ends once the failure mode has been initiated. The progression rating can then be applied to the subsequent events leading to an extreme or catastrophic failure. Importantly, such rating systems can be further tailored to suit the TSF owner.

Hence, to calculate the Criticality (C) of a failure mode:

Criticality (C) = I × P × E, a numerical value ranging from 1 – 125.

In the case that there is a desire to convert criticality to annual exceedance probability (AEP), this could be done on a log basis, as shown in Figure 4.

Tables A1 to A3 in the Appendix provide guidance when selecting these criticality parameters. As with a quantified approach for risk analysis, it is important for the failure mode to be well understood and described to ensure that it is credible and can be understood for the application of the ALARP process.

Tables A4 to A6 in the Appendix provide a means of rating the consequences resulting from a failure for potential life loss, economic loss and company reputation, and social and environmental losses. This

rating system can then be used to evaluate the effectiveness of risk reduction measures (RRMs), using plots of either the calculated probability of failure or the Criticality values against the various consequences.

It should be noted that when plotting data and using it for reducing risks ALARP, as shown in Figure 4, there should not a limit of tolerability for acceptance, as there may still be remedial measures that are needed even when a tolerability limit is reached. Notwithstanding this, it is known that some corporations do include a limit of tolerability, and this should be used with caution.

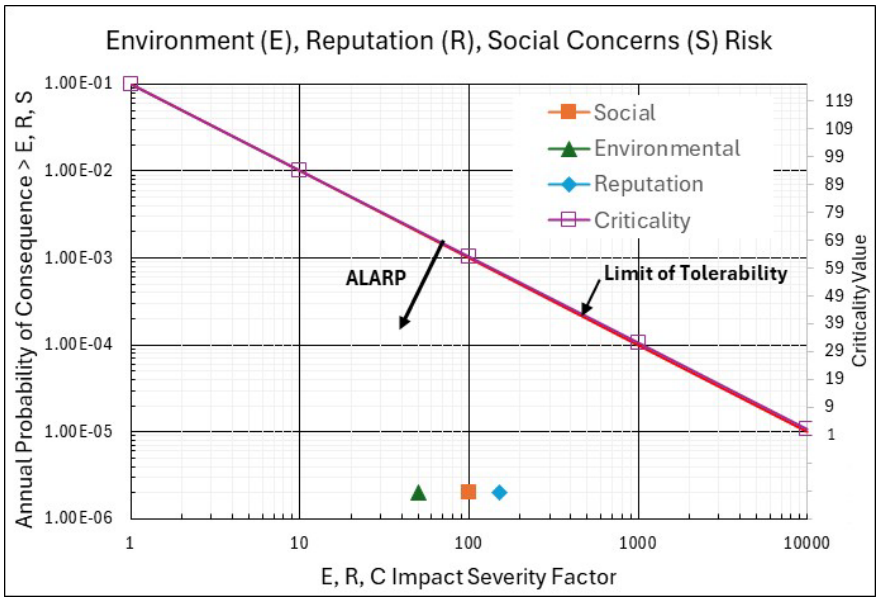

Figure 4: Risk plot of annual probability or criticality versus impact severity factor for environmental, reputational and social concern

Assess good practice and precedent

The UK Health and Safety Executive (HSE) guidance material states that good practice is defined as "*those standards for controlling risk that HSE has judged and recognised as satisfying the law, when applied to a particular relevant case, in an appropriate manner.*" Some sources of good practice include:

- industry standards;
- guidelines;
- precedence – be careful as some aspects of precedence may not be appropriate for your TSF; and
- benchmarking.

Identify risk reduction measures

In practical terms, mitigations against each failure mode identified in the risk analysis can be described in terms of recognized good practice.

Screen options using hierarchy of controls

Having identified the RRMs, a ranking and screening tool is used to assist in the selection of the RRMs for further analysis. A typical multi-criteria analysis (MCA) tool can be used to rate each measure against categories relevant to the ALARP assessment, as shown in the example in Table 2 below for the qualitative and quantitative assessments. An example of the multi-criteria screening tool is shown in Table 3, noting that elements and metrics of such rating systems can be tailored to suit the TSF owner, and weightings can be applied to metrics depending on their relative importance within the context being considered. The MCA total rating in this example is the addition of each of the weighted scores.

Table 2: Risk reduction measures screening factors

Qualitative Assessment	Quantitative Assessment
Understand Failure Modes	Understand Failure Modes
Hierarchy of Controls (How well does the RRM address the Controls?)	Hierarchy of Controls (How well does the RRM address the Controls?)
Implementation cost	Implementation cost
Level of risk reduction achieved (Matrix)	Level of risk reduction achieved (R-value per ANCOLD, 2022). See below
Interdependency with other RRMs	Percentage of total risk contribution addressed by RRM
Additional risk introduced by the RRM	Interdependency with other RRMs
	Additional risk introduced by the RRM

Table 3: Example of multi criteria analysis screening tool score categories

Implementation Cost	Weighted score
>$30M	0
$15M to $30M	1
$10M to $15M	2
$5 to $10M	3
$2M to $5M	4
$1M to $2M	5
$750k to $1M	6
$500k to $750k	7

Significant - comprehensive controls and detailed analyses required	-8
Catastrophic - unlikely to be controlled	-10

Heirarchy of Controls	Weighted score
Eliminate the Hazard	0
Substitute the Hazard	1
Isolate the Hazard	2
Engineering Controls	3
Administrative Controls	4
PPE	5

Existing risk level and risk reduction benefit of options

An example of the existing risk level and risk benefit for a RRM is shown in Figure 5 for a quantitative and qualitative risk quantification.

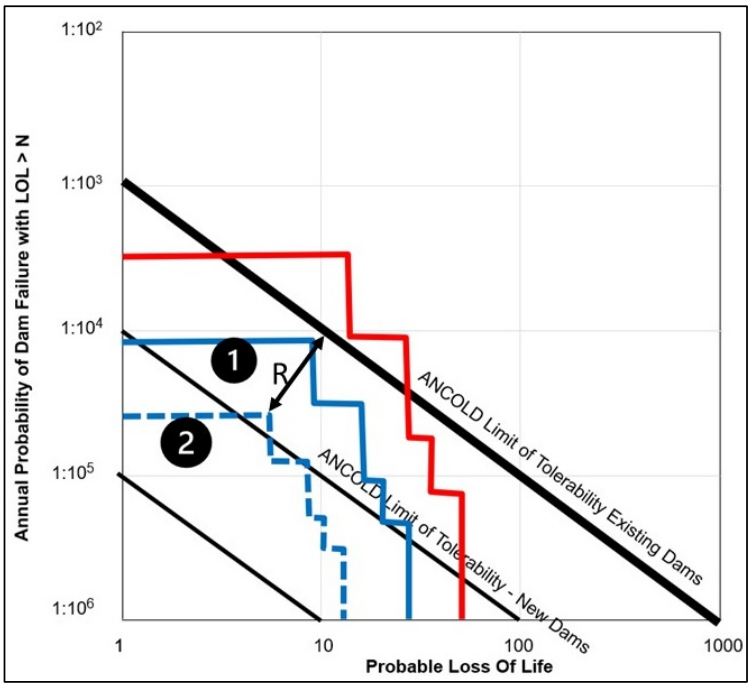

Figure 5: Risk level and risk reduction benefit for quantitative (FN) risk analyses

Where the ALARP assessment is based on a quantitative risk analysis, the level of risk (R) shown for the quantitative assessment can be calculated as defined in the equation below (ANCOLD, 2022).

$$R = -\log\frac{Worst\ risk\ point\ on\ F-N\ Curve}{Limit\ of\ Tolerability} = -\log\frac{(F\times N)_{MAX}}{10^{-3}}$$

Where:

- R is the level of risk expressed in orders of magnitude below the Limit of Tolerability
- $(F\times N)_{MAX}$ is the product for the worst risk pair of F and N
- F is the cumulative annual probability of failure with expected loss of life ≥N

For individual risk:

$$R = -\log\frac{Individual\ Risk}{Limit\ of\ Tolerability}$$

The value R is also used in assigning the disproportion factor for estimation of the Cost to Save a Statistical Life (CSSL) defined by ANCOLD (2022). Recommendations for the interpretation based on the considerations above are shown in Figure 5 for the quantitative risk analysis.

Figure 6 includes an example of how to portray the level of risk reduction for a qualitative matrix approach, where that reduction can be established by a simple ratio of the change of numerical value in the matrix. In the example shown in Figure 6, this ratio would be 9/4=2.25.

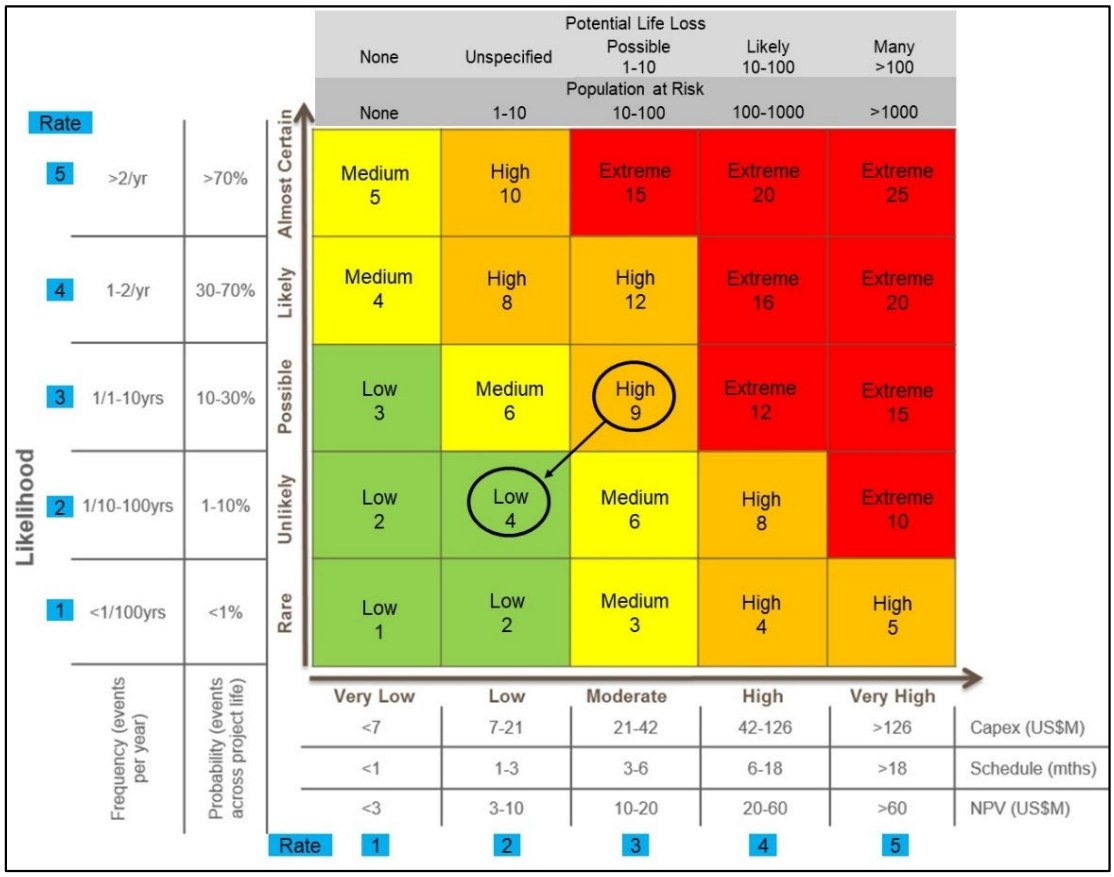

Figure 6: Risk level and risk reduction benefit for qualitative (matrix) risk analyses

Cost effectiveness

Quantitative assessment of cost effectiveness

The R-values achieved by each combination of RRMs, when plotted against the cumulative cost of implementation, can provide a useful visual assessment of when the cost of the next most viable RRM is grossly disproportionate to the risk benefit achieved, and also be used as a RRM prioritization sequence.

Figure 7 presents an example plot for a dam, which clearly shows the benefit gained from the considerable expenditure to deliver RRM 5 and RRM 6 is grossly disproportionate to the risk benefit (when compared to RRMs 1 – 4).

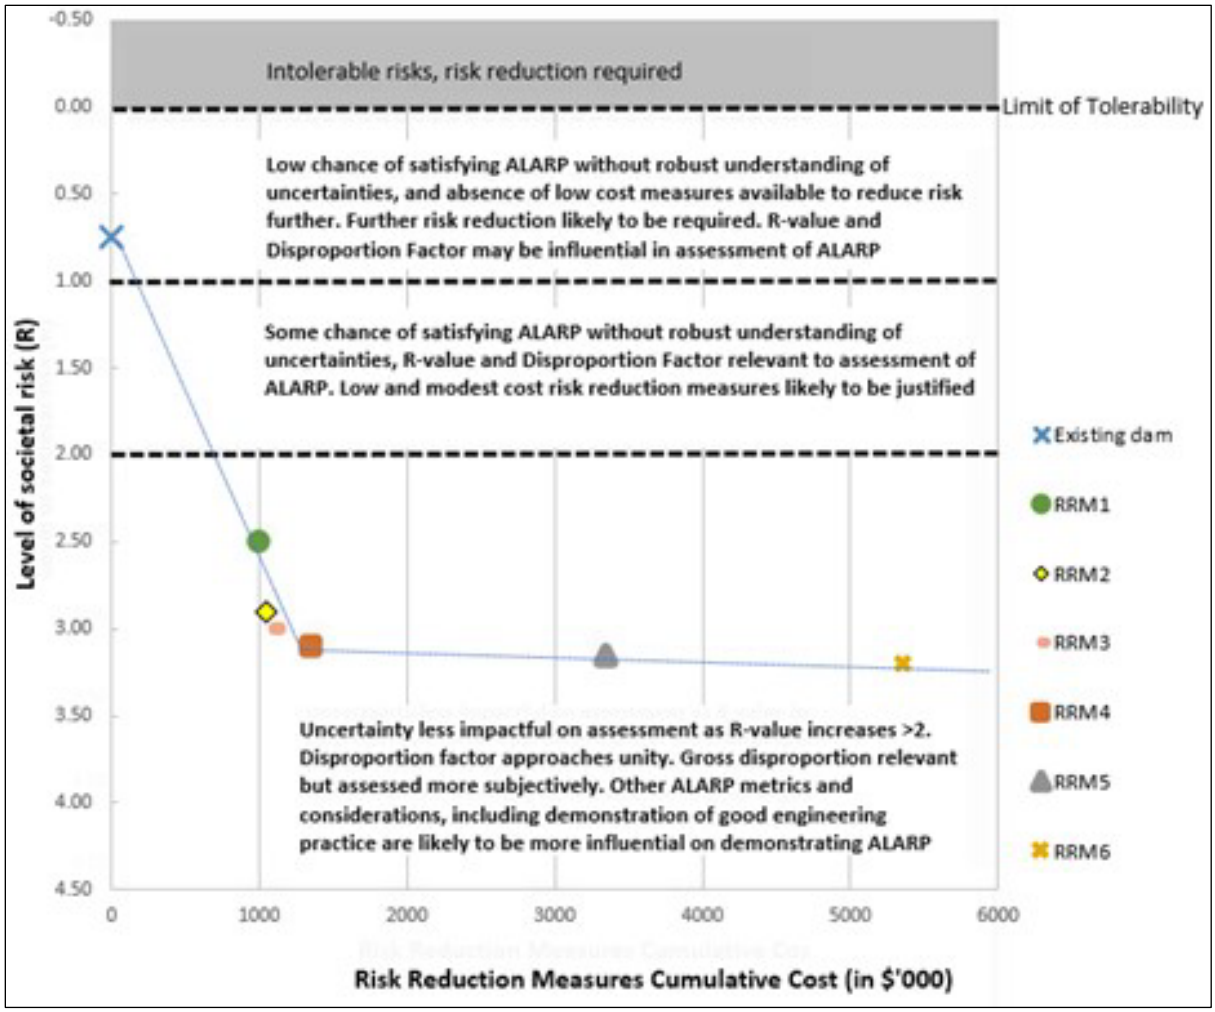

Figure 7: Level of reducing existing risk (R) as additional measures are added versus cumulative cost (Topham et al., 2024)

ANCOLD (2022) provides an approach to evaluate the gross disproportionality of costs relative to the Limit of Tolerability using the R value and CSSL, as well as a cost benefit ratio (CBR). In the authors' experience, once the risk is lowered below the Limit of Tolerability, the CSSL and CBR are not generally strong drivers for ALARP, but rather the remaining factors.

Qualitative assessment of cost effectiveness

In the case of the matrix approach, it would be mandatory for the risk to be lowered to at least the Medium to High range. As discussed above, the level of risk reduction can be established by a simple ratio of the change of numerical value in the matrix, which is 2.25 in Figure 6. The axis in Figure 6 would be adjusted to suit the range of risk reduction, and a similar plot would be produced for each RRM.

Societal concerns

If the TSF in question has characteristics that would suggest an elevated level of societal concern regarding a failure, then a lower risk target may be warranted, compared to a more remote, less critical TSF. Relevant considerations are as follows:

- The hazards and uncertainty regarding the risks.
- High Consequences. Dread owing to the scale of consequences. Will society have greater leverage for reducing risks to ALARP?
- Vulnerable People. Who are they and where are they with respect to any potential failure scenario, and can they be moved to another location in order to eliminate the risk?
- Critical Infrastructure/loss of services. Is there any critical infrastructure affected for the future operation of the site or affected areas in the event of a failure?
- Equity of distribution of risk and benefits. Where would it be best to implement changes in operation of infrastructure to achieve equitable risk reduction across the system?
- Climate Change. Has climate change been considered in the ALARP decision?

Table A5 in the Appendix provides a descriptive means for quantifying societal concerns that can be used as a direct measure for seeing the impact in changes of likelihood for each RRM.

Creation of new risks

Creation of new risks where the remedial works change the configuration of a site or result in placement of material over areas that may be affected in future operations. This is particularly important where a "temporary fix" becomes a "permanent fix" and the resulting effects on the structure can lead to failure if the failure modes are not well understood.

Environmental and sustainability

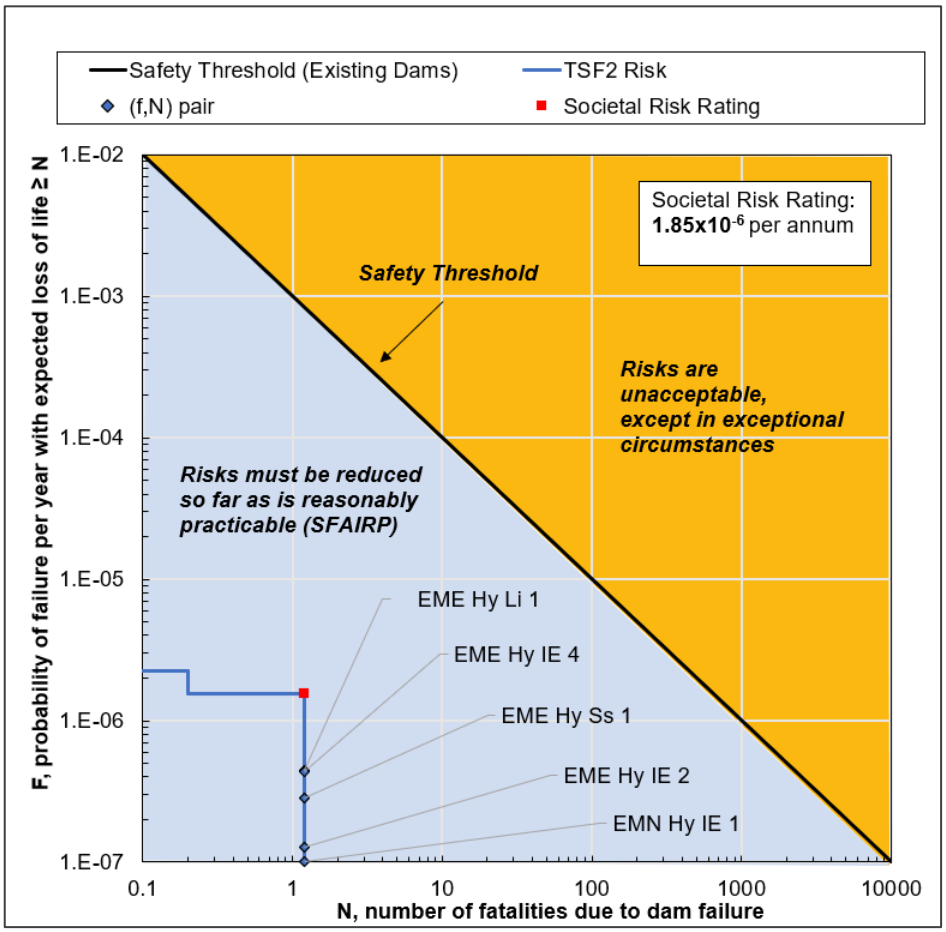
The potential differentiation between risk reduction measures on the basis of environment or sustainability should be considered, in line with the owner's corporate strategy and risk appetite as well as any legislative or regulatory requirements.

Table A6 in the Appendix provides a descriptive means for quantifying environmental impacts that can be used as a direct measure for seeing the impact in changes of likelihood for each RRM.

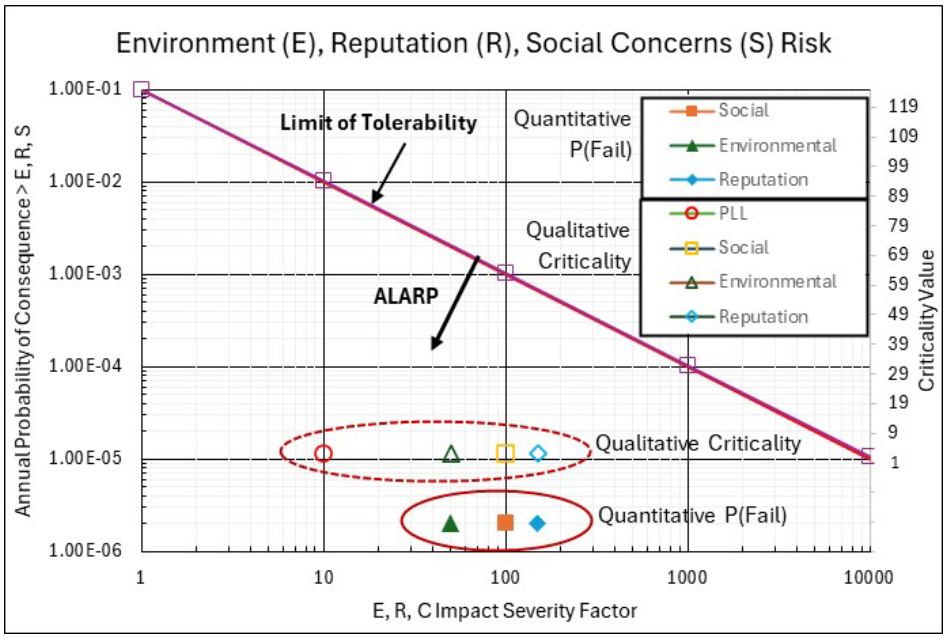
Low-cost measures

In accordance with ANCOLD (2022), measures that are sufficiently low-cost should be adopted regardless of whether they provide a material or measurable risk reduction benefit, especially if they represent recognized good practice.

Case study (Dam A)



The following case study is provided to demonstrate the application of ALARP using the quantitative and qualitative approaches. The qualitative approach assumes that we do not have the probabilistic AEP for failure and an overall probability of failure is taken based on the failure modes.



The structure is a 29 m high TSF with four embankments constructed via either centerline or upstream raises, creating a turkey's nest structure (an off-river storage that does not capture any external surface water). The decant system includes a tower located at the center of the tailings impoundment and a conduit that goes under one of the TSF walls to return water to a process water pond. The assessment is taken for the closure condition with the TSF at maximum height and a free overflow spillway, following a final downstream raise expected to be finished in three years. The key metrics relevant to the ALARP assessment are presented in Table 4.

Table 4: Characteristics relevant to ALARP assessment for Dam A at closure

Description of Dam	29 m high center line and upstream raised TSF embankment using clay and tailings for construction, with 3,500 m long perimeter embankments. The starter embankment was constructed in 2012 and there have been 2 upstream raises and 2 center line raises to date. Closure condition assumes a final downstream raise and capping.
Consequence Category	Downstream consequences include flooding of the mine site, underground mine works, and public land. Population at Risk estimated to be up to 17 persons, with potential loss of life around 1 person. Quantitative PLL: 1 Qualitative PLL Severity: 5 (uncertainty as to 1 PLL) Social Concerns Severity: 100 Environmental Severity: 50 Reputation Severity: 150
Summary of Risk Position	This dam is well below the Limit of Tolerability (LoT) or Safety Threshold for the quantitative assessment (R = 2.7), with key contributors to total risk position as follows: • Flow liquefaction of the eastern wall embankment and tailings under loading conditions including blasting, machinery vibrations, drillings, phreatic level changes, etc. leading to a brittle failure mechanism and breach of the embankment (27%) • Internal erosion and piping at the foundation due to presence of the decant conduit (26%) • Slope instability through embankment leading to settlement and loss of freeboard under normal loading (17%) Qualitative Criticality • Initiation 1 (Good knowledge and practice in design and construction) • Progression 2 (Possibility cannot be ruled out) • Control 1 (Effective and reliable) • Criticality = 1x2x1 = 2
	RRM 1: additional downstream berm to reduce the likelihood of failure by slope stability, internal erosion and flow liquefaction. RRM 2: stockpile of materials in the dam break flow path to direct dam break inundation away from the underground works tunnel entrance (and hence avoid PLL)

Risk Overview

ALARP Element	Conclusions
State of Knowledge	The dam is a relatively new tailings structure, with the starter embankment constructed in 2012. The most recent raises, stage 3 and stage 4, were designed with reference to many current design codes, such as relevant Australian Standards and ANCOLD design guidelines for tailings, which represent recognized good practice. There is good design and construction documentation including photographs and QA documentation. The operation and maintenance manual and emergency response plan are in place and well prepared. The ALARP assessment can be considered to be adequate given the state of knowledge.
Legislation and Regulation	The ALARP assessment is to be completed using the ANCOLD guidelines and the Water Act.
Recognized Good Practice	At closure, existing known risks will be resolved in line with recognized good practice. The critical failure mode for this dam relates to the risk of liquefaction of the tailings retained by the eastern embankment. This risk is mitigated by the centerline/downstream raise of the structure, which provides additional stability against both slope stability and liquefaction of tailings and represents recognized good practice. Following recognized good practice, the dam owner is already upgrading the surveillance/monitoring system and decommissioning the decant conduit.
Gross Disproportion – Cost Analyses	**Quantitative Assessment** At closure, the dam plots almost 3 orders of magnitude under the limit of tolerability for an existing structure using quantitative analysis. It is therefore expected that the cost of all conceivable RRMs would be grossly disproportionate to the risk reduction achieved. To prove that this is the case, a modified CSSL assessment was completed which indicated a "Poor" justification rating for any RRM which costs above $3,100. **Qualitative assessment** Based on good design and construction for closure, the Progression can be reduced to a value of 1 resulting in a Criticality of 1
Gross Disproportion – Level of Risk vs. Cost	RRM 1 (Large downstream filter and rockfill berm intersecting the foundation) is estimated to cost several million dollars and hence meets the gross disproportionality threshold, demonstrating it is not justified. The cost of RRM 2 (stockpile of materials to direct dam break flow path away from works and towards the water process ponds) is a lost opportunity cost (to use this area for another purpose), but with stockpile of materials to proceed regardless of location, this can be considered negligible. Its impact on the Societal (F–N) curve would be to limit the Potential Loss of Life to itinerants, and hence achieve material risk reduction for low cost, meeting a key ALARP test. Hence RRM 2 was recommended.
Creation of New Risks	For the low-cost option, consideration must be given to the location of the redirected dam break flow path to ensure no new risks are created by the RRM. The redirected flow pathway does not result in additional environmental or life safety risks because it would be directed towards the water process ponds.
Societal concerns	Given the potential for loss of jobs and dislocation of people, the severity factor was set at 100 for the existing facility and for RRM 2, this was reduced to 20, as shown in Figure 8.
Equity/Efficiency	Considered neutral to ALARP determination.
Environmental	Environmental risks during construction are considered manageable given the Stage 4 raise currently taking place; however, it was considered likely that fauna and stock would be affected, and the existing dam was given a severity factor of 50 and following RRM 2, this was reduced to 10.
Low-cost measures	RRM 2 is considered to be a practicable, low-cost measure with a meaningful reduction in life safety risk and is therefore included in measures recommended to reach an ALARP risk position. Along with these two risk reduction measures, the dam owner is currently implementing several measures following recognized good practice by default, including an upgrade of the monitoring system, a TSF safety review and risk assessment, update of the consequence assessment and emergency action plan (non-structural measures).

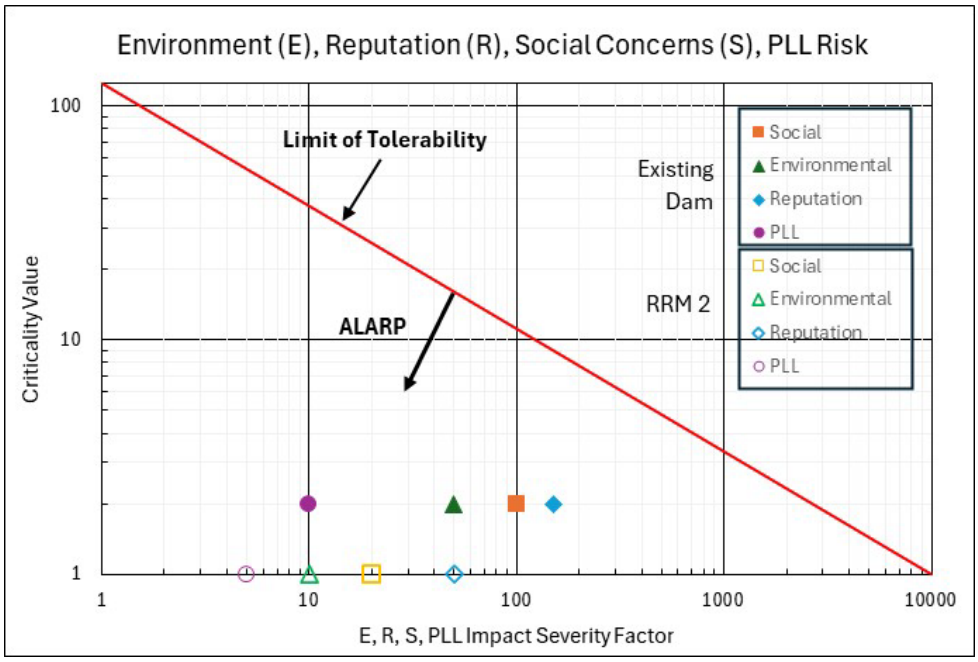


Figure 8: Qualitative presentation of existing risk and RRM 2 risk reduction

This dam represents an example of where the ALARP approach can justify avoidance of an expensive structural risk mitigation measure on the basis that the costs are grossly disproportionate to the risk benefit gained, particularly considering the existing low-risk position. However, the identification of RRM 2 to use stockpiled materials to train dam break flows away from the mine is a very low-cost measure, which would have a material risk benefit, as shown in Figure 8. RRM 2 represents a simple measure that lowers the risk position so far as is reasonably practicable, as long as no new risks are created by the redirection of the potential dam break flood. Along with these two risk reduction measures, the dam owner is currently implementing several measures following recognized good practice.

Conclusion

The question we normally ask is: "Do you think the risk profile of the dam is ALARP?" However, a better question is: "Have we documented our ALARP considerations effectively?" Always remembering that if the dam failed and there were fatal consequences or environmental damage, you would want to be able to confidently answer in the affirmative to the question: "Has ALARP been achieved, or were all reasonably practicable actions completed with respect to the known event?"

The proposed approach to ALARP solutions provides a means of documenting the process of reaching an ALARP solution for risk reduction for both quantitative and qualitative risk assessment approaches.

Documentation of ALARP determinations as shown above can be compared to the intent of a Safety Case of a high hazard facility, to document and justify the managed risk profile.

Criticality rating tables

Table A1: Example of Initiation Rating (I) Progression Rating (P) (Adapted from GHD, 2023. Dam X containing GHD technical memo dated 15 June 2022, proposed new Criticality Ranking System for FMEA)

Numerical Value (I, P)	Qualitative Rating	Indicative Quantitative Probability Range (AEP)	Likelihood Descriptor
1	Rare	< 1E-4	A failure pathway can be described; however, several events must occur concurrently or in series to cause failure. All the events individually have a low likelihood of occurrence.
2	Unlikely	1E-3 to 1E-4	The event has been known to occur elsewhere, however, at present the conditions do not exist for this event to occur and the failure pathway cannot be specified with confidence. The possibility of this failure mode occurring cannot be ruled out but there is no evidence that suggests it has occurred or that the fundamental condition has been met that could lead to it occurring.
3	Possible	1E-2 to 1E-3	Postulated physical processes or conditions exist that can be described and specified. AND/OR The fundamental defect or condition required for the failure mode to take place exists. OR Existing evidence suggests the failure mode is weighted towards "less likely" than "more likely."
4	Likely	1E-1 to 1E-2	Known physical processes and conditions exist that can be described and specified with confidence. Similar conditions have caused a known failure for a comparable structure OR The fundamental defect or condition required for the failure mode to take place exists. OR Existing evidence suggests the failure mode is weighted towards "more likely" than "less likely."
5	Almost Certain	1 to E-1	Known physical processes and conditions exist that can be described and specified with confidence. Similar conditions have caused known failures elsewhere OR Existing evidence suggests this failure mode has initiated or is expected to occur in near future, or has a frequent initiator

Table A2: Example of control effectiveness (E)

Numerical Value of E	Qualitative Rating	Likelihood descriptor
1	Effective and Reliable	In combination, the Control(s) are considered to be adequately designed, reliable, and operating effectively. In line with good practice
2	Satisfactory, could be improved. OR Effective but limited influence on FM	In combination, the Control(s) are considered to be adequately designed, but may not be reliable in all situations, or there are some operating difficulties. Mostly effective. Largely in line with contemporary industry practice for this failure mode. Control(s) effective but have limited influence on Failure Mode
3	Marginal	In combination, the Control(s) are not considered to be adequately designed, or may be unreliable to impact this failure mode, or at a frequency that is not suited to the failure mode. Partially effective. Below contemporary industry practice for this Failure Mode
4	Weak ineffective	Few controls relevant to this Failure Mode. Control(s) are considered weak, or ineffective for this Failure Mode
5	Absent	No Controls

Table A3: Criticality rating (C)

Numerical Value of C	Qualitative rating
1 to 12	Low: Failure mode not expected and/or well managed. Continue to monitor and maintain effectiveness of controls to prevent, detect and intervene.
13 to 60	Moderate: Failure mode is of material concern. Look for opportunities to better understand mechanism, lower the likelihood of failure mode initiating and progressing to failure. Improve controls reliability. Review consequence management controls for improvements.
61 to 125	High: Urgent focus required to lower the likelihood of failure mode initiating and progressing to failure. Improve controls reliability. Review consequence management controls for improvements

Consequences tables

Table A4: Life, economic and company consequences

Factor	Minimal Loss	Not Significant	Significant	Major	Catastrophic
Population at Risk	None	1 – 10	10 – 100	100 – 1000	> 1000
Potential Life Loss	<0.1	0.1 – 1	1 – 5	5 – 50	> 50
Infrastructure and Economics ($US)	< 1M	1M – 10M	10M – 100M	100M – 10B	>10B
Company Reputation	Minor	Limited Region	Substantial State	Serious National	Severe Global
Severity Factor	1	10	100	1000	10,000

Table A5: Health and societal impacts

Severity Level	Description (time months)	Human Health and Loss of Services (People affected)	Loss of Heritage	Dislocation of People (person months)	Employment (jobs lost)	Severity Factor
5	Severe (Catastrophic) (12)	1000	International facility	1000	100	10,000
4	Serious (Major) (6 to12)	100	National facility	100	50	1,000
3	Substantial (Medium) (2 to 6)	10	Regional facility	10	10	100
2	Measurable but Limited (Low) (1 to 2)	1	Local facility	1	5	10
1	Minor (<1)	<1	Local buildings	<1	1	1

Table A6: Environmental impacts severity level

Severity Level	Description	Area of Impact (km^2)	Stock and Fauna	Ecosystem recovery	Rare and Endangered Species	Severity Factor
5	Severe	>20	Significant health impacts from contaminates water supply	> 10 yrs	Permanent loss of species	10,000
4	Serious	10 to 20	Measurable health impacts from contaminates water supply	3 to 10 yrs	Severe impact recovery over number of years	1,000
3	Substantial	5 to 10	Contaminates water supply used by stock and fauna	1 to 3 yrs	Recover over a number of years	100
2	Measurable but Limited	1 to 5	Contaminates water supply used by stock and fauna health impacts not expected	<1 yr	Minimal Species damage	10
1	Minor	<1	No contamination of water supply	Recovers with little intervention	No species affected	1

Conformance vs. Compliance: Contrasting the Voluntary GISTM to 9 years of Federal CCR Regulations

Steven F. Fecht, Ramboll Americas Engineering Solutions, USA
Nguyet Nguyen (Wit Win), Ramboll Americas Engineering Solutions, USA

Abstract

The failures of tailings facilities at metals mines in the mid to late 2010s were preceded by similar failures of coal combustion residual (CCR, which is sometimes considered a type of tailings) surface impoundments that occurred at Kingston in 2008 (Tennessee, USA) and Dan River in 2014 (North Carolina, USA, 2014). The Kingston failure involved the static liquefaction of an industrial waste impoundment and a corresponding catastrophic flow-failure and offsite release of industrial waste. Similarly to the later tailings facility failures, the CCR failures also led to offsite environmental impacts, significant public scrutiny, a loss of public trust and social license to operate for the impoundment owners, damage claims and litigation, and corresponding efforts by stakeholders to develop systems to prevent similar failures from occurring again.

The prevention systems to reduce the occurrence of future failures differ significantly for CCR and tailings. For CCR, the system is one of mandatory compliance through federal regulation by the United States Environmental Protection Agency (USEPA) under 40 C.F.R. Part 257 (CCR Rule). This approach has been successful, as no failures have since occurred. However, the CCR Rule utilizes prescriptive technical criteria, provides limited allowance for risk quantification or site-specific variations, is the subject of ongoing litigation, and was significantly expanded in scope by USEPA in 2024. This approach is significantly different than the 2020 Global Industry Standard for Tailings Management (GISTM), which is a system of voluntary conformance[1] through a stakeholder-developed program that allows for site-specific variations, while requiring robust levels of governance and overlapping review. This paper will

[1] All members of the International Council of Mining and Metals (ICMM) have committed to conforming with the ICMM. Conformance with the GISTM is voluntary for non-ICMM members, although many non-ICMM member companies have committed to GISTM conformance.

contrast the two methods of prevention – compliance[2] vs. conformance[3] – and elaborate on the relative advantages of the GISTM over the CCR rule, as well as lessons learned from CCR compliance that may prove helpful for GISTM practitioners.

Introduction

Coal combustion residuals (CCRs) are a class of residual materials left over from the burning of thermal coal (i.e., ash), primarily for electric utility generation. They are sometimes considered to be a type of tailings. Most CCRs consist of fly ash, typically silt-sized, and bottom ash, typically sand-sized, though some power plants equipped with scrubber systems produce silt-sized gypsum. CCRs have historically been managed like mine tailings. This has included storing CCRs in wet-sluiced industrial waste impoundments, which often share design features, construction methods, operations, environmental concerns, and failure mechanisms with mine tailings storage facilities. CCR impoundments are common in countries relying on thermal coal for electricity, including, but not limited to, the United States (US), China and India. This paper will focus on CCR disposal facilities in the US, where nearly 700 impoundments (USEPA, 2016) are estimated to be present.

CCR surface impoundments gained significant publicity after the catastrophic 2008 Kingston failure in Tennessee, which released around 5.4 million cubic yards of CCR and wastewater into the Clinch River (AECOM, 2009). Public outcry over the Kingston failure and concerns related to groundwater and surface water contamination at other impoundments prompted USEPA to begin the process of regulating CCR at the Federal level in 2010 (USEPA, 2024a), leading to the promulgation of 40 Code of Federal Regulations (C.F.R), Part §257, known as the "CCR Rule." This rule provides comprehensive environmental, structural, and closure regulation of CCR surface impoundments and landfills.

There are many parallels between the events that ultimately led to the promulgation of the CCR Rule and the development of the Global Industry Standard for Tailings Management (GISTM) (Global Tailings Review, 2020) in 2020. However, the overarching systems developed to improve management and prevent failures for each waste stream – regulatory compliance for CCR and stakeholder standard conformance for tailings – are fundamentally different. This paper will evaluate the differences between each system and provide lessons learned from the experience of the authors supporting impoundment owner/operators in supporting both CCR Rule regulatory compliance and GISTM standard conformance activities. The authors

[2] "Compliance" is defined, for the purposes of this paper, as an activity that an entity (*i.e.*, waste impoundment owner/operator) is mandated to perform by an external governmental agency under legal authority, and where a lack of compliance may directly subject the entity to litigation and/or other legal penalties.

[3] "Conformance" is defined, for the purposes of this paper, as an activity that an entity voluntary performs and is in accordance with standards and/or guidance documents developed by 3rd-party non-governmental organizations (i.e., stakeholder groups), and where a lack of conformance may subject the entity to stakeholder scrutiny, but is unlikely to directly subject the entity to litigation and/or legal penalties.

aim to provide a case study that will benefit tailings impoundment owners and practitioners, based on these lessons learned. Additionally, this paper will address the challenges posed to the industrial waste management industry by a mandatory Federal regulatory program, as well as some of the potential challenges and shortcomings associated with a voluntary and stakeholder-based program like the GISTM relative to a mandatory program.

CCR impoundment management practices and waste characteristics

Most CCR impoundments in the US were initially constructed in the 1950s through the 1970s to support the widespread construction and operation of coal-fired power plants associated with postwar industrialization and economic growth. Impoundments were often constructed adjacent to the power plants, which were nearly always adjacent to a large water body (i.e., river, lake, or reservoir) that provided cooling water. Most impoundments were initially constructed with an earthen starter dike with later capacity increases using dike raises. CCR was typically wet-sluiced into the facility, and dike raises for some, but not all impoundments, were constructed using the upstream method, where the raises were constructed wholly or partially over a foundation of wet-sluiced industrial waste. However, not many CCR surface impoundments used single-stage or downstream earthen construction methods, due to site characteristics and other factors.

The geotechnical behavior of wet-sluiced CCRs is in many ways similar to wet-sluiced tailings. This generally includes susceptibility to brittle behavior (i.e., static and seismic liquefaction), flow failure when co-stored with water, and a relatively high shear strength at relative low strains during drained loading.

CCR impoundment failures

The most significant CCR impoundment failure occurred at the Tennessee Valley Authority (TVA) Kingston Fossil Plant (KIF) in Roane County, Tennessee, on December 22, 2008. The event was a catastrophic flow-failure of an 84-acre (34-hectare) CCR dredge cell, resulting in the release of approximately 5.4 million cubic yards (4.1 million cubic meters) of CCR over an approximately 300-acre (121 hectare) area (Figure 1). The release occurred without warning at approximately 1:00 AM local time and impacted the adjacent Emory River, along with onsite and offsite areas. It caused serious damage to several residences but did not result in any injuries or fatalities (AECOM, 2009; WBIR, 2018).

Figure 1: Post-failure photographs of Kingston CCR impoundment failure (USEPA, 2017)

A root cause analysis commissioned by the TVA (AECOM, 2009) identified that the failure was clearly a static liquefaction event induced by excessive deformation in upstream-constructed containment dikes. The report noted that the deformation was induced by the construction of the starter dike and subsequent dike raises over a previously unknown thin foundation layer of weak slimes. The effects of the deformations were exacerbated by strain incompatibility between the relatively plastic foundation slimes and the saturated, contractive CCR within the impoundment that behaved in a semi-brittle manner. After the dike deformed enough to trigger a breach, the flow-failure event was initiated and rapidly occurred.

The Kingston failure was followed by the Dan River failure in Eden, North Carolina, USA, in 2014. The Dan River failure occurred when a stormwater conduit buried beneath an inactive CCR surface impoundment failed, causing approximately 82,000 tons of CCR and 27 million gallons of CCR wastewater to flow into the Dan River (USEPA, n.d.). While the Dan River failure was significantly smaller than the Kingston failure, it was also driven by the tendency of CCR to exhibit flow-failure behavior, and it caused striking visual impacts to approximately 70 miles of the Dan River downstream from the site (NC DEQ, 2014) (Figure 2).

Both failures were similar to several of the tailings facility failures that occurred in the 2010s, including the sudden and unexpected nature of the events, the flow-failure of the material, and significant impacts to offsite areas. Both failures also received widespread press coverage in the US and significant attention by non-governmental organizations (NGOs), environmental groups, state environmental regulatory agencies, and Federal regulatory agencies.

Figure 2: Post-failure CCR impacts in the Dan River (NC DEQ, 2014)

The USEPA CCR Rule

In 2010, USEPA proposed to regulate CCR under the Resource Conservation and Recovery Waste (RCRA) of 1976, to reduce the risks posted by CCR surface impoundments and landfills. After a multi-year rule development and multiple public comment periods, USEPA issued the final CCR Rule on December 14, 2014, thereby regulating CCR under Subtitle D of RCRA (USEPA, 2024a), with an effective date of April 15, 2015.

Features of the Rule

The CCR Rule was initially "self-implementing," as USEPA did not have direct enforcement authority under RCRA Subtitle D in 2015. Instead, the enforcement of the rule was left to citizen lawsuits. Direct enforcement of the CCR Rule was later granted to USEPA under the Water Infrastructure Improvements for the Nation Act (WIIN Act) in 2016; this act also allowed states to implement their own CCR permit programs after USEPA review and approval. As of the date of this paper, only three state permit programs

(Oklahoma, Georgia, and Texas) have been approved while one program (Alabama) has been denied by USEPA (USEPA, 2024b).

Compliance with the CCR Rule is required to be demonstrated via a public internet website, hosted by the CCR unit owner/operator, and required to contain multiple Professional Engineer-certified documents, including, but not limited to, location restrictions (§257.60-64), design criteria (§257.71), structural integrity (§257.73), air criteria (§257.80), hydrologic and hydraulic capacity (§257.82), routine inspections (§257.83), groundwater monitoring and corrective action (§257.90-98), and closure and post-closure care (§257.103-104).

Comparison to the Global Tailings Standard

This section will compare several, but not all, of the key portions of the CCR Rule to the GISTM. Both the CCR Rule and GISTM are extensive and far-reaching documents; a comparison of all requirements of both documents is beyond the scope of this paper.

Implementation and adoption

Compliance with the CCR Rule is mandatory for all electric utilities and independent power producers in the US. While there were some exemptions in the CCR Rule based on the operational status of the power plant in 2015, many of these exemptions were later removed under an expansion of the CCR Rule in 2024, termed the "CCR Legacy Rule." Non-compliance or non-adoption with the CCR Rule can result in direct enforcement action by USEPA or citizen lawsuits under RCRA Subtitle D (i.e., self-implementation).

All members of the International Council on Mining and Metals (ICMM) have committed to implementing the GISTM, along with multiple non-ICMM members. However, there is no requirement for non-ICMM members to adopt the GISTM. The non-ICMM members who have committed to the GISTM have done so voluntarily, although sometimes at the request of investors and/or other stakeholders. The GISTM is also self-implementing, with implementation overseen by the tailings facility owner/operator directly as opposed to a dedicated and independent external agency[4]. This is similar to the initial implementation of the CCR Rule, prior to the WIIN act.

Community and project-affected people engagement

Community and project-affected people engagement within the CCR Rule is limited to public postings of various hydrogeologic and engineering certification documents, annual inspection reports, and routine groundwater and fugitive dust monitoring reports. The CCR Rule also requires CCR unit owner/operators

[4] As of the date of this paper, an external 3rd party auditing program for GISTM conformance is in the early stages of development, but is likely several years away from being implemented.

to list contact information for submitting questions. No other requirements for the engagement of the local community or project-affected people are included in the CCR Rule; this includes a lack of engagement requirements for design or planning-related activities, such as the siting of a new CCR unit or the closure of an existing CCR unit, and a lack of a mechanism for grievances to be reported and addressed. However, it should be noted that many state regulatory programs (i.e., water quality, dam safety, landfill permitting programs) do have public meeting requirements that are outside of the CCR Rule.

The GISTM, in Principle 1 and Principle 2, requires the meaningful engagement of project-affected people and the community. This includes documenting the engagement of project-affected people and developing a grievance mechanism to address the complaints of project-affected people. Additionally, the GISTM requires that the design of the tailings facility consider the local environmental, social, and economic context, and that the potential impacts of a tailings facility failure be considered during the complete lifecycle of the tailings facility (Principle 3).

Design criteria

The CCR Rule includes prescriptive criteria for the hazard potential classification, minimum slope stability factors of safety for multiple dike stability loading conditions (§257.73), rainfall frequencies for the inflow design flood control plan (§257.82), and seismic event return intervals. The slope stability factors of safety and seismic design events are the same regardless of the hazard potential classification, while the frequency of the inflow design flood control plan varies based on the hazard potential classification. Design criteria are the same for an operational and a closed unit. The maximum flood frequency is the probable maximum flood (PMF) for a "High" hazard potential classification CCR unit. There are no mechanisms that explicitly allow for temporary non-compliance with the design criteria; non-compliance may trigger mandatory closure of the impoundment, enforcement action by USEPA, or citizen lawsuits.

For operating facilities, the GISTM includes prescriptive criteria for flood and seismic events ranging from a 1/200-year to a 1/10,000-year event, based on the consequence classification of the facility. For facilities in a state of passive-care closure (i.e., "safe closure"), 1/10,000-year seismic and flood events are required. Other seismic events such as the Maximum Credible Earthquake (MCE) or Maximum Design Earthquake (MDE) may also be used for closure design, although these concepts are not explicitly mentioned in the GISTM. Specific safety factors or analysis methodology are not included for geotechnical and hydraulic analysis. Instead, the GISTM requires that the design criteria of the tailing facility be selected in a site-specific manner considering multiple factors, including the risk posed by the facility (Principle 4). Additionally, instances of non-compliance with the GISTM can be addressed through the development and implementation of risk mitigation plans, when approved by tailings facility owner/operator governance systems and external reviewers (Principle 4).

Risk assessments

The CCR Rule does not include any requirements for CCR unit owner/operators to perform risk assessments, potential failure mode assessments, or failure mode and effects analyses. Instead, the CCR Rule relies on the certification by a Professional Engineer that the facility meets §257.73 and §257.82 structural stability design criteria requirements for all facilities. In the experience of the authors, some CCR unit owner/operators voluntarily and proactively performed risk assessments as part of internal risk management and governance program. However, these assessments were not mandated, and the CCR Rule does not include the over-arching concept of continual risk reduction to "as low as reasonably practicable" (ALARP) that is a central focus of the GISTM. In fact, outside of the inflow design flood event, the CCR Rule inherently treats the design criteria for CCR units in a "one-size-fits-all manner" (i.e., factors of safety, monitoring an OMS requirement, dam safety reviews), regardless of the level of risk posed by the facility (i.e., potential environmental and human impacts of a failure, size and location of the CCR unit).

The GISTM requires risk assessments to be performed for all tailings facilities and utilized to inform the design of the facility. Additionally, the GISTM, in Principles 4 and 5, requires that designs be robust, consider all identified failure modes, and reduce risk to ALARP. The GISTM also inherently allows for the use of RIDM to provide for flexible and site-specific design criteria. This approach inherently allows for each tailings facility to be viewed independently, with an implied goal of allocating additional resources and applying more conservative design criteria to high-risk facilities.

Management of change

The CCR Rule requires the update of certifications for the structural integrity (§257.73) and hydraulic and hydrologic capacity (§257.82) every five years, regardless of the hazard potential classification of the impoundment. This process is similar to a Dam Safety Review (DSR), as opposed to a formalized Management of Change process. Documentation of changes to the local social, environmental, and economic context outside of the facility are not required as part of the periodic certification process or any other CCR Rule requirements.

The GISTM requires the ongoing review and evaluation of material changes not only to tailings facilities but also to the surrounding social, environmental, and economic context. Tailings facility owners and operators are required to define material changes and update multiple documents, including but not limited to, impact assessments, breach assessments, and design basis reports, based on material changes (Principles 2, 3, and 4).

Management and governance

There are substantial differences in the role of corporate management and governance between the CCR Rule and the GISTM, as discussed in this section.

Role of the Engineer of Record

CCR Rule

The CCR Rule requires certifications for various rule requirements to be prepared and posted to a public website. These certifications must include the seal and signature of a qualified Professional Engineer in the state with where the CCR Unit is located (e.g., the Certifying Engineer). No specific requirements are listed for the minimum qualifications for the Certifying Engineer. CCR Rule certifications are prepared for multiple portions of the CCR rule, including but not limited to, the design and operating criteria (§257.71-73, 82) and certifications for both closure plans and closure completion (§257.102-103). The scope of the certification only includes the explicit regulatory requirements.

It is commonplace for multiple Certifying Engineers, often from multiple consulting firms, to certify different sections of the CCR Rule for the same CCR unit within a given year (e.g., a different Certifying Engineer for annual inspections vs. the initial design and operating criteria). It is also not uncommon for Certifying Engineers to be changed between initial and periodic certifications. The CCR Rule does not require or imply that the various Certifying Engineers need to communicate with one another. Additionally, the CCR Rule does not contain any requirements for continued engagement or communication between the Certifying Engineer(s) and CCR Unit owner/operators between required certifications. When Certifying Engineers are changed, there are no requirements for the new Certifying Engineers to communicate with the previous Certifying Engineers.

GISTM

The GISTM requires the formal engagement of an Engineer of Record (EoR) for all active tailings facilities and closed facilities with a "High" or higher consequence classification (Principle 9). The GISTM requires that the EoR have relevant experience, skills, and time to fulfill the role. The EoR must be empowered through a written agreement explaining the obligations of the EoR and owner/operator to each other, and the EoR's activities must be governed by a quality management program. Additionally, the GISTM stipulates that EoR selection decisions be made by the Accountable Executive rather than by procurement personnel. Furthermore, the GISTM requires the development of a knowledge transfer plan in case of a change in the EoR.

The EoR is also expected to be continually involved in the tailings facility's design and operation. This includes preparing an Annual Inspection Report; reviewing operational, monitoring, and surveillance (OMS) data; and communicating with the Responsible Tailings Facility Engineer.

Corporate governance

The CCR Rule requires CCR Unit owner/operators to certify compliance with certain portions of the CCR Rule (i.e., Part A demonstrations via §257.103). Most other requirements of the CCR Rule are expected to

be implemented via certifications prepared by Certifying Engineers. The CCR Rule does not include any specific provisions or requirements for owner/operators to implement corporate governance programs for managing their CCR units. However, some CCR unit owner/operators have self-implemented corporate governance programs.

The GISTM includes multiple requirements for corporate governance (Topic IV). These requirements include, but are not limited to, appointing an Accountable Executive to oversee tailings management; reporting to the Board of Directors; appointing a Responsible Tailings Facility Engineer for each tailings facility; providing training for workers involved in tailings management; implementing lessons learned from internal and external failures; developing a whistleblower protection system; and implementing both Tailings Management Systems and Environmental and Social Management Systems.

Independent reviews

The CCR Rule does not include any provisions for the independent review of certifications and assessments performed by Certifying Engineers. The CCR Rule does not prohibit a sole Certifying Engineer from preparing a certification with no independent or external review, although in practice, most certifications are prepared by engineering firms and reviewed by internal subject matter experts independent of the Certifying Engineer prior to completion. Once a certification has been prepared, it may be reviewed by a state permit agency (if present), USEPA, or an individual or non-governmental agency (NGO) and potentially challenged via a citizen lawsuit. Challenges to the certification statements would then be addressed via a prolonged regulatory review and/or litigation processes, instead of via an independent review process performed prior to finalizing design activities.

The GISTM requires multiple levels of independent review. This includes assigning a Senior Independent Technical Reviewer or an Independent Tailings Review Board (ITRB) to provide high-level review of most documents and studies prepared by the EoR. Additionally, the GISTM requires auditing of compliance with the Tailings Management System (TMS) and Environmental and Social Management System (ESMS), along with periodic risk assessments using a multi-disciplinary team. Furthermore, the GISTM requires the Accountable Executive (AE) to be involved in technical decision making for certain high-risk tailings facilities.

Dam safety reviews

The CCR Rule requires periodic certification of structural integrity (§257.73) and hydrologic and hydraulic capacity (§257.82) to be prepared on a five-year basis for all surface impoundments. Initial certifications were required in 2016, the first periodic certifications were prepared in 2021, and the next periodic certifications will be required in 2026. While the scope of the periodic certifications is somewhat similar to a Dam Safety Review (DSR), the CCR Rule does not include specific guidance other than certifying that

the CCR Unit still meets all of the structural integrity and hydraulic capacity requirements. The CCR Rule also does not have any independence requirements for periodic certifications; they can be prepared by the initial Certifying Engineer or any other qualified Certifying Engineer, including allowing the same Certifying Engineer to prepare multiple concurrent periodic certifications. In practice, periodic certifications often involve a review of monitoring data for the impoundment over the past 5 years, a site visit, and updated engineering analyses to verify that the impoundment still meets the CCR Rule criteria.

The GISTM requires that a DSR be performed at least every five years for high-consequence facilities and every ten years for all other facilities. The DSR engineer must be different from the EoR, and the same DSR engineer cannot conduct consecutive DSRs at the same facility. Additionally, the DSR engineer must certify their avoidance of conflicts of interest.

Closure planning and design

The CCR Rule contains a detailed closure performance standard in §257.102 including the preparation of a closure plan; requirements to remove liquids from the CCR unit; prescriptive final cover requirements, such as an 18-inch-thick compacted clay low-permeability layer or a geomembrane with an 18-inch-thick protective cover and six inches of topsoil; and requirements for a closure to be completed within five years of initiation unless an extension is prepared. Additionally, as part of the 2024 Legacy Rule updates, §257.102 was revised by USEPA to include a more restrictive performance standard regarding the removal of both impounded free liquids and free liquids contained within the CCR mass, and to clarify that CCR units could no longer be closed where the waste is in contact with groundwater under long-term, post-closure conditions.

The GISTM requires that the closure design be performed under the same requirements as the design of an active facility. Specific information related to the final cover system design or the management of liquids within the tailings facility is not included in the GISTM. However, the GISTM does not preclude closure of a facility in accordance with local regulations that may be more restrictive than the GISTM itself.

Post-closure care

The CCR Rule requires a minimum 30-year post-closure care period for all CCR units (§257.104) that are closed in place. The post-closure care period may extend beyond 30 years if groundwater impacts attributable to the CCR unit remain present. There is no upper limit to how long a CCR unit with groundwater impacts must remain in post-closure care. During post-closure care, the CCR Rule requires that the owner/operator maintain the final cover system and embankments, conduct groundwater monitoring, and maintain any leachate collection systems.

The GISTM divides the closure lifecycle of a tailings facility into “active care closure” and “passive care closure,” also known as “safe closure.” The GISTM does not include any minimum or maximum

durations for post-closure care, presumably due to varying requirements in local regulations. However, the GISTM's "safe closure" concept requires an extensive assessment by the EoR, with review by a Senior Independent Technical Reviewer or ITRB, to demonstrate that the tailings facility no longer poses a risk to the environment or people.

Groundwater monitoring and corrective action

The CCR Rule requires active groundwater monitoring of all CCR surface impoundments that are not in a post-closure care state, per §257.90-94. This includes the design and certification of a groundwater monitoring program by a Certifying Engineer, and the routine collection of groundwater samples for specific constituents with the results posted to a public website. If a statistically significant increase above background levels is noted in one constituent, the CCR Unit must enter an assessment monitoring program (§257.95). Depending on the results of the assessment monitoring, groundwater corrective measures may be performed (§257.96-98).

The GISTM does not include detailed requirements for groundwater monitoring or groundwater corrective action. However, the GISTM does require documentation of the social, economic, and environmental context of the tailings facility (Topic II), as well as environmental monitoring (Principle 7) and implementation of an ESMS to observe the effects of the tailings facility on the environment (Principle 6). It should be noted that many tailings facilities may still have groundwater monitoring and corrective action requirements as part of state regulatory programs.

Legacy sites

CCR Rule

The CCR Rule initially was restricted to apply only to power stations where the coal-fired boiler was active on or after October 15, 2015. For these stations, the CCR Rule only applied to units that contained CCR and liquids on or after this date and were not in a state of being "capped or otherwise maintained (i.e., in a state of post-closure care with no liquids remaining). If the power station was inactive prior to October 15, 2015, all CCR surface impoundments at the station were exempted from regulation. These exemptions resulted in a significant number of impoundments that were not initially regulated by the CCR Rule.

In 2024, USEPA significantly expanded the scope of the CCR Rule by issuing the "Legacy Rule," which rescinded many of these exemptions and expanded the rule to include CCR disposed of outside of CCR units on the power plant site for uses such as structural fill. These legacy CCR surface impoundments and management units will now have to comply with many of the requirements of the 2015 rule, including, but not limited to, design criteria, structural stability, groundwater monitoring, and closure. The first litigation regarding the legacy rule was filed on June 13, 2024 (City Utilities of Springfield, Missouri vs. EPA, No. 24-1200, D.C. Circ.) and additional litigation is expected.

GISTM

The GISTM does not include an exemption for legacy tailings facilities at active mine sites or legacy mine sites. Per the definition of a "tailings facility" in the GISTM, these legacy tailings disposal areas are generally interpreted to still be a tailings facility, are in a state of active-care closure, and are still subject to all the requirements of the GISTM until they are demonstrated to be in a state of "safe closure." The GISTM does not include explicit provisions for an accelerated or more limited safe-closure demonstration for legacy tailings facilities, even though some of these tailings facilities have been closed and/or reclaimed for decades and may have little resemblance to an active tailings facility. However, the GISTM does not explicitly prohibit an accelerated path for safe-closure for these facilities, which can leave these facilities in a grey are.

Conclusion

The GISTM and CCR Rule offer fundamentally different approaches to supporting the safe and environmentally responsible management of otherwise similar types of industrial waste. Some of this difference stems from the CCR Rule being developed via a multi-year agency rulemaking process with thousands of public comments, as required under US law (e.g., compliance), while the GISTM was developed in an accelerated manner outside of a regulatory setting using the input from various industry and external stakeholder groups (e.g., conformance). This section will discuss conclusions regarding the effectiveness of both approaches for failure prevention, key advantages of the GISTM over the CCR Rule, and potential challenges that GISTM implementation may pose relative to the CCR Rule.

Success of the CCR Rule in failure prevention relative to the GISTM

Anecdotally, the mandatory CCR Rule has been highly effective in preventing failures of CCR impoundments in the US. The authors are not aware of any significant releases of CCR from surface impoundments in the US that have occurred since Dan River in 2014, nor of any catastrophic flow-failures that have occurred in the US since Kingston in 2008.

However, it is the authors' opinion that multiple other factors beyond the CCR Rule have contributed to the effective elimination of CCR surface impoundment failures. For example, many CCR unit owners and operators self-implemented strategic CCR management and governance programs after the Kingston and Dan River events. These programs often included performing detailed engineering studies and risk assessments that, in many cases, exceeded the minimum requirements of the CCR Rule. These programs also resulted in the implementation of risk mitigation projects (i.e., buttressing of embankments, spillway improvements, enhanced monitoring and surveillance programs). Many of these programs and mitigation projects were implemented or in the process of implementation prior to the effective date of the

CCR Rule in 2015. Additionally, many unit owners/operators proactively transitioned some of their plants from wet disposal to CCR dewatering with waste storage in regulated landfills, to reduce impoundment-related risks.

Another potential factor in the successful elimination of CCR impoundment failures is the decline in CCR storage volume in the US. Production decreased by nearly 50% between 2008 and 2021, while the percentage of CCR utilized for beneficial use increased from approximately 47% to 67% over the same period (American Coal Ash Association, 2022). This is due to the closure of multiple coal-fired power plants, which also led to an increased demand of CCR for beneficial use applications such as concrete. Many CCR surface impoundments were also dewatered and closed due to either plant closure and/or CCR Rule-related closure triggers. Therefore, the lack of CCR impoundment failures may also be influenced by significant declines in both the volume of new CCR making it into impoundments, as well as the total number of remaining active impoundments.

Conversely, the GISTM is still a relatively new standard, with initial implementation for high-risk facilities completed in August 2023 for ICMM members. Lower-risk facilities are not required to be conformant with the GISTM until August 2025, while non-ICMM members who choose to implement the GISTM are not bound by a formal conformance schedule. While multiple failures of tailings facilities and heap leach pads have occurred since the GISTM was promulgated, such as the Jagersfontein collapse in South Africa and the Williamson failure in Tanzania, the authors are not aware of any failures involving a tailings facility that has successfully implemented the GISTM.

Unlike CCR, both the number and size of active tailings facilities is expected to increase significantly in the future, due to increased demand for metals. Additional time will be required to assess the success of the GISTM in failure prevention and "zero harm," particularly for new and larger tailings facilities that will be constructed in the future. This also may provide a future opportunity to study the incident and/or failure rate of GISTM-conformant tailings facilities compared to those that have are not conformant or have not adopted the GISTM.

Advantages of the GISTM over the CCR Rule

In many ways, the GISTM is a more robust and holistic standard than the CCR Rule, due to the incorporation of concepts that are not part of the CCR Rule. These concepts include, but are not limited to:

- Active community and project-affected people engagement throughout all aspects of the tailings facility lifecycle, including a community grievance mechanism, as opposed to one-way engagement via certification document postings.
- Significant requirements for corporate governance, including the assignment of specific governance roles for all tailings facilities.

- Robust requirements to document minimum qualifications for key tailings related roles, based on site-specific circumstances.
- Requiring the long-term engagement of a single Engineer of Record or Designer of Record to providing ongoing, sustained support for the facility, rather than multiple Certifying Engineers who are not required to be involved in facility operation outside of certification preparation.
- Requirements for multiple layers of overlapping, independent review of work performed by the Engineer of Record, including independent reviewers or review boards and dam safety reviews performed by independent engineers, rather than allowing certifications to be based on the judgment of a single Certifying Engineer.
- Requirements to utilize site-specific risk assessments to drive decision-making, using a multi-disciplinary team, and requirements that the design of the facilities consider the risk assessments.
- Including the concept of minimizing risk to "as low as reasonably practicable" for all known failure modes.
- Allowance for significant differences in the design of tailings facilities (i.e., minimum safety factors, design freeboard, analysis methods) based on local and regional practices and the overall risks posed by the tailings facility.
- Providing an intensive process for terminating post-closure care, including a demonstration with independent review that the tailings facility no longer a risk to people or the environment, as opposed to maintenance over a defined period and reliance on groundwater monitoring results.
- Wording requirements in a manner that is sufficiently flexible to accommodate site-specific considerations based on local regulatory practices, as opposed to requiring detailed interpretation of a Federal regulation, which may be subjected to ongoing litigation and changes in interpretation (i.e., Utility Solid Waste Activities Group vs. EPA. No. 15-1219, D.C. Circ. June 14, 2016).

Potential challenges of the GISTM relative to the CCR Rule

There are several aspects of the GISTM that may prove challenging during continued adoption and conformance activities, based on observations by the authors in supporting CCR Rule compliance activities. These aspects include, but are not limited to:

- For non-ICMM members, the GISTM is a voluntary standard. While many non-ICMM members have chosen to implement the GISTM, others may forego implementation. Therefore, the ability of the GISTM to achieve "zero harm" caused by tailings facilities may always be limited by the number of tailings facility owners and operators who choose to implement the standard.

- The GISTM is primarily focused on preventing catastrophic failures of tailings facilities through corporate governance and multiple layers of review. The GISTM includes more limited requirements to address other environmental impacts caused by tailings facilities, such as fugitive dust emissions, groundwater impacts, and surface water discharge impacts. While these impacts are mentioned within the GISTM (via the requirements for Impact Assessments, maintaining a knowledge base, and TMS and ESMS programs), they are generally non-specific and overshadowed by the focus failure prevention requirements. Based on the experience of the authors with the CCR Rule, public and regulatory attention may shift away from catastrophic failure prevention and towards long-term environmental impacts near the end-of-life for tailings facilities, particularly during the transition to closure. This may lead to the potential for future public, regulatory, and corresponding cost uncertainties related to long-term environmental remediation, particularly if closure-related regulations become more stringent.
    - This has occurred for CCR surface impoundments, as 2024 updates to the CCR Rule by USEPA have effectively prohibited surface impoundments to be closed in a manner where the CCR will remain in contact with groundwater under post-closure conditions, regardless of known or predicted future impacts to groundwater, human health, and ecological health.
    - Additionally, many environmental groups and/or NGOs publicly advocate for the closure of essentially all CCR surface impoundments by excavating all CCR from the impoundments and placing it regulated landfills (e.g., closure-by-removal), for the perceived benefit of reducing groundwater impacts. This type of closure method can have a very high cost and can be disruptive to local areas due to the required construction disturbance and/or hauling of material on adjacent roadways.
- With the GISTM being a flexible and self-implementing standard, much like the pre-WIIN CCR Rule was, there is the potential for significantly different interpretation of its requirements among tailings facility owners. While the GISTM will undoubtedly result in more consistent and robust tailings management practices, interpretation differences may cause challenges for EoR/DoR firms working for multiple tailings facility owners, as well as third-party stakeholders reviewing tailings disclosures. This may also cause challenges for future 3rd party audits of GISTM conformance, as auditors may have different opinions than facility owner/operators and their EoRs, with both opinions being valid interpretations of the GISTM.
- The current lack in a formalized 3rd-party audit program may also prove challenging, as future auditors may encounter significantly different tailings management and GISTM conformance

practices for different facilities and owner/operators, several years after those owner/operators have started GISTM conformance activities.

- Addressing legacy sites will continue to be a challenge for the GISTM. With the CCR Rule, legacy facilities were initially unregulated for nearly 9 years, which allowed the industry significant time to focus resources on active CCR surface impoundments, which typically have a higher risk profile. However, legacy tailings facilities, which like legacy CCR facilities typically, but not always, have a lower risk profile, are not exempted by GISTM, nor is conformance on a different schedule than active facilities. The GISTM also lacks an explicit, accelerated "safe closure" pathway for these facilities. Bringing these legacy facilities into GISTM conformance, prior to completing a safe closure demonstration, may be a substantial effort and may divert key engineering and financial resources away from often higher-risk, active tailings facilities.
    - The CCR industry is currently undergoing a similar challenge due to the 2024 Legacy Rule, which is inducing a chronic shortage in CCR engineering and environmental resources.
    - One potential way to address this for tailings impoundments would be to revise the GISTM to include an explicit accelerated safe closure demonstration mechanism for low-risk legacy impoundments that have been inactive or reclaimed for years, pose little risk to people or the environment, and in many cases may no longer visually resemble a tailings facility.
- Currently the authors are not aware of significant efforts at the Federal level in the US to regulate tailings facilities in a manner like the CCR Rule. However, in the event of new country-wide regulations, whether in the US or another country where tailings are not regulated at the federal level, challenges may occur for tailings facility owners to conform with the GISTM requirements, country-wide regulatory requirements, and local regulatory requirements. This may cause different types of assessments, certifications, and documents to be prepared and posted to disclosure websites or provided to regulatory agencies. This is currently occurring in some states in the US who have developed state-specific CCR regulatory programs that are not yet approved by USEPA, such as Illinois, which can result in burdens for the regulated entities.

Conclusion

It is the intent of the authors to highlight the relative advantages and corresponding challenges of a voluntary, stakeholder-developed standard like the GISTM over a mandatory regulatory approach such as the CCR Rule for achieving the safe and environmentally responsible management of industrial waste storage facilities. The authors are not advocating for the voluntary adoption of the GISTM for CCR unit

owner/operators. The authors would consider such an approach to be duplicative and potentially unnecessary, due to the nearly 10 years of successful failure prevention and risk management achieved by the CCR Rule. The authors hope that this paper is helpful for tailings practitioners and facility owners/operations in realizing the importance of GISTM implementation to achieve successful failure prevention, social responsibility, and environmental responsibility in a voluntary manner, as well as some of the challenges they may encounter while implementing a conformance-based program.

A Screening Approach for Preliminary ALARP Assessments of Societal Risks of Existing Tailings Dams

Chao Han, Red Earth Engineering – A Geosyntec Company, Australia
Wade Ludlow, Red Earth Engineering – A Geosyntec Company, Australia

Abstract

The ALARP (As Low as Reasonably Practicable) principle has recently been applied to tailings dams via the Global Industry Standard for Tailings Management (GISTM, 2020) and is used to inform risk reduction to a level that is tolerable and justified by the benefits. ALARP assessment involves risk identification, assessment, and evaluating the risk reduction measures. ALARP assessment considers the existing risks and the risk reduction measures, and determines whether the risks are tolerable, provided that they are reduced to the lowest level that is reasonably practicable and can be justified by the benefits. ALARP assessment is a complex and subjective process that requires the involvement and acceptance of various stakeholders, such as regulators, operators, communities, and investors. Currently, the authors consider that there is a lack of consensus on how to conduct ALARP assessment for tailings dams, especially for the societal risks that affect the public safety and welfare.

This paper discusses the approaches for ALARP assessment of tailing dams outlined in various standards and guidelines and proposes a screening-level approach for the ALARP assessment of the societal risks of existing dams, based on the cost benefit analysis method in ANCOLD (Australian National Committee on Large Dams) guidelines. The key parameters, assumptions, methodology, and results for the proposed approach are presented, along with a flow chart that illustrates the main steps and decision points. The paper also highlights the key threshold features beyond which a more comprehensive ALARP assessment among wider stakeholders is warranted and demonstrates the application of the proposed approach via an example. The authors also discuss some of the shortcomings of the current ALARP assessments used for tailings dams and some proposed improvements.

The proposed approach can provide a useful tool for a high-level screening of the necessity and feasibility of risk reduction measures and can support the decision-making process for achieving ALARP outcomes.

Introduction

ALARP stands for As Low as Reasonably Practicable, which is a principle that guides the management of risks in various industries, such as mining, oil and gas, nuclear, and civil engineering. According to this principle, risks should be reduced to a level that is acceptable to society and the regulator, taking into account the costs and benefits of risk reduction measures. ALARP assessment is a process of evaluating the existing and residual risks of a system or an activity and demonstrating that they are tolerable, and that further risk reduction is either impractical or disproportionate to the improvement gained.

The ALARP principles have historically been used for water dam safety related decision making and have recently been adopted for tailings dams via requirements set out in the Global Industry Standard on Tailings Management (GISTM, 2020). However, there is no universally accepted framework or methodology for conducting and documenting ALARP assessments. Different countries and organizations have adopted different approaches, criteria, and terminology for defining and demonstrating ALARP, which may lead to inconsistencies and ambiguities in the evaluation and communication of risks.

The International Commission on Large Dams Bulletin 189 (ICOLD, 2020) has documented the responses submitted by national committee members to a survey conducted in 2019. The survey contained a range of questions regarding legal, regulatory, and enforcement arrangements, as well as general considerations and risk analysis, evaluation, management and communication. The questions most relevant to risk evaluation and ALARP principles are extracted below, with the responses summarized in Table 1.

Q 4.5: What are the criteria or guidelines for risk tolerability/acceptability used to address societal concerns?

Q 4.11: Is the principle of As Low as Reasonably Practicable (ALARP) applied and if it is, what is the legal context within which it is applied and how it is used in demonstrating the tolerability of risk?

Table 1: Survey results summary based on ICOLD (2020)

Country	References	Q 4.5 Societal Risk Tolerability		Q 4.11 ALARP Demonstration
		Individual	Cumulative	
Argentina	Program underdevelopment	Not specified	Not specified	Not applied
Australia	ANCOLD (2003)	1×10^{-4} (existing); 1×10^{-5} (new)	Limit of tolerability	Good practice + cost-effectiveness
Canada	No criteria	Not specified	Not specified	Not applied
Czech Republic	No criteria	Not specified	Not specified	Not applied
France	No criteria	Not specified	Not specified	Limited use
Italy	No criteria	Not specified	Not specified	Not applied

Country	References	Q 4.5 Societal Risk Tolerability		Q 4.11 ALARP Demonstration
		Individual	Cumulative	
The Netherlands	Not specified	Not specified	Not specified	Not applied
USA	FERC (2016)	1 x 10^{-4}	Tolerable risk reference line	Good practice + cost-effectiveness
	USACE (2014)	1 x 10^{-4}	Societal risk limit line	Good practice + cost-effectiveness
	USBR (2019)	1 x 10^{-4}	Expected annualized life loss of 1E-3 per facility	Not specified

It is clearly demonstrated that concepts of ALARP principles are not equally familiar to the survey participants around the world. That is, respondents answered that ALARP Demonstration is not applied in Argentina, Canada, Czech Republic, France, Italy and the Netherlands, while the survey indicated it is applied as good practice in Australia and the USA. The ICOLD survey was largely based on water dams, so the ALARP concept is even less apparent in the tailings dam industry.

The GISTM (2020) and Tailings Management *Good Practice Guide* (2021) created by the International Council on Mining and Metals (ICMM) require that the operators of tailing dams follow a risk-based approach to manage the risks of their facilities to ALARP, and that they apply the best available technology and the best available practices to prevent and minimize the potential impacts of the failure. However, they do not provide specific guidance on how to conduct ALARP assessment for tailing dams; instead, they recommend that the operators follow the existing regulations or guidelines that are applicable to their jurisdictions to conduct ALARP assessment and demonstrate the acceptability of their risks.

The ANCOLD Tailings Guidelines (2020) reference ANCOLD (2003) for risk assessment of higher and extreme consequence dams to quantify the risk tolerability of specific elements or features of a tailings dam, such as spillway capacity. However, no guidance has been provided for the overall risks of tailings facilities. ANCOLD (2003) was recently revised in ANCOLD (2022).

This paper presents a simplified screening approach based on ANCOLD (2022) methodology to facilitate the ALARP demonstration process for the societal risks of existing tailings facilities.

Methodology

ANCOLD method

ANCOLD (2022) acknowledges that risk evaluation is a matter for dam owners, who need to ensure that the risks meet, or are lower than, any legal requirements and relevant guiding criteria, and that dam owners need to be aware that they may have a legal duty to reduce risks to ALARP under both statute and common

law. The criteria relevant to community, public safety, and workers' risks are highlighted below:

- For existing dams, an individual risk to the person who is most at risk that is higher than 10^{-4} per annum is unacceptable, except in exceptional circumstances. This limit has considered the background risk to the population, which varies with age, as shown in Figure 1, based on data from the Australian Government Actuary, 2017. The limit value of 10^{-4} is slightly higher than two times the minimum average background risk for females aged 12.
- For existing and new dams, a societal risk that is higher than the limit line, shown in Figure 2, is unacceptable, except in exceptional circumstances. The anchor point (i.e., F value of 10^{-3} at N=l) and the slope of the line (i.e., a slope of -1.0 for equal log scales on both axes representative of a risk neutral position) that define the F-N criterion line have been chosen by review of societal risk criteria by Ball and Floyd (1998). The concept of a vertical truncation adopted by other authorities is not considered practical or appropriate and hence is not included in Figure 2.
- The concept of "broadly acceptable" level of risk that was used historically has been abandoned by ANCOLD, which instead provides that ALARP should be applied indefinitely below the limit of tolerability as the primary basis for determining the tolerable risk in a particular case.
- The above guidelines on the tolerability of public safety risk were also put forward for the risks to workers at the dam and at integral workplaces below the dam.

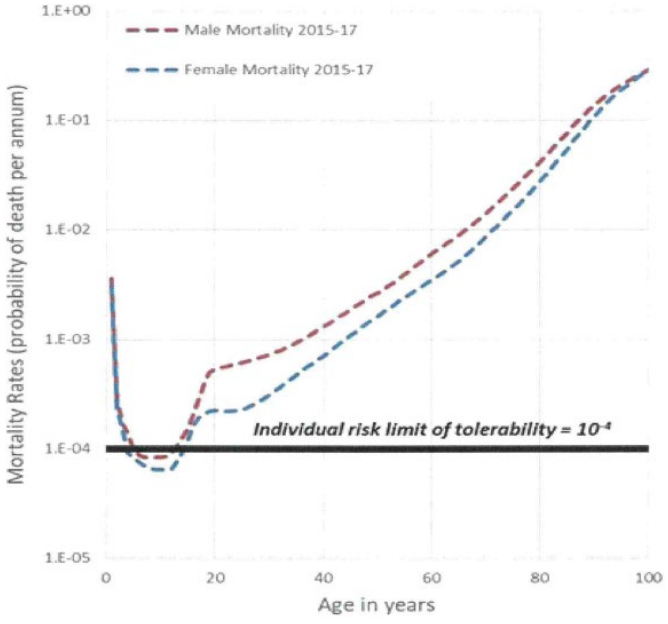

Figure 1: Average background risk (Australian Government Actuary, 2017) and ANCOLD (2022) Individual Risk Guidelines

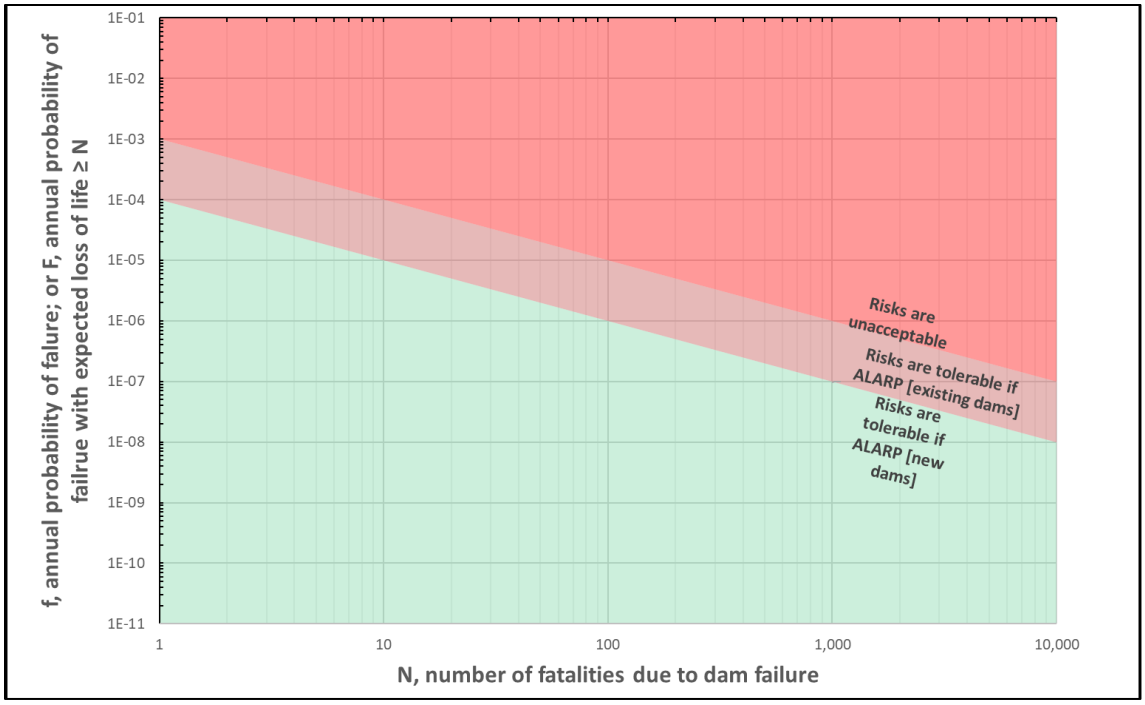

Figure 2: ANCOLD (2022) societal risk guideline

ANCOLD (2022) stipulates that if risks are above the tolerable limits for individual and societal risks, then necessary risk reduction methods are required, regardless of any cost considerations. If the risks are below the tolerable limits, then a demonstration for ALARP can be undertaken. C11-7-4 summarizes the steps required to demonstrate ALARP, which includes the assessment of the dam and its components for compliance with current standards-based good practice, and subsequent determination of a justification rating of cost-to-save-a-statistical-life (CSSL) for those measures that can practicably be implemented. Compliance with current standards-based good practice can be assessed through conventional engineering approaches, which is excluded from the current paper topics. The calculation of adjusted CSSL can be undertaken using Equation 1:

$$CSSL(A) = \frac{(C_A\text{-}(E[R{:}e]\text{-}E[R{:}pr])\text{-}([O{:}e]\text{-}[O{:}pr])\text{-}F_D(E[S{:}e]\text{-}E[S{:}pr])}{(E[L{:}e]\text{-}E[L{:}pr])} \quad \text{(Equation 1)}$$

Where:

- *CSSL(A)*: Adjusted cost-to-save-a-statistical-life, with the provision that a negative value is taken as zero.
- C_A: Annualized cost of implementing risk reduction measure, dollars per annum.
- *E[R:e]*: Expected value of economic and financial consequences of dam failure (failure probability times monetary losses) for the existing dam, dollars per annum.

- *E[R:pr]*: Expected value of economic and financial consequences of dam failure (failure probability times monetary losses) post-risk reduction, dollars per annum.
- *E[L:e]*: Expected value of life loss for existing dam, lives per annum.
- *E[L:pr]*: Expected value of life loss post-risk reduction, lives per annum.
- *O:e*: Existing operating costs, dollars per annum.
- *O:pr*: Operating costs post-risk reduction, dollars per annum.
- F_D: Disproportion factor, dimensionless. Table 8.6 of ANCOLD (2022) provides guidance on F_D values for maximum potential loss of N ranging from 0 to 10, and suggests that for N greater than 10, the N = 10 values apply.
- *E[S:e]*: Expected value of the costs of safety benefits for the existing dam, dollars per annum. Benefits can include avoidance of deployment of emergency services and avoidance of countermeasures such as evacuation and post-accident decontamination.
- *E[S:pr]*: Expected value of safety benefits post-risk reduction, dollars per annum.

The justification rating of CSSL can be determined using Table 2, where:

- VPF: Value in preventing a facility, $AU7.7 million by end of September 2021 quarter, based on a 50% increase on the Office of Best Practice Regulation (OBPR, 2021) value of $AU5.1 million, which is considered a defensible adjustment by Abelson (2007). According to the Reserve Bank of Australia (RBA) Inflation Calculator (2024), the equivalent VFP by end of March 2024 quarter is $AU8.8 million.
- A "Poor" Justification Rating indicates the corresponding risk reduction cost can be shown to be grossly disproportionate.

Table 2: Demonstration of gross disproportion (modified from ANCOLD, 2022)

Justification Rating	Range of CSSL ($AU/Life)	
	Greater than or equal to	Less than
Very Strong	0	0.05 x F_D x VPF
Strong	0.05 x F_D x VPF	0.2 x F_D x VPF
Moderate	0.2 x F_D x VPF	F_D x VPF
Poor	F_D x VPF	–

Analysis details

A series of cost-effectiveness analyses have been carried out using the ANCOLD methodology outlined above to inform the practicality of demonstrating ALARP for societal risks of hypothetical existing dams

based on the Justification Rating in Table 2. These analyses are subsequently used to develop a proposed screening approach to assess the necessity and feasibility of risk reduction measures. To facilitate the simplified approach, the following assumptions have been incorporated into the analyses:

- E[S:e] - E[S:pr] ≈ 0, indicating the net safety benefits between the existing and post-risk reduction scenarios are negligible, compared to the cost of implementing risk reduction measures.
- [O:e] - [O:pr] ≈ 0, indicating the same operating costs between the existing and post-risk reduction scenarios.
- A range of assumed existing risks are tabulated in Table 3, which represent zero to three orders of magnitude (OoM) lower than the limit of tolerability of 10^{-3} lives per annum. For each scenario the post-risk reduction societal risks are assumed to have a failure probability of one to three orders of magnitude lower than the existing risks, without any changes to the failure consequence. An illustration of Risk ID 3 with a two order-of-magnitude reduction is shown in Figure 3.
- A range of assigned monetary losses due to dam failure are summarized in Table 4, which represent the possible combination of the ANCOLD (2020) failure impact severity level and the potential life loss (PLL, equivalent maximum N in Table 3) in the consequence category assessment. The monetary loss values have been assigned to be ten times higher than the lower bound of infrastructure damage cost for the corresponding severity level. The impact durations have been assigned to be the lower bound of the corresponding severity level, so that a reasonably high annual monetary loss can be calculated using the Capital Recovery Method in Equation 2, where the discount rate is assumed to be 7%.

$$Annualised\ Monetary\ Loss = Monetary\ Loss \times \frac{Discount\ Rate}{1-(1+Discount\ Rate)^{-Impact\ Duration}} \quad \text{(Equation 2)}$$

Table 3: Assumed existing risk scenarios

Risk ID	Order of Magnitude below Limit of Tolerability	Maximum number of fatalities, N	Existing Risk	
			Probability of Failure	Expected Life Loss, E[L:e]
			–	(Lives per annum)
1	1	1	5.0E-04	5.0E-04
2	1	10	5.0E-04	9.5E-04
3	1	100	5.0E-04	1.4E-03
4	2	1	5.0E-05	5.0E-05
5	2	10	5.0E-05	9.5E-05
6	2	100	5.0E-05	1.4E-04

Risk ID	Order of Magnitude below Limit of Tolerability	Maximum number of fatalities, N	Existing Risk	
			Probability of Failure	Expected Life Loss, E[L:e]
			–	(Lives per annum)
7	3	1	5.0E-06	5.0E-06
8	3	10	5.0E-06	9.5E-06
9	3	100	5.0E-06	1.4E-05

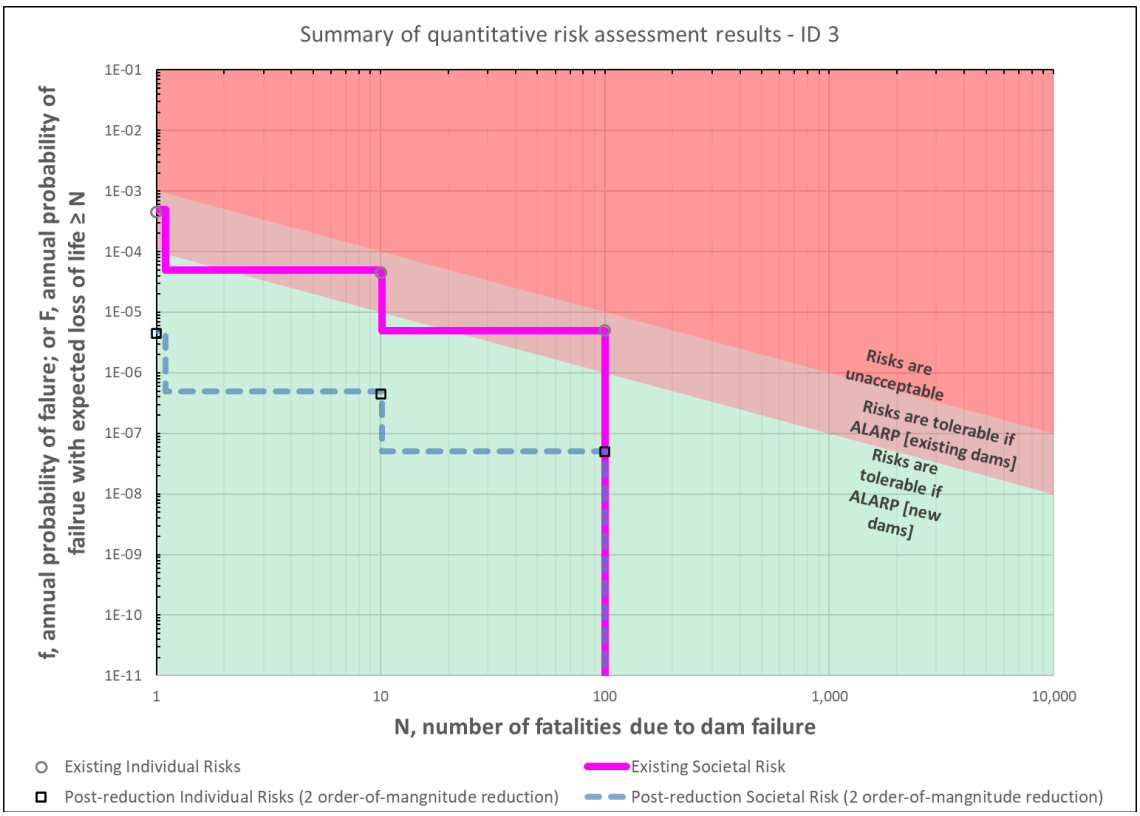

Figure 3: Illustration of existing risk ID 3 and two order-of-magnitude reduction

Table 2: Assigned severity levels

Failure Impact Severity Level	Monetary Loss ($AU)	Impact Duration (year)	Capital Recovery Factor at 7% Discount Rate	Monetary Loss per Annum ($AU)
Medium	$100,000,000	1	1.07000	$107,000,000
Major	$1,000,000,000	5	0.24389	$243,890,694
Catastrophic	$10,000,000,000	20	0.09439	$943,929,257

Based on the above assumptions, the threshold value of C_A to define gross disproportion in Table 2 can be calculated by rearranging Equation 1 and adopting CSSL = F_D × VPF, where VPF = is $AU8.8

million by the end of the March 2024 quarter. The calculations were undertaken in spreadsheets with all possible combinations of the input parameters tabulated in a table. It is worth reiterating that for this assessment it is assumed that the N value (loss of life) is not reduced as part of the risk reduction measure.

Results and discussions

A total of 81 scenarios were calculated, and the threshold value of C_A are shown in Figure 4. Based on the authors' experience with tailings facilities, it is generally difficult to identify any effective risk reduction measures with a cost less than $AU100,000 per annum, reflected by the red dashed line in Figure 4. The results have led to the following observations:

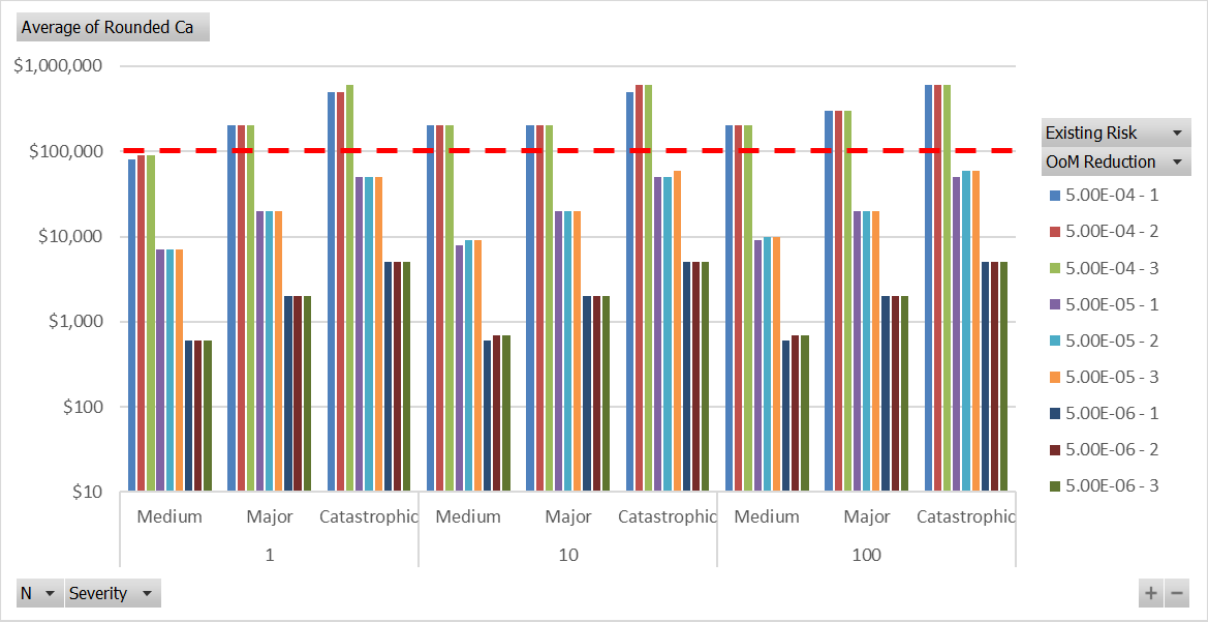

Figure 4: Analysis result summary

- The effectiveness of risk reduction methods represented by the OoM risk reduction has limited impact on the threshold value of C_A, compared to other input parameters such as existing risks and failure consequences.
- The calculated threshold value of C_A increases with severity level and decreases with reduced existing risk. The sensitivity to maximum N is less pronounced given a certain combination of existing risks and severity level. Therefore, the dominant factor in determining the threshold value of C_A is the product of severity level and existing risk.
- The results indicate that for tailings facilities with an existing societal risk in the range of 10^{-4} to 10^{-3} lives per annum, it is likely that there exist risk reduction measures with very strong to

moderate justification ratings, unless the potential dam failure would result in medium severity consequence and no more than a single fatality.

- It is also suggested that for tailings facilities with an existing societal risk lower than 10^{-4} lives per annum, it is most likely that any risk reduction measures would have a poor justification rating (i.e., would be defined as grossly disproportionate).

For tailings facilities at which the impact severity level is governed by the combined effect of infrastructure cost and impact duration, their consequence categories can be determined from Table 5. Therefore, the equivalent consequence category assessed in this study ranges from High C to Extreme. The above discussed results indicate:

- For High C or lower consequence category dams, they could be considered to meet ALARP if their existing risks are lower than the limit of tolerability.
- For High B or higher consequence category dams, they could be considered to meet ALARP if their existing risks are more than two orders of magnitude lower than the limit of tolerability.
- ALARP demonstration with cost-effectiveness considerations is expected for High B or higher consequence category dams with existing risks less than two orders of magnitude lower than the limit of tolerability.
- The above points are interesting outcomes of the assessment; however, each facility may have other risks, issues, or constraints that may require additional consideration or review.

Table 5: ANCOLD (2012) Consequence Category Table based on PLL

Potential Loss of Life (PLL)	Severity of Damage and Loss			
	Minor	Medium	Major	Catastrophic
<0.1	Very Low	Low	Significant	High C
≥0.1 to <1	Significant	Significant	High C	High B
≥1 to <5	*(Note 1)*	High C	High B	High A
≥5 to <50		High A *(Note 2)*	High A	Extreme
≥50		*(Note 1)*	Extreme	Extreme

Note 1: *With a PLL equal to or greater than one (1), it is unlikely Damage will be minor. Similarly with a PLL in excess of 50 it is unlikely Damage will be classified as Medium.*
Note 2: *Where PLL is in the range ≥5 to<10, the Category level can be reduced to* ***High B.***

Proposed screening approach

Based on the above results, a simplified screening approach is developed, as shown in Figure 5. Due to the assumptions incorporated into the analyses, the proposed approach should only be used for the following scenarios:

- The differences in safety benefits between existing and post-risk reduction scenarios should be negligible.
- The differences in operational costs between existing and post-risk reduction scenarios should be negligible.
- The risk reduction measures should focus on reducing failure probability with a minimal change to failure consequences.

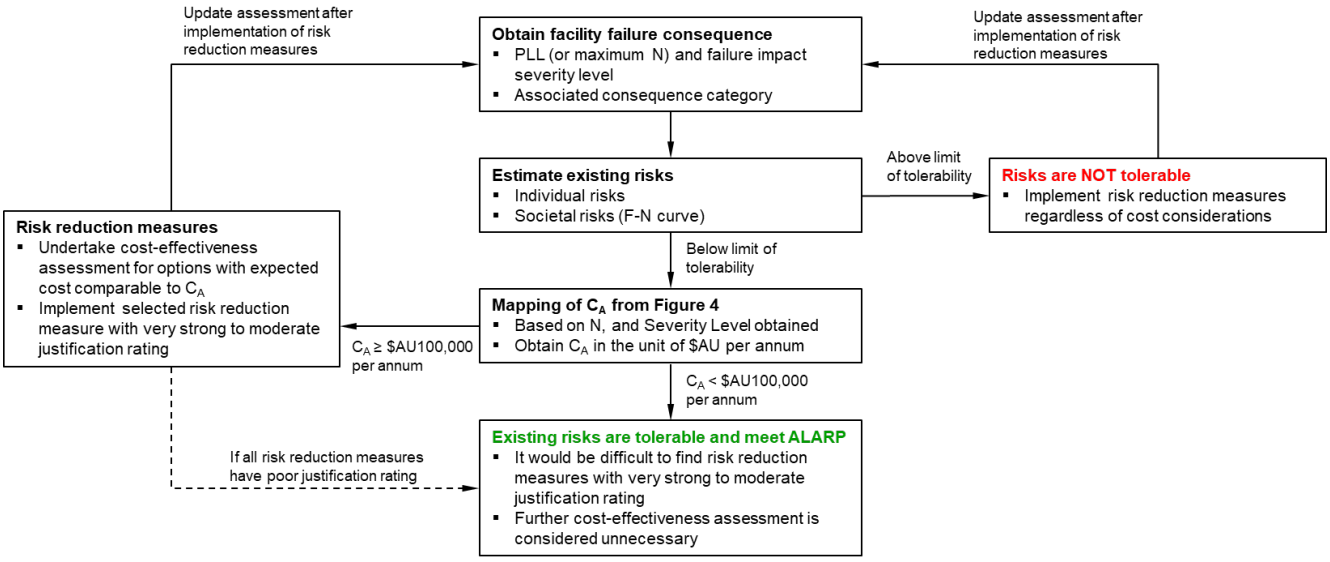

Figure 1: Proposed ALARP screening approach

Application example

A hypothetical mining company has a number of tailings facilities, with the risk profiles summarized in Table 6. Forming part of the GISTM compliance requirements, the company's appointed Accountable Executive is required to endorse the documentation stating the ALARP status of their tailings facilities. As a starting point, the company needs to decide which facilities have intolerable risks that require further risk reduction measures regardless of cost; which facilities can be considered to meet ALARP with a high confidence level; and which facilities require additional resource allocations to demonstrate ALARP with more detailed cost-effective assessments.

The company decided to use the proposed screening approach, and the results shown in Table 7 demonstrate that the existing risks for Facilities 2 and 3 are likely to meet ALARP. For Facility 1, ALARP

is unlikely to be achieved with the existing risks and the risk reduction Option B is preferred, with a detailed cost benefit analysis recommended to support this option.

Table 6: Summary of application example

Facility ID	Consequence Category	Existing Societal Risks		Risk Reduction Options	ALARP Demonstration Required based on Screening?
		Risk Rating	Max. N		
1	Extreme	10^{-4}	10	A. Buttress C_A of at least \$1 million per annum B. Improve Monitoring System C_A below \$100,000 per annum	A. Screening suggests option is unlikely to be cost-effective B. Screening suggests ALARP needs to be demonstrated
2	High B	10^{-5}	1	Buttress C_A of at least \$1 million per annum	Screening suggests already ALARP
3	Significant	10^{-4}	<1	Larger pumps to control water (C_A of at least \$1 million per annum)	Screening suggests already ALARP

ALARP limitations

While the authors have found ALARP to be a fairly rigorous review of risk ratings and a good tool to communicate the benefit of risk reduction options, it is limited to Potential Loss of Life. It does not account for environmental, cultural heritage risks, reputational, and other similar risks. A number of approaches are available to attempt an ALARP assessment as follows.

One option is to review the current and residual risks and look at the reduction on the risk matrix. This goes some way towards showing the reduction of risk and gives an indication of an ALARP condition, and can be used for environmental, cultural heritage, and business reputation risks that cannot be quantified on an F-N plot. An example is shown in Figure 6 using the AS/NZS 4360: 2004 Risk Management Guidelines, in which the ALARP boundary should be defined by the dam owners based on the individual company's risk appetite. This is an area that requires further development so that ALARP conditions can be demonstrated for risks other than loss of life.

Level	Criteria	Description
1	Rare	Almost never happened
2	Unlikely	Rarely happening
3	Possible	Can happen every once in a while
4	Likely	Often occur
5	Almost Certain	Can happen any time

Source: Likelihood criteria adopted from standard AS/NZS 4360: 2004.

Level	Criteria	Description
1	Insignificant	No injury and/or no disease caused and/or no effect on the environment, small financial loss
2	Minor	Minor injury and/or illness with mild symptoms and/or small effect on the environment, small financial loss
3	Moderate	Moderate injury and/or chronic illness requires medical treatment and/or moderate effect on the environment, sizeable financial loss
4	Major	Serious injury and/or chronic illness require medical treatment and/or serious and long-term environmental damage, big loss, production disruption
5	Catastrophic	Fatal and/or chronic diseases require serious medical treatment and/or very serious and long-term environmental damage, huge losses and very broad impacts, cessation of all activities

Source: Severity criteria adopted from standard AS/NZS 4360: 2004.

Likelihood	Severity				
	Insignificant (1)	Minor (2)	Moderate (3)	Major (4)	Catastrophic (5)
Almost Certain (5)	M	H	VH	VH	VH
Likely (4)	L	M	H	VH	VH
Possible (3)	L	M	H	VH	VH
Unlikely (2)	L	L	M	H	VH
Rare (1)	L	L	M	H	H

ALARP

R1 R2 R3

Source: Risk assessment matrix adopted from AS/NZS 4360: 2004 standard.

Figure 6: Example of ALARP approach to environmental risks

Another option would be to assume a monetary loss commensurate with the environmental risk assessed. Based on the severity level for a dam failure in ANCOLD (2020) in Figure 7, a medium risk environmental consequence could be assumed to have a similar dollar value consequence in the table ($10M to $100M) and the practitioner would select a suitable value within this range for the cost benefit assessment.

Both of the above methods need further development, but as GISTM requirements become more widespread and further experience is gained, it will be necessary to demonstrate ALARP for all major risks including potential loss of life, environmental, cultural heritage, etc.

DAMAGE TYPE	MINOR	MEDIUM	MAJOR	CATASTROPHIC
Infrastructure (dam, houses, commerce, farms, community)	<$10M	$10M-$100M	$100M-$1B	>$1B
Business importance	Some restrictions	Significant impacts	Severe to crippling	Business dissolution, bankruptcy
Public health	<100 people affected	100-1000 people affected	<1000 people affected for more than one month	>10,000 people affected for over one year
Social dislocation	<100 person or <20 business months	100-1000 person months or 20-2000 business months	>1000 person months or >200 business months	>10,000 person months or numerous business failures
Impact Area	<1km²	<5km²	<20km²	>20km²
Impact Duration	<1 year	<5 years	<20 years	>20 years
Impact on natural environment	Damage limited to items of low conservation value (e.g. degraded or cleared land, ephemeral streams, non-endangered flora and fauna). Remediation possible.	Significant effects on rural land and local flora & fauna. Limited effects on: A. Item(s) of local & state natural heritage. B. Native flora and fauna within forestry, aquatic and conservation reserves, or recognised habitat corridors, wetlands or fish breeding areas.	Extensive rural effects. Significant effects on river system and areas A & B. Limited effects on: C. Item(s) of National or World natural heritage. D. Native flora and fauna within national parks, recognised wilderness areas, RAMSAR wetlands and nationally protected aquatic reserves. Remediation difficult	Extensively affects areas A & B. Significantly affects areas C & D. Remediation involves significantly altered ecosystems.

Figure 7: Example of assigning dollar values based on environmental impacts (ANCOLD, 2020)

Conclusion

This paper reviews relevant standards and guidelines that recommend ALARP assessment of tailings dams and suggests a screening-level approach for ALARP assessment of the societal risks for existing tailings dams, based on the cost benefit analysis method in ANCOLD guidelines. The paper presents the main

parameters, methodology, assumptions, and supporting results for the suggested approach, supported with a flow chart that shows the main steps and decision points. The paper also shows the key threshold features that require a more detailed ALARP assessment among wider stakeholders and applies the proposed approach to the risk evaluation of hypothetical tailing dams via an example. The shortcomings of the current ALARP assessments used for tailings dams such as environmental, cultural heritage, and business reputation risks are also discussed, and the proposed improvement options are suggested.

The suggested approach can help identify the existing tailings facilities that meet ALARP with the existing risks, since it would be difficult to find risk reduction measures with strong to moderate justification ratings. For the facilities that do not meet ALARP with the existing risk, this approach can help screen for the need for and feasibility of risk reduction measures for subsequent detailed ALARP demonstration.

Integrating Geometric Deposition and Hydrological Water Balance in Tailings Management: a Semi-Probabilistic Approach

Paulo Victor S.A. De Castro, GeoMerry, Brazil
Miguel Palape, Minebridge, Chile
Roberto Cezar Rego Silva, WSP, Brazil
João Marcus S.A. De Castro, GeoMerry, Brazil

Abstract

This paper introduces an innovative approach to tailings disposal, merging geometric deposition techniques with hydrological water balance within a semi-probabilistic framework. The primary tools employed in this methodology are Muk3D for geometric deposition and GoldSim for hydrological water balance. The process is dynamic and iterative, effectively tracking tailings from their source to the pond, identifying deposition points, and establishing the tailings surface. This methodology significantly enhances accuracy in estimating volumes of tailings and lakes, ensuring that errors stay within predetermined permissible error margins for both tailings and pond volumes.

The dynamic nature of the model facilitates automated dam raising, treated as discrete events, thereby ensuring immediate updates to reservoir geometry. This is accomplished through a Python-based programming environment, which boosts efficiency and facilitates independent processing. By incorporating semi-probabilistic techniques and selecting a cumulative probability volume, this method not only improves long-term decision-making, but also addresses uncertainties inherent in tailings management effectively.

The implementation of this integrated strategy offers valuable insights into efficient tailings management and robust risk assessment. It represents a potential paradigm shift in industry standards, providing a comprehensive and advanced approach to overcoming the challenges faced in the mining industry. The findings from this study are expected to make a significant contribution to the field of tailings management, setting a new benchmark for future practices.

Introduction

The management of tailings in the mining industry is a complex and evolving challenge, demanding

innovative approaches to ensure environmental safety and operational efficiency. This paper introduces a novel methodology for tailings disposal, combining geometric deposition techniques with hydrological water balance within a semi-probabilistic framework. The primary tools employed in this methodology are Muk3D for geometric deposition and GoldSim for hydrological water balance, integrated within a dynamic and iterative process that tracks tailings from their source to the pond, identifies deposition points, and establishes the tailings surface. This approach significantly enhances the accuracy of volume estimations for both tailings and lakes, maintaining errors within predefined permissible margins.

The dynamic model facilitates automated dam raising, treated as discrete events, ensuring immediate updates to reservoir geometry. This process is executed within a Python-based programming environment, enhancing efficiency and allowing for independent processing. By incorporating semi-probabilistic techniques and selecting a cumulative probability volume, the methodology not only improves long-term decision-making but also effectively addresses the uncertainties inherent in tailings management. Oboni and Oboni (2020) highlight the significance of innovative approaches in tailings management, emphasizing the need for accurate and reliable methods to mitigate environmental impacts and enhance operational efficiency.

In the numerical simulation of reservoir filling, this paper proposes the use of Muk3D software. The model applied in Muk3D for simulating tailings disposal follows an iterative process of geometric approximation between the lake volumes and the tailings to be disposed of in the reservoir. To ensure the final configuration is physically consistent, the geometric approximation adheres to the following constraints:

- beach angles of the tailings;
- positioning of spigots as the highest point of the tailings surface;
- location of the lake; and
- maximum elevation of the lake.

Consequently, the tailings surfaces are defined by the beach angles and the spigot positions, with the beach angle varying when in contact with the horizontal lake surface. The iterative process ensures the dynamic interaction between tailings and lake surfaces is accurately modeled.

The implementation of this integrated strategy offers valuable insights into efficient tailings management and robust risk assessment. It represents a potential paradigm shift in industry standards, providing a comprehensive and advanced approach to overcoming the challenges faced in the mining industry. The findings from this study are expected to make a significant contribution to the field of tailings management, setting a new benchmark for future practices.

Methodology

For the numerical simulation of reservoir filling, Muk3D software was utilized. The model employed in Muk3D for tailings disposal simulation involves an iterative process of geometric approximation between the lake volumes and the tailings to be disposed of in the reservoir. To ensure the final configuration is physically consistent, the geometric approximation adheres to the following constraints:

- beach angles of the tailings: the lake's interaction area affects the subaqueous and subaerial angles. Because of the particle deposition pace along the tailings beach, a bigger lake area in a reservoir results in a different angle shift (from subaerial to subaqueous) than a smaller lake;
- positioning of spigots as the highest point of the tailings surface;
- location of the lake; and
- maximum elevation of the lake.

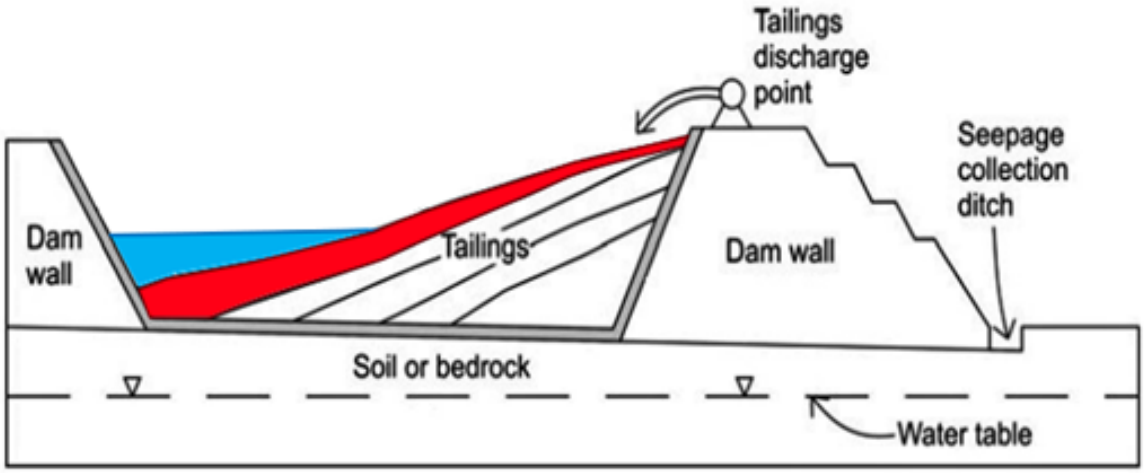

Figure 1: General view of a tailings deposition plan

The diagram in Figure 2 illustrates the automated model workflow, integrating GoldSim, Python, and Muk3D. GoldSim handles the water balance and hydrological assessments, managing tailings volumes and raising areas. Muk3D simulates tailings geometric deposition and dam raising. Python coordinates the processes, linking elevation, area, and volume data between GoldSim and Muk3D. This iterative loop ensures continuous updates and adjustments, enhancing accuracy and efficiency.

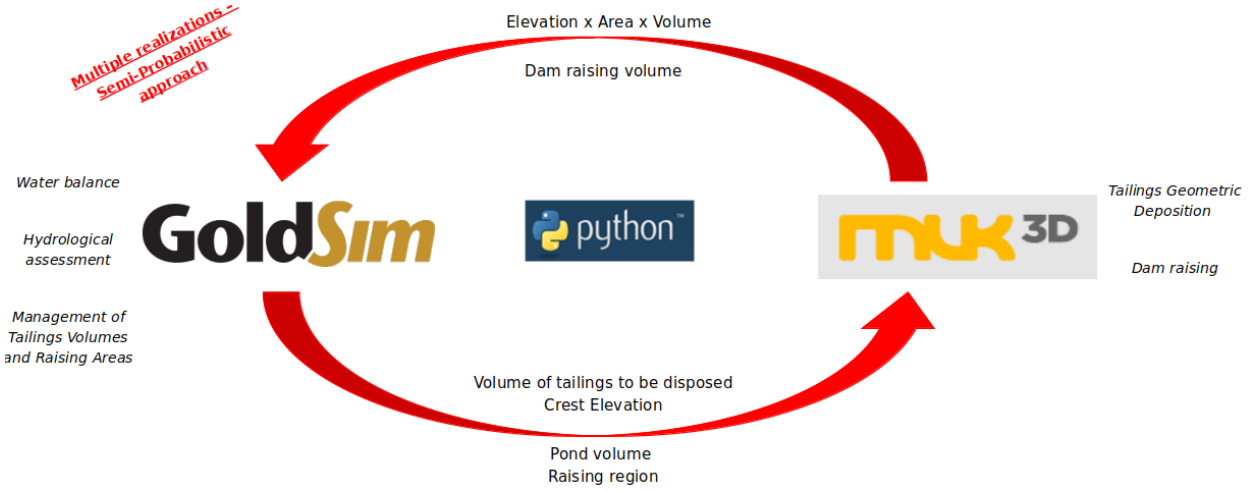

Figure 2: Simulation process interaction

Thus, the tailings surfaces are defined by the beach angles and the position of the spigots. The beach angle varies when in contact with the horizontal lake surface, and the iterative process is defined to achieve the configuration as presented.

The spigot positions over time determine the deposition points considered in the model for surface formation. This iterative process approximates the lake and tailings volumes until the error between the target volume and the calculated volume is within acceptable limits:

- tailings volume = 1%
- lake volume = 10%

The disposal plan considers continuous dam raising, using tailings as the material for construction. The model manages the regions to be raised based on reservoir filling, constructing in 1-meter layers and following a counterclockwise cycle.

In the geometric deposition of tailings, curves representing elevation versus area are generated. For model optimization, only vectorized curves of elevation versus area are imported into GoldSim. For hydrological verifications, GoldSim's numerical integration tool determines the corresponding volume for a given elevation and area pair by integrating the entire interval up to that pair. Thus, interactions with lake elevation, area, or volume elements update the lookup table with data generated from Muk3D.

The semi-probabilistic approach described in the study integrates a probability distribution for lake volumes. Given the computational limitations, specific lake volumes with cumulative probabilities are used for geometric deposition modeling. This approach accounts for the intrinsic variability of input variables such as rainfall, evaporation, tailings production rates, moisture content, beach angles, and uncertainties in tailings properties.

This model has the advantage of accommodating all these variabilities, allowing the simulation of disposal scenarios that better represent risk conditions, including both extreme and more probable scenarios. The adjustments to this coupled model can significantly assist in risk management for structures that, for example, require maintaining a lake near the catchment area, have discharge restrictions, need verification of the contingency storage volume, among other aspects. By considering scenarios with cumulative probabilities, the model can provide a comprehensive assessment of risks and help in strategic decision-making for tailings management throughout the mine's life.

Results

The results of the hypothetical case study demonstrate the application of the integrated, automated model for tailings and water management. The probabilistic volume of the lake over time, the volume of tailings disposed of over time, and the crest elevation of the dam were analyzed under non-linear probabilistic conditions.

Probabilistic lake volume over time

The model's output for the lake volume over time incorporates the variability of rainfall, evaporation, and other hydrological factors. The lake volume was tracked at cumulative probabilities. This analysis helps in understanding the range of potential scenarios for water management, as shown in Figure 3.

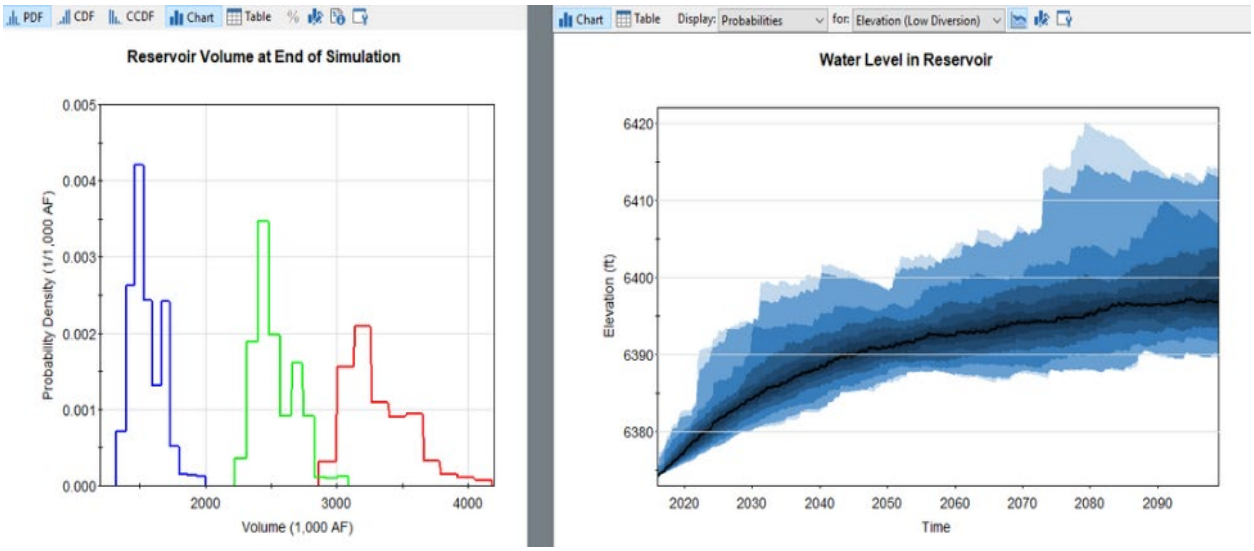

Figure 3: Probabilistic lake volume over time

Volume of tailings disposed over time

The volume of tailings disposed of was monitored, showing the impact of varying production rates and tailings properties. This probabilistic approach provides insights into the expected range of tailings volumes, aiding in strategic planning for tailings management as shown in Figure 4.

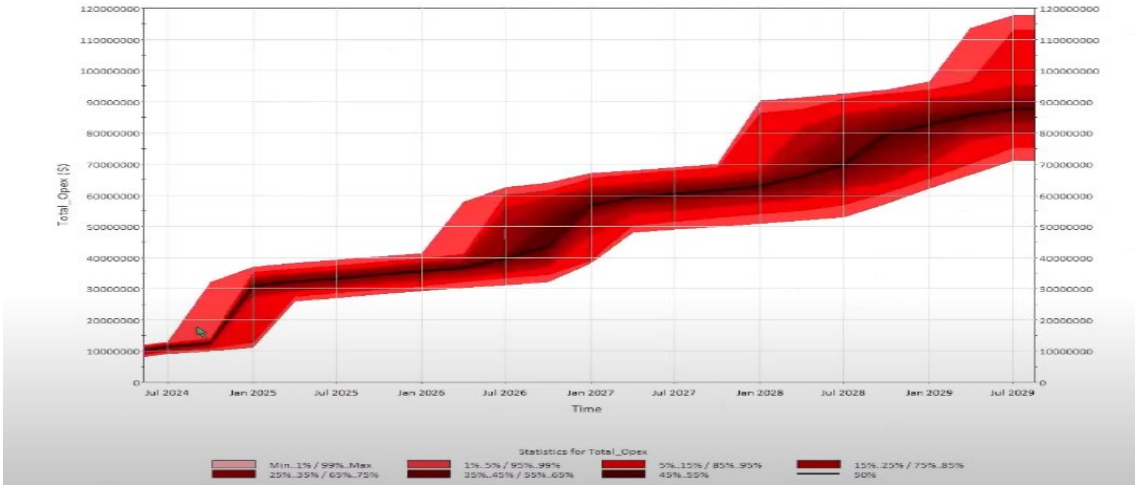

Figure 4: OpEx for tailings disposed over time

Crest elevation of the dam

The crest elevation of the dam was adjusted iteratively, based on the deposition model. The results, presented in Figure 5, show how the dam height changes with the cumulative probability scenarios, highlighting the importance of accurate modeling for effective dam raising. The more information provided about the criteria that the operation evaluates for the most current date and future perspectives, the more accurate the model is. The accuracy of the modeling directly influences the operationality of the structure, providing the necessary volumes and timelines for the raising, while also correlating the modification of auxiliary structures with the crest elevation increase, such as the alteration of the spillway channel, modification of tailings pipelines, and other auxiliary structures.

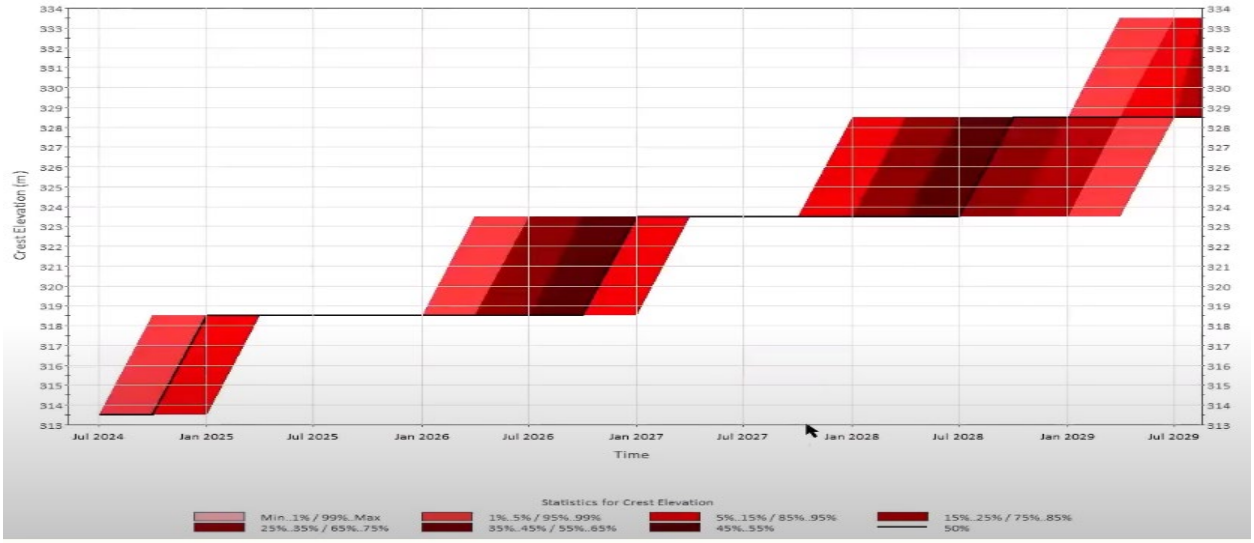

Figure 5: Crest elevation of the dam

Discussion

The probabilistic approach highlights the non-linear responses of the system under varying conditions. The ability to simulate different scenarios provides a robust framework for assessing risks and planning for tailings management. This hypothetical case study lays the groundwork for detailed modeling of real-world cases, incorporating the specific nuances and complexities of each site. The results underscore the potential of this integrated model to improve decision-making and operational efficiency in tailings and water management.

Conclusion

The integrated and automated use of geometric deposition models and hydrological balance presented in this article demonstrates significant potential for enhancing tailings management. The ability to automate control of various variables, such as flood transit verification, overflow volumes, and occurrence probabilities, offers a comprehensive approach to managing tailings. This method ensures effective dam raising, addresses water demand risks for industrial plants, and manages operational contingencies. Additionally, the automated identification and positioning of tailings discharge points streamline operations, providing a robust framework for improved safety and efficiency in tailings management.

Understanding these risks and their dimensional knowledge clarifies strategic decision-making for tailings management directions throughout the life of the mine. This comprehensive understanding is crucial for optimizing long-term planning and ensuring the sustainability and safety of mining operations.

Acknowledgements

We extend our gratitude to MineBridge Software for their support and access to Muk3D software, which was pivotal for our geometric deposition simulations. We also thank GeoMerry for their expert guidance and collaboration in waste disposal and management planning, which significantly contributed to the success of this study.

Incorporating Lifespan Considerations into ALARP Decision-Making for TSFs: a Practical Methodology

Ignacio A. Cueto, SRK Consulting, Argentina
Osvaldo N. Ledesma, SRK Consulting, Canada
Franco Oboni, SRK Consulting, Canada

Abstract

ALARP (As Low as Reasonably Practicable) is featured in several state-of-the-art guidelines, such as those of the Canadian Dam Association (CDA), the Mining Association of Canada (MAC), and the Australian National Committee on Large Dams (ANCOLD), as well as in GISTM/ICMM, which all address risk evaluation and recommend the use of ALARP. In some literature ALARP is essentially represented as the trade-off equilibrium between mitigation costs and risk reduction benefits. However, its most modern definition is that a residual risk, i.e. the risk after mitigation, shall be as low as reasonably practicable, and to be considered ALARP it must be possible to demonstrate that the cost involved in reducing it further would be grossly disproportionate to the benefit gained.

Being able to demonstrate ALARP status, that is locating the minimum ALARP point (LMALARP) is therefore paramount to owners, the Engineer of Record (EoR), the public, insurers, lenders and regulators.

Rationally, LMALARP yields better decisions, enhances the value of projects and avoids mitigative Capital Expenditure (CAPEX) squandering. LMALARP should not be seen as a static process, as it has to encompass various time horizons in the life of a project/facility. Indeed, the short-term ALARP may be very different from the long-term one due to different uncertainties, changing system conditions and external evolution, such as for example land use around the considered facility, which will require adaptation.

This paper showcases how to quantitatively incorporate lifespan in the ALARP assessment when looking at a specific mitigation program and/or to compare different mitigation options. To do so, annualized quantitative risks must be evaluated for each mitigative alternative, and the cost of the various mitigative actions estimated. For each time horizon the result is the trade-off equilibrium between mitigation costs and risk reduction benefits, which represents the minimum theoretical ALARP point. Various considerations can then guide decision-makers to select the point where the cost involved in reducing it further would be grossly disproportionate to the benefit gained.

This process has been applied to existing facilities, showing how the optimum solution varies, not only when the weighting of the different consequences is shifted (environmental vs. financial vs. reputation, etc.), but also when the lifespan of the structured is considered.

Introduction

ALARP (As Low as Reasonably Practicable) is featured in several state-of-the-art guidelines, such as those from the Canadian Dam Association (CDA), the Mining Association of Canada (MAC), and the Australian National Committee on Large Dams (ANCOLD), as well as in GISTM (Global Tailings Review, 2020) and ICMM, which all address risk evaluation and recommend the use of ALARP.

In some literature, ALARP is essentially represented as the trade-off equilibrium between mitigation costs and risk reduction benefits. However, its most modern definition is that a residual risk, i.e. the risk after mitigation, shall be as low as reasonably practicable, and that to be considered ALARP it must be possible to demonstrate that the cost involved in reducing it further would be grossly disproportionate to the benefit gained.

This paper shows quantitative solutions to Locate Minimum ALARP (LMALARP) threshold level, the trade-off equilibrium point cited above, and how to integrate various time horizons to this evaluation. The disproportionate mitigation investment lies to the right of the LMALARP in Figure 1b.

ALARP concept evolution

The principle of ALARP was originated in British case law, with examples dating back to 1949. One of these cases dealt with whether it was reasonably practicable to prevent any possibility of a rock fall in coal mines, and established the concept of "reasonably practicable," distinguishing it from being "physically possible," as these terms are applied to risk mitigation measures. Thus, it can be said that ALARP was born from mining applications. The court at that time established that: *"Reasonably practicable is a narrower term than 'physically possible' and implies that a computation must be made ... in which the quantum of risk is placed in one scale and the sacrifice involved in the measures necessary for averting the risk (whether in time, trouble or money) is placed in the other and that, if it be shown that there is a great disproportion between them – the risk being insignificant in relation to the sacrifice – the person upon whom the obligation is imposed discharges the onus which is upon him."* (Edwards vs. National Coal Board, 1949) to do so. Interestingly, the judge used the word "computation" and did not even consider a qualitative approach.

Historic definitions

The UK Health and Safety at Work Act of 1974 (HSWA) formally adopted the ALARP principle (HSE,

2024). Several countries around the world have employed elements of the ALARP concept including Australia, Abu Dhabi, Belgium, Brazil, Denmark, Hong Kong, Ireland, Netherlands, Saudi Arabia, and the U.S.A. In the U.S.A., the ALARP principle has been employed by the U.S. Army Corps of Engineers (USCE) since 2009 (USCE, 2009, 2019)

Historically, ALARP was defined as a probability level, paired with a number of potential fatalities (see Figure 1a, from Hain, 2015), i.e., a risk measured with a fatality metric. Some studies even defined ALARP as a fixed probability threshold.

Unfortunately, such a graph does not allow the determination of ALARP, not even as a trade-off, but states that if a failure is below the intolerable region, then it is ALARP or, for lower values, even broadly acceptable. Beyond the arbitrary nature of the risk levels, we find that mixing the definition of ALARP with tolerance creates unnecessary confusion. Furthermore, the fatality metric does not allow the evaluation of ALARP for multidimensional consequences (compounded fatalities, environmental, direct losses, indirect losses), which are the ones generating risk in notorious mining events.

In some literature, however, ALARP is essentially represented as the trade-off equilibrium between mitigation costs and risk reduction benefits. The ALARP framework implicitly assumes that full elimination of risks cannot be achieved and that there is always some trade-off between residual risk after mitigation and the associated mitigative cost. Figure 1b shows the ICMM guidance (ICMM, 2021) which depicts ALARP as the trade-off point.

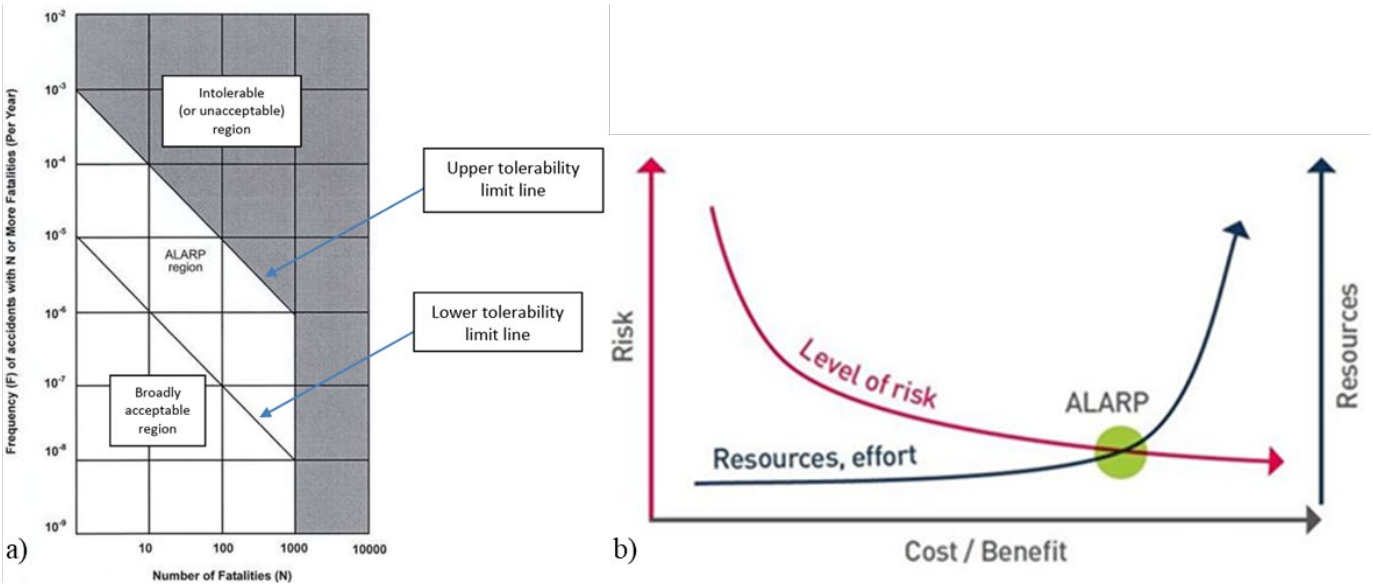

Figure 1: a) A generic ALARP graph (Hain, 2015). b) ICMM 2021's concept of assessing benefit of mitigation effort to residual risks with ALARP at trade-off point, called herein LMALARP (ICMM, 2021)

These definitions appear in many studies and papers and create some confusion because the definition nowadays has shifted, as shown in the next section.

Modern definitions

It appears that the definition of ALARP is now back to its origins (Edwards vs. Coal Board, 1949), i.e. a residual risk, the risk after mitigation, for which it must be possible to demonstrate that the cost involved in reducing it further would be grossly disproportionate to the benefit gained (Hain, 2015). The minimum trade-off point (the intersection between the two curves shown in Figure 1b, which we call the LMALARP, the location of the minimum ALARP) can be evaluated using quantitative risk evaluations (Oboni and Oboni, 2022a; 2022b; 2022c), while the final decision on what constitutes disproportion , i.e. the shifting of ALARP to the right of the horizontal axis of Figure 1b, relies on human judgement.

This definition thus encompasses demonstrating disproportionate investment for limited risk reduction (to the right of the trade-off point of Figure 1b). It is our opinion that the shift to the right is strongly influenced by public opinion, which has become a fundamental driver recognized by a UNEP partner (Roche et al., 2017), Oboni and Oboni (2019), and then GISTM.

Determining the trade-off to elicit a rational decision on ALARP

Who is interested in rational estimates of ALARP?

As a result of the prior discussion, being able to find the LMALARP is paramount to owners, the Engineer of Record (EoR), the public, insurers, lenders, and regulators.

The ability to rationally discern the LMALARP fosters better decision making, enhances the value of projects, and avoids mitigative CAPEX squandering.

Why should ALARP consider various planning time horizons?

The LMALARP should not be seen as a static process, as it has to encompass various planning time horizons over the life of a project/facility. Indeed, the short-term ALARP may be very different from the long-term one due to various uncertainties, changing system conditions, and external evolution, such as for example land use around the considered facility. Because of this it is paramount to be able to deliver a view of ALARP evolution for increasing time horizons, while keeping in mind that inevitably conditions will change, making it necessary to adapt and review in the future.

Finding a solution

Analysis concepts

This paper showcases a development allowing users to quantitatively incorporate lifespans in the ALARP assessment when looking at a specific mitigation program and/or to compare different mitigation options. The methodology proposes the quantitative inclusion of the time/lifespan concept into the ALARP principle. To do so, annualized quantitative risks have to be evaluated for each mitigative alternative and the cost of the various mitigative actions estimated. For each time horizon the result is the trade-off equilibrium between mitigation costs and risk reduction benefits, which represents the minimum theoretical ALARP point. Various considerations can then guide the decision-makers to select the point where the cost involved in reducing it further would be grossly disproportionate to the benefit gained.

For this methodology to be useful the total quantitative annualized risk must be evaluated using multidimensional quantified consequences, i.e., the sum of harm to people, environmental damages, direct and indirect costs, and estimated reputational consequences converted into a single metric such as monetary quantity. The evaluation system is generally discussed with corporate key stakeholders and reflects the company's criteria. To use the scheme shown in Figure 1b, both curves must have the same units, since having two different axes means the intersection point depends on the axis scale. As a result, the annualized residual risks (after each mitigation scenario) are expressed as the multiplication of the annualized probability of failure by the potential consequences in monetary value per annum, for instance USD/yr. With that, a classic optimization problem can be defined as the sum of the mitigation cost and the annualized risk over a planning time horizon, a schematic of the objective function plotted against the different scenarios can be seen in Figure 2. It should be noted that this plot corresponds to a specific maximum time horizon selected for each study. The planning time horizon should not exceed a few decades, and it should be clearly stated that beyond this, re-evaluation should be expected.

For each assessed planning time horizon, a different mitigation alternative might come as the optimum solution, resulting in multiple plots, such as those shown in Figure 2. A different way to look at this is to plot the mitigation alternatives total cost as a function of the planning time horizon, as shown in Figure 3, where the y-axis at time equal zero represents the mitigation cost, and the slope of the line is the annualized risk after mitigation. Figure 3 shows when a mitigation alternative becomes more attractive than others: in the example shown, after year 7, alternative 2 (the green line) becomes more attractive.

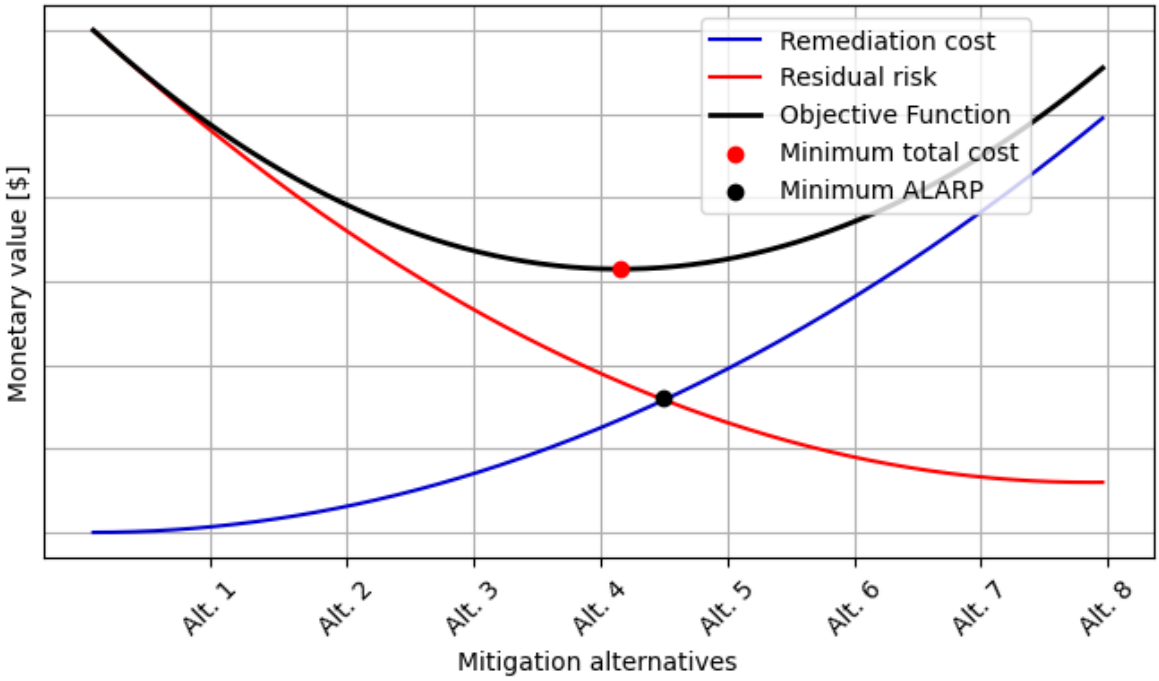

Figure 2: Objective function definition based on the mitigation and residual risk cost for a given time horizon

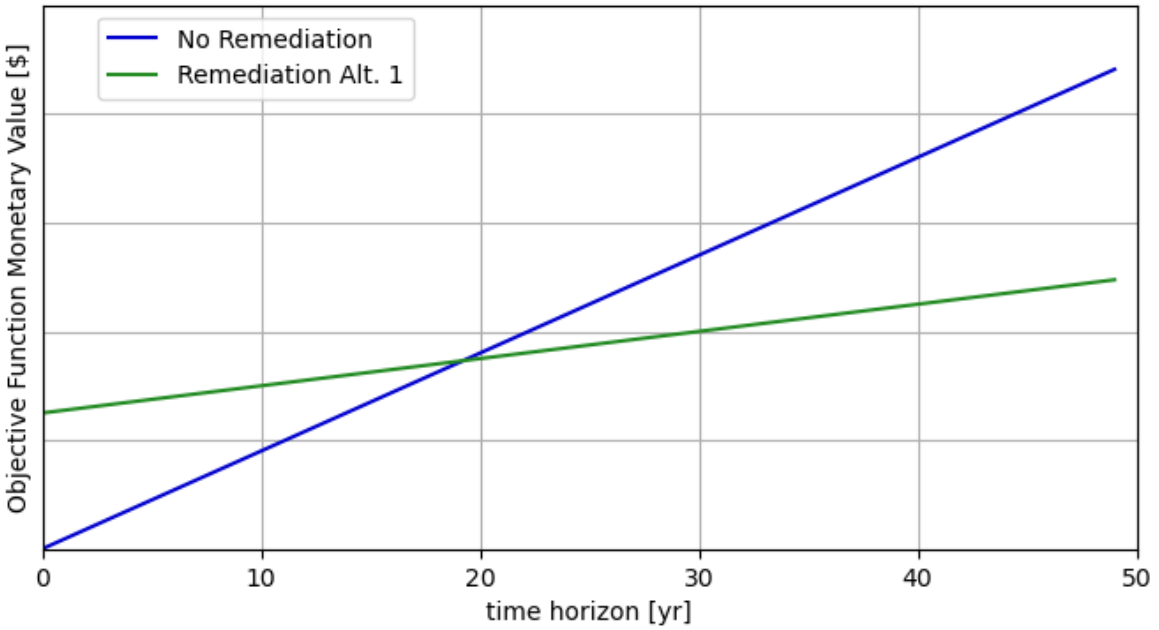

Figure 3: Objective function vs. time horizon for two different risk mitigation alternatives

Application example

This process has been applied to existing facilities, and has shown how the optimum solution varies, not only when the relative value of the various consequence dimensions changes (environmental vs. financial

vs. reputation, etc.), but also as a function of the structure's lifespan.

The tailings management area of this example (similar to a real-life case the authors studied in the recent past) is composed of 2 tailings storage facilities (TSFs) referred to as TSFS A and TSF B. A river that is the habitat of several species runs at 100 to 150 meters from the toe of both facilities, and a small population is located downstream across the river.

The TSF's current condition and several mitigation alternatives were evaluated with a quantitative risk assessment (QRA), using a bow tie structure linking hazards to consequences. The bow tie includes fault trees for the various failure modes/causalities on the left side (event probability side), and an event tree enabling the evaluation of consequences, on the consequence side. The potential mitigations considered for this example are buttressing the facilities, population relocation, and a combination of both. The obtained annualized risk per mitigation alternative is summarized in Table 1.

Table 1: Risk and mitigation cost

Mitigation alternative	TSF A annualized risk (M USD/yr)	TSF B annualized risk (M USD/yr)	Total annual risk (M USD/yr)	Mitigation cost (M USD)
Current	3.0	11.0	14.0	0.0
Buttress on A	1.0	11.0	12.0	12.0
Buttress on B	3.0	4.0	7.0	93.0
Buttress on A & B	1.0	4.0	5.0	105.0
Population Relocation	2.8	7.0	9.8	20.0
Buttress on A & B + Population relocation	0.9	3.0	3.9	125.0

Figure 4 shows an analysis of total monetary value (mitigation cost and annualized risk) for different time horizons: 3, 12, and 30 years. It can be seen how the optimum solution changes for the different time horizons considered. Of course, these evaluations will require adaptation and re-evaluation, especially for longer time periods.

Figure 5 shows how, depending on the planning time horizon being considered, the mitigation alternative that yields a minimum objective function changes.

If the time horizon for mitigation was shorter than 5 years, and the closure design considered stabilization of the facilities and an improvement of the surface water management system, the optimum alternative is to do nothing. But on the other hand, if this time was longer and there were more than 18 years of operation ahead, the optimum mitigation alternative is to buttress TSF A and B and relocate the downstream population. If the projected time to mitigation was in between those values a relocation of the population would be shown to be the optimum solution.

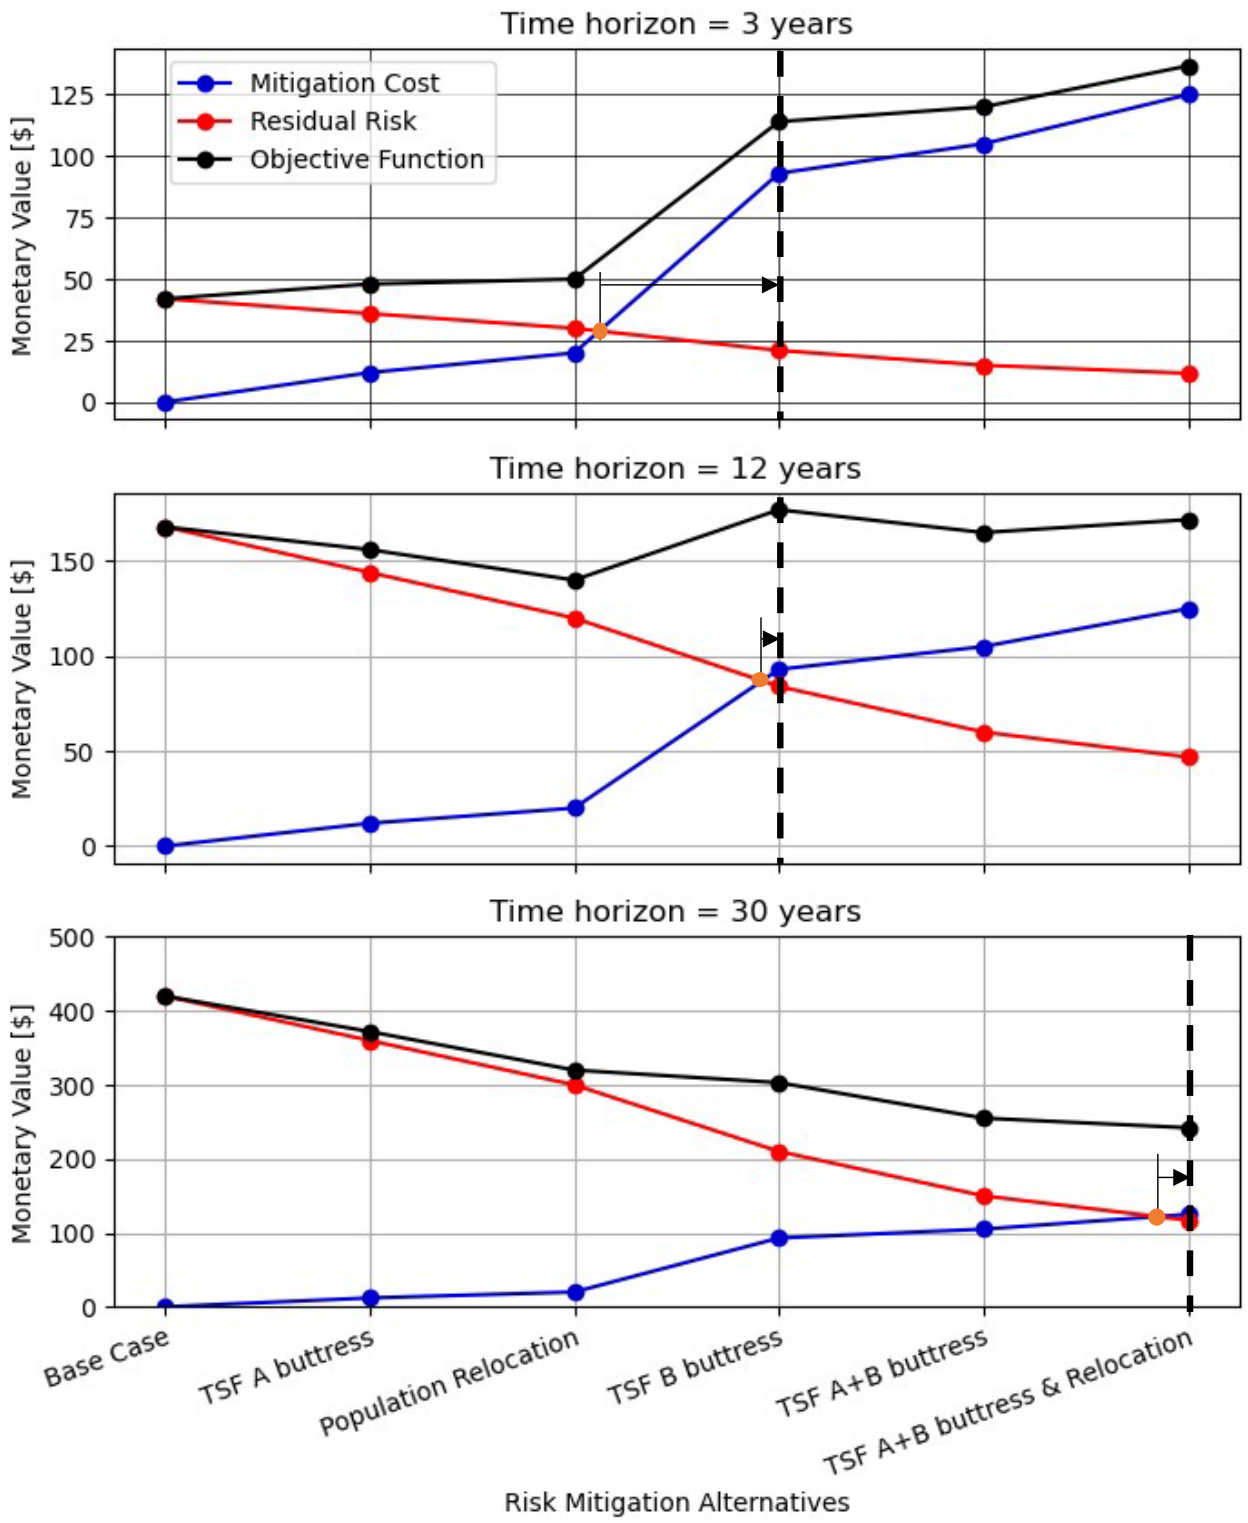

Figure 4: Objective function, mitigation, and risk cost for a 3-, 12- and 30-year time horizon

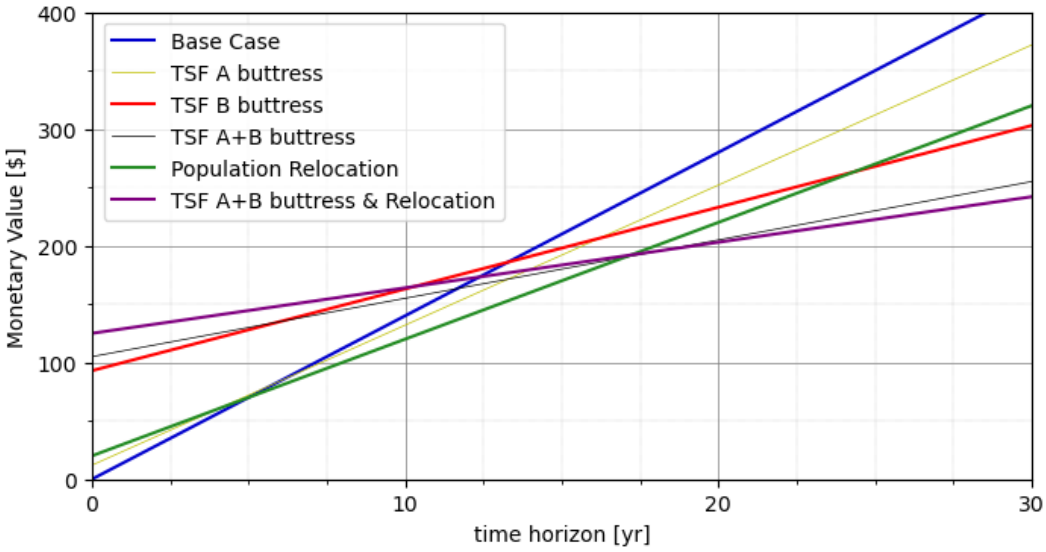

Figure 5: Objective function value vs. time horizon for each risk mitigation alternative

Conclusion

This paper presents a methodology for incorporating lifespan considerations into ALARP decision-making. The approach emphasizes the necessity of evaluating all mitigation costs, risk estimations, and risk reductions in consistent units, specifically, annualized values. This consistency is crucial for accurately determining the minimum ALARP point, which represents the trade-off equilibrium between mitigation costs and risk reduction benefits.

The optimization of system mitigation must account for the time horizon as a variable. The findings indicate that the minimum ALARP point is not static, but varies with the selected time horizon. Shorter time horizons may justify lower mitigation levels as minimum ALARP points, whereas longer horizons may necessitate more comprehensive mitigations to achieve a minimum ALARP point. This temporal variability underscores the importance of a dynamic approach to ALARP assessments, one that adapts to changing conditions and evolving system states.

The methodology presented in this paper allows for the quantitative inclusion of lifespan in ALARP assessments. By evaluating annualized quantitative risks for each mitigative alternative and estimating the associated costs, decision-makers can identify the theoretical minimum ALARP point for various time horizons. This process facilitates a rational decision-making framework that enhances the value of projects and prevents unnecessary capital expenditure on mitigative measures.

The application of this methodology to existing facilities demonstrates its practical utility. The example reveals how the optimum mitigation solution varies not only with the weighting of different consequence dimensions (environmental, financial, reputational) but also with the lifespan of the structure.

The results highlight the importance of considering multiple time horizons in ALARP assessments to ensure that mitigation strategies remain effective and economically viable over the long term.

Furthermore, this process must recognize that conditions will inevitably change, necessitating periodic reviews and adaptations of the assessments. The method aims to support the evaluation of the minimum ALARP, which is then subject to discussions that incorporate public perception and the interests of other stakeholders. This inclusive approach ensures that ALARP assessments remain relevant and responsive to the evolving landscape of TSF management.

In conclusion, the integration of lifespan considerations into ALARP decision-making provides a robust framework for optimizing risk mitigation strategies. By adopting this methodology, stakeholders can achieve a balanced approach that aligns with regulatory requirements, enhances project value, and addresses public and environmental concerns.

A Risk-Based Approach for Management of Change of Tailings Storage Facilities

Bryan Bale, Teck Resources Ltd., Canada
Shawn Gravel, Teck Metals Ltd., Canada
Adam Chiorando, Teck Alaska Inc., USA

Abstract

The Global Industry Standard on Tailings Management requires a formal change management system that triggers the evaluation, review, approval, and documentation of changes to design, construction, operation or monitoring of a tailings storage facility (Principle 6.5). Teck has guidance for change management processes at the corporate and site levels and has recently trialed a proposed approach for management of technical changes at tailings facilities. This paper presents a risk-based approach for management of change that is appropriate as part of a change management system for complex and significant technical or operational changes. Guidance for use of the approach, including stakeholder preparation, risk assessment, change management actions, and decision approval are presented. The approach was developed through two management of change examples at Teck's operating mine sites. The management of change approach was used to identify the risks that these changes would introduce as well as the actions required to lessen these risks.

Introduction

The Global Industry Standard on Tailings Management (GISTM) requires that tailings storage facility owners implement a formal change management system (Principle 6.5). The change management system has the objective of disciplining and coordinating the change process, and should include an evaluation of the change, a review and formal approval of the change, followed by detailed documentation including action plans (Global Tailings Review, 2020). These requirements for management of change are included in the site and company management systems at Teck. To facilitate fully implementing the GISTM requirements, Teck developed and trialed a suggested procedure for management of change for tailings facilities.

This paper presents a risk-based approach for a management of change process that is appropriate for complex and significant technical and operational changes that impact a tailings storage facility. The

approach was developed through two real scenarios where a significant change was considered at Teck's tailings storage facilities. The suggested process evolved during these scenarios as lessons were learned along the way, to the point where the authors concluded that the approach was ready for implementation as a standard method. It was also recognized that sharing this approach with the broader industry would be worthwhile. This paper presents the two case studies where this management of change approach was developed, the lessons learned through these examples, and recommendations for use. The key steps in the risk-based approach include stakeholder preparation, risk assessment, change management actions, and decision approval. The approach also meets the GISTM requirements and definitions. We also learned that management of change should be considered in parallel with a structured decision-making approach.

Management of change for tailings storage facilities

"Management of change" can be defined as "a systematic approach to managing changes to ensure that they are implemented safely, efficiently, and effectively" (Center for Chemical Process Safety, 2008a). "Management of change" refers to the technical aspect of the change, while "change management" often refers to the behavioral aspect of the change. Management of change is the more appropriate term for the expectations described by the GISTM.

The management of change approach as presented in this paper can be considered as an element of a change management system. The management of change process defined by Teck includes the steps shown in Figure 1.

Figure 1: Management of change steps

Teck's Management of Change Standard aligns with these steps, and a key aspect of the standard is the requirement for risk assessment.

Identify the change

The first step in management of change is to recognize that a change is proposed or occurring (Identify the Change step in Figure 1). As per GISTM, the changes can be to the design, construction, operation or monitoring of the tailings facility. This requires diligent review of these aspects and is primarily the responsibility of the Responsible Tailings Facility Engineer supported by the Engineer of Record (ICMM, 2021).

The Change Management System should provide guidance on the management of change procedure to use. Not all changes require a formal risk assessment. For example, a minor deviation in construction may be handled with a non-conformance report with acceptance and corrective actions included. More complex changes may warrant a risk-based approach as described in this paper.

Teck's Red Dog Mine has a useful management of change screening tool checklist as part of their Change Management System. The checklist is intended to be completed with a group of stakeholder representatives, and it lists questions that could trigger more rigorous management of change requirements. Questions cover topics related to various stakeholder's perspectives including environmental, regulatory, design, safety, cost, standard operating procedures, training, human resources, maintenance, external communities and more. The screening tool also serves to document if a risk-based management of change approach is warranted, who should be involved, and approval to proceed with further study of the proposed change (Pre-Approval step in Figure 1).

Risk assessment

A risk assessment is central to the management of change process for more complex or significant changes (refer to Figure 1). There are numerous risk-assessment approaches that can be considered. A "What-If Analysis" (Center for Chemical Process Safety, 2008b) was selected as an appropriate risk-assessment method for the proposed change examples described in this paper.

As defined in a procedure for Teck Metals' Trail Refinery, a What-If Analysis technique follows a brainstorming approach in which a group of experienced people familiar with the subject process ask questions or voice concerns about possible undesired events that could occur because of the proposed change. The purpose of a What-If Analysis is to identify hazards, hazardous situations, or specific event sequences that could produce undesirable consequences. The approach requires the group to identify possible abnormal situations, their consequences, existing safeguards, and then suggest alternatives for risk reduction where obvious improvement opportunities are identified or where safeguards are judged to be inadequate. The method can involve examination of possible deviations from the design, construction, modification, or operating intent. It requires a basic understanding of the process intention, along with the ability to mentally combine possible deviations from the design intent that could result in an incident.

Figure 2 illustrates the What-If Analysis approach with suggested questions for the facilitator, and Figure 3 shows the analysis worksheet.

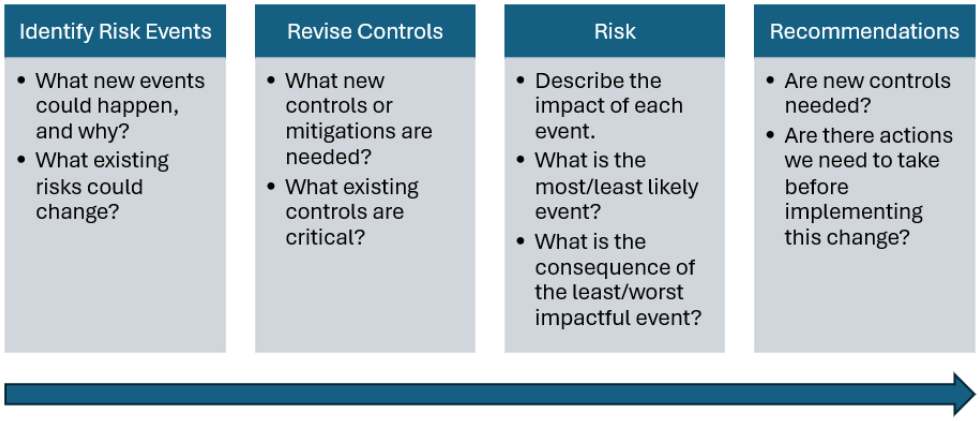

Figure 2: Thought process and facilitator questions for a "What-If" analysis

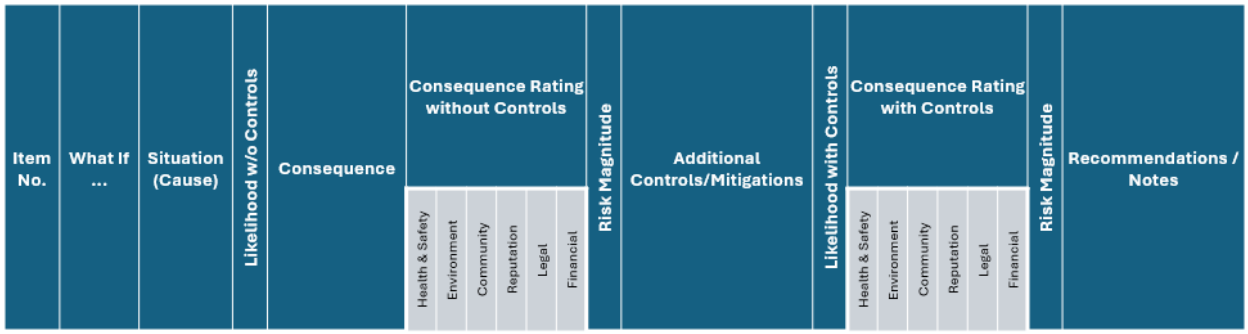

Figure 3: Teck's "What-If" analysis worksheet

The brainstorming provided by this method is valuable to gather a list of risk events without constraining the thinking to findings of previous risk assessments. The use of third-party and cross-functional participants minimizes bias and encourages broader thinking. Additional controls, mitigations, and recommendations should be suggested freely throughout the brainstorming portion. The details of the risk-evaluation portion can be completed after, with a smaller group using the standard risk-classification system for the company and considering the risk with and without additional controls. The method is appropriate for a tailing storage facility change where there is access to subject matter experts. Examples of this risk assessment are provided next as they were important to evaluate the utility of this risk assessment method.

Example #1 – Red Dog Mine – tailings pipeline on dam

Problem and proposed change

Teck's Red Dog Mine is a zinc and lead mine located in Alaska, USA. Tailings are deposited as a slurry

within a tailings storage facility. Two dams form the containment on opposite ends of a valley, with a water pond covering most of the tailings surface. Tailings are deposited near the dams to form a beach above water to maintain separation between the dams and the water pond, and this requires tailings pipelines running along the upstream side of the dams.

The tailings deposition pipelines along the dam have traditionally been placed on a compacted tailings pipe grade located on the tailings beach adjacent to the dam. This presented challenges as the construction of the pipe bench would occasionally damage the liner, requiring repairs. The pipe bench also had to be raised incrementally after each dam raise, which resulted in the deposition pipelines often being too low and missing the opportunity to maximize the beach width. Employees also had to access valves on the pipe bench, requiring difficult access down the lined dam face. The proposed operational change was to move the tailings deposition pipeline onto the dam crest, and to use slotted downspouts to ensure that the deposition pipes would not plug as the tailings beach elevation increased and buried the deposition pipes. Figure 4 illustrates the proposed change.

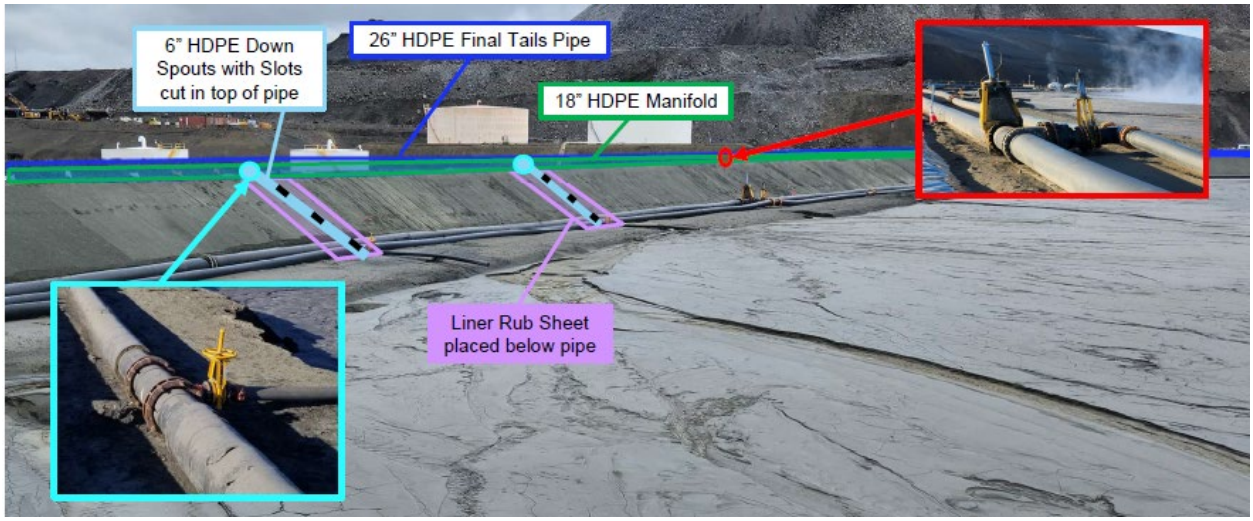

Figure 4: Proposed change to move the tailings deposition pipeline onto the dam crest

Management of change approach

The management of change screening questionnaire developed by Red Dog Mine was used as a first step once the change was identified. A group of stakeholders from the mine met to review the problem statement and proposed change. The questionnaire was used to document the potential implications of the proposed change discussed at this meeting. It was recognized that the proposed change of moving the deposition pipeline onto the dam crest could introduce a risk of tailings spills onto the dam, as well as other implications. The proposed change could affect numerous groups, including maintenance crews, operators, tailings planners, the Engineer of Record, and local community groups. The recommendation from the group, guided by the questionnaire, was to pursue a formal risk-based management of change process. This

screening questionnaire served to identify the change, justify using a risk-based management of change approach, and document the pre-approval to consider the change from site management.

At this stage, the Tailings Department staff at Red Dog Mine recognized that they would need to develop a risk-based approach that was appropriate for this scenario. They reached out for support within Teck, and a What-If Analysis was suggested. The What-If Analysis approach was suggested as it is a standard method in use at Teck Metals' Trail Refinery and is common in the Process Safety field.

The risk assessment was conducted in two sessions. The first 2-hour session began with setting a common understanding amongst the varied stakeholder groups and introduced the risk-assessment approach. The problem statement and proposed change were discussed. The Engineer of Record provided their perspective on the proposed change as a technical deliverable, including assessment of the flow rate that would occur during a pipe break, and the low potential for erosion on the dam. Events that could occur because of the proposed change were suggested using a brainstorming approach. Additional controls, mitigations, and recommendations were suggested throughout the discussion. Upon completion of the event list, the likelihood and consequences of some of the risk events were completed as a group, and the rest were completed after the meetings by the facilitator. A second 1-hour session was required to review and finalize the risk-assessment results.

Results and lessons learned

The risk events introduced by the change are summarized in Table 1. All risk events can be managed without an increase in risk level with the addition of new controls and mitigation measures.

Table 1: Summary of risk events introduced by pipeline relocation

What-If Event	New Controls/Mitigations
Pipe leaks tailings onto dam crest	Place geomembrane under valves and flanges, Install containment berm, Reduce number of flanges, Implement installation QC program, Modify daily inspection form, Develop Safe Work Plan for pipe moves, Develop pipe condition assessment, Install traffic control and vehicle barriers.
Downspout damages liner	Install a rub sheet.
Pipe maintenance is needed	Install spill containment under valve.
Snow drifts form behind pipe	Use snowblowers rather than loader, Delineate pipeline location.

Based on the conclusion that the new risks can be managed without an increase in the risk level, the recommendation to proceed with the proposed change was made. The Engineer of Record provided a report documenting the design for the change and the new controls and mitigations, with the risk assessment appended as a basis for their recommendations. A standard Decision Memorandum was used to document the change, gather approval signatures from management, and document the new controls and mitigations that need to be implemented (Final Approval and Planning steps in Figure 1). These new controls and mitigations were tracked using an existing site system prior to relocating the tailings pipeline (Implementation step in Figure 1). The proposed change was also presented to the Independent Tailings Review Board prior to commissioning. New controls including inspection forms were developed to verify the new controls and were added to the Operation, Maintenance and Surveillance Manual (Verification step in Figure 1).

The management of change approach tested for this case followed all steps as described in Figure 1. The approach was robust and effective. It was helpful that Red Dog Mine had a pre-existing change screening questionnaire that served to identify the change, identify stakeholders, and document the approval from management to proceed with a formal risk-based approach. It was also noted that the initial meetings were hampered by discussion of other alternatives that had been previously eliminated, and that the risk assessment was time-consuming. These lessons were carried forward to the next example for optimization.

Example #2 – Highland Valley Copper operations – modification of a spillway intake gate

Problem and proposed change

Figure 5: Highmont tailings storage facility spillway intake channel and control gate

Teck's Highland Valley Copper Mine is in British Columbia, Canada. There are several closed tailings facilities on the property, including the Highmont Tailings Storage Facility. There is a control gate located in the spillway intake channel that is used to temporarily store water during the spring snowmelt and allow most of the water to be diverted for use in the site process. It was identified that more water could be temporarily stored if the control gate was modified to be 75 cm taller, which would reduce the frequency that the flow would discharge to the receiving environment. The implications of this change on the dam safety profile required further consideration. Figure 5 shows the spillway inlet channel with the control gate structure.

Management of change approach

The proposed change presented potential trade-offs between dam safety and environmental management perspectives. The Highland Valley Copper tailings staff requested support to manage this change. Considering the recent trial with the Red Dog Mine site, the same team offered to facilitate this change using the template developed at Red Dog Mine, with the goal of creating a standard approach for the company.

Several lessons were learned from the Red Dog Mine example that were incorporated for this second case. It was recognized that a lot of time was invested by a large group for the Red Dog Mine case, and reducing the total time for this task was a goal. To accomplish this, a site Change Owner and facilitator were assigned to lead the work, with less reliance on the full team.

Like the Red Dog Mine example, the first meeting was a brief (30-minute) session to set a common understanding with all stakeholders and introduce the risk-assessment method. Although the goal was just to understand the problem statement and proposed change, inevitably there were suggestions of the risks to consider, alternate solutions, and suggested actions. These were captured in the risk-assessment worksheet for the next session. It was interesting to note that the discussion was again complicated when other alternative solutions were suggested during this session, indicating that we had not properly informed all stakeholders of the alternative evaluations completed previously.

Following the introductory session, the Change Owner and facilitator pre-populated the What-If Analysis with events they identified. The second session (2-hours) was then held with a cross-functional group of stakeholders, including the Engineer of Record, to review the event list and suggest other events. It was noted that several new events were suggested, likely because the obvious technical events were pre-populated leaving more time for brainstorming. New controls/mitigations and recommendations were captured for each. Lastly, a few events were assigned risk scores, focusing on the most and least impactful events leveraging the cross-functional team. The facilitator and Change Owner completed the risk assessment after the meeting, using the events scored with the group as benchmarks to evaluate the rest.

Results and lessons learned

The risk events introduced by the change are summarized in Table 2. Identified new events that could occur because of the change have a lower risk score than the "do-nothing" case. The Engineer of Record demonstrated that the water pond volume would be temporarily increased by a relatively small amount, while maintaining freeboard or stability requirements.

Table 2: Summary of risk events introduced by gate raise

What-If Event	New Controls/Mitigations
The risk profile for the dam increases (perceived)	Review change with Independent Tailings Review Board and Community Groups, Perform commissioning testing of the gate, Update Operations Manual.
Vegetation around the pond is drowned	Develop plan to revegetate with flood tolerant species.
Water quality is worsened	Develop monitoring plan to identify if this occurs and be prepared to reverse the change.
Wildlife is displaced	Establish new vegetation that supports existing wildlife use.

The results of the risk-assessment workshop were provided in a report from the facilitator and submitted to the stakeholder group for review. Highland Valley Copper is progressing through this change, with the next steps to follow a similar approach as was used in the Red Dog Mine example. This will include formal documentation of the proposed change from the Engineer of Record, review by the Independent Tailings Review Board, management approval using a Decision Memorandum, and tracking of completion of the new controls and mitigations.

After using this management of change approach twice, the time required for the broader team was reduced. This was mostly due to pre-populating the event list and using the team meetings to focus on identifying events that were missed and assigning risk ratings to only a few events with the rest completed by the Change Owner and facilitator. Including the "do-nothing" case was also a useful addition.

Part of a structured decision-making approach

It was noted that both examples were complicated when new ideas were suggested during the workshop. It was realized that management of change and structured decision-making are related, and both should be considered in parallel. In hindsight, the same cross-functional team should be involved as alternatives are considered or be informed prior to proceeding the management of change of the preferred option. Figure 6 illustrates the steps in a structured decision-making approach.

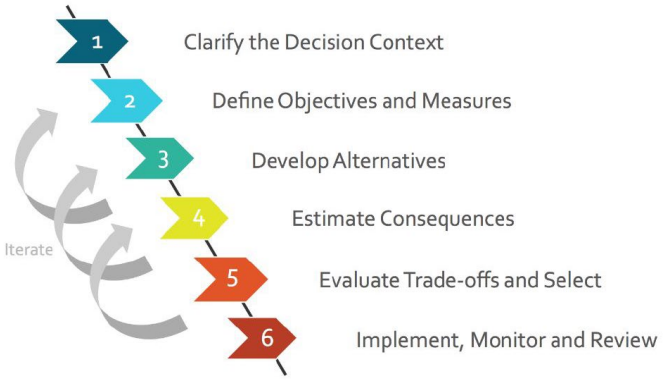

Figure 6: Steps in a structured decision-making approach (Compass Resource Management, 2024)

Recommended approach for management of change

Based on these examples, the following approach is recommended for management of change of technical and operational changes for a tailings storage facility.

1. Evaluate alternate options for the problem as part of a structured decision process. Ensure that all feasible options are considered and documented before starting on the management of change for the preferred option. Note that rushing into management of change will be derailed as other ideas are suggested if this is not done. A document listing the alternate ideas and the reason for pursuing the proposed change can be used in preparing the group for the risk assessment.
2. Identify the change – the questionnaire form used by the Red Dog Mine was useful. Implications of the proposed change from various stakeholders' perspectives and the decision that a formal risk assessment was required were captured using this form. Considering the time investment to conduct a good risk assessment, this screening tool is very useful.
3. Pre-approval of the proposed change – ensure that management agrees with the concept for the change and endorses the subsequent risk assessment. Multiple stakeholders will need to participate, and they may need direction to do so. Again, the form used by Red Dog Mine documented this approval and was effective.
4. Risk assessment – the What-If Analysis described here is recommended as a suitable format that identifies new risk events that arise from the event, or changes to the existing risks. Cross-functional representation is valuable to both identify the new risks that could be introduced, and to evaluate the consequences. Ensure that any new participants are oriented to the problem, alternatives, and proposed change prior to beginning this step. Leverage the group for the key brainstorming of risk events and risk calibrations and complete the rest with a smaller team to minimize the time commitment. The risk assessment method should be scaled appropriately depending on the significance of the change. The "do-nothing" case should be considered.

5. Final approval – the approval for the change should be documented. A Decision Memorandum with signatures from the appropriate management level is a suitable tool. The risk assessment documentation and endorsement from the Engineer of Record can be appended. The Deviance Accountability Report should also be updated to document the change.
6. Planning – including identification of the additional actions and controls addressed during the risk assessment. These can be documented in the Decision Memorandum as for Step 5.
7. Implementation of the change – the new actions and controls should be tracked to completion using formal systems before the change is made.
8. Verification of the change should be embedded into the Operations, Maintenance and Surveillance Manual, and other similar documents.

Conclusion

The GISTM requires that tailings storage facility owners implement a formal change management system. It was identified that developing an appropriate, standardized system for the technical and operational changes that arise for tailings storage facilities would be useful. This paper presented a suggested approach for management of change using a risk assessment. The management of change approach was developed through two real scenarios at Teck operating mine sites where a significant change was considered.

A "What-If Analysis" was selected as an appropriate risk-assessment method. The brainstorming provided by this method was valuable to gather a list of risk events without constraining the thinking to findings of previous risk assessments. The use of third-party and cross-functional participants minimized bias and encouraged broader thinking. The approach was trialed at two sites and was found to be effective in identifying the new controls and mitigations that were required to safely implement the change.

Lessons were learned through the example cases that were incorporated into the recommended approach. A key finding was the realization that management of change is related to structured decision-making, and that omitting this idea-generating step can side-track the risk assessment. It was also apparent that the change identification questionnaire used by Red Dog Mine was very useful and aligns with this approach. Including the "do-nothing" case was also a valuable consideration. Lastly, it was important to have a facilitator and site Change Owner to minimize the amount of time required from the broader cross-functional group.

An 8-step management of change approach was suggested that includes stakeholder preparation, risk assessment, change management actions, and decision approval. Recommendations for use of a screening tool, the risk-assessment method, and decision approval documentation were provided. The management of change approach described could be adopted as a procedure or guideline under a company's broader Change Management system.

Global Climate Change due to Earth Cycles and Implications for GISTM Standards

Kris Hojka, Worley Consulting Ltd, Canada
Fariba Yavari, AtkinsRéalis, Canada

Abstract

Tailings storage facilities (TSFs) face critical challenges during passive closure, adhering to GISTM standards that mandate a flood design criteria equivalent to a 1/10,000-year return period. While 10,000 years is a brief period geologically, it spans over a significant period of human history, when civilizations have been lost due to natural climate changes. This study explores our civilization's vulnerability to natural climate change over 10,000 years, driven by the Earth's cycles, particularly the Milankovitch cycles – Earth's Eccentricity, Obliquity, and Axial Precession. Historical climate transformations, from Biblical floods shaping the Black Sea and Persian Gulf to changes in the Sahara and Great Lakes, highlight these cycles' profound impacts.

Statistical models typically use a 100-year precipitation record to estimate severe rainfall events, often overlooking natural global climate changes. Predicting extreme events like a 1-in-10,000-year flood is challenging due to climate change's unpredictability over such a long timeframe. Therefore, the focus should shift from a 1-in-10,000-year flood parameter to eliminating risks through innovative tailings disposal technologies. Methods like dry stacking, in-pit disposal, and paste disposal offer viable alternatives for risk reduction and environmental rehabilitation. For operational or actively closing TSFs, a 1-in-10,000 flood criterion minimizes current risk but escalates during passive closure due to global climate change. This necessitates continuous evaluation and proactive measures to address evolving climate challenges. In summary, this study advocates for a comprehensive approach to TSF management, recognizing the intertwined nature of geological, climatic, and technological factors. It emphasizes shifting from predicting extreme events to actively eliminating risks, promoting sustainability and resilience in TSFs.

Introduction

Climate change has long been a powerful influence on Earth, shaping coastlines, landscapes, and ecosystems over millions of years. Its primary drivers have been geological processes such as volcanic activity and the movement of continents, as well as Orbital Earth Cycles. These cycles have led to at least

five major ice ages in the last 2 billion years. The most recent ice age began 3 million years ago and persists to this day. We are currently in a warm interglacial period that started 11,000 years ago.

Milankovitch cycles and global climate change

Milankovitch (Orbital) cycles have a profound influence on Earth's climate and the mechanisms through which changes in Earth's orbit and axial tilt shape long-term climate trends. Milotin-Milankovic's groundbreaking hypothesis proposed that changes in the Earth's position relative to the Sun, known as Milankovitch cycles, played a key role in climate change and the onset of the ice ages. Three key orbital motions, including eccentricity, tilt, and precession, are examined in detail for their influence on the distribution of solar radiation and weather patterns.

Eccentricity refers to the shape of the Earth's orbit around the Sun, with variations affecting the distance between the Earth and the Sun and the amount of solar radiation received. The tilt of the Earth's axis affects the intensity of seasons and the extent of glacial periods, and larger tilt angles favor deglaciation. Precession, the direction of the Earth's axis of rotation, contributes to changes in the timing and distribution of solar radiation, especially in high latitude regions.

The Milankovitch cycles contribute to the periodic onset of ice ages, which occur every 41,000 years, and the transition to longer interglacial periods, which occur every 100,000 years. While the exact mechanisms behind this transition remain a matter of science, Milankovitch's theory has been widely accepted and supported by subsequent research. Evidence from deep-sea sediment cores and ice cores in Greenland and Antarctica supports the role of Milankovitch cycles in driving major climate changes on geological time scales (NASA Science Editorial Team, 2020). Despite ongoing research to further understand the complex interactions between Earth's rotation and climate dynamics, the Milankovitch cycle theory of glacial-interglacial cycles is well established in the scientific community.

According to the Milankovitch cycle, the Earth is currently in a position where its long-term cooling trend, which began 6,000 years ago, is projected to persist for the next 23,000 years. Over the next 100,000 years, Earth's orbit will become less eccentric, resulting in changes dominated by variations in obliquity rather than eccentricity. Consequently, it is unlikely that there will be a significant decline in insolation to trigger a new glacial period within the next 50,000 years (NASA Science Editorial Team, 2020). However, it is essential to note that while orbital variations provide insights into future climate, other factors such as human-induced greenhouse gas emissions can significantly influence climate dynamics.

In the context of contemporary climate debates, the potential for another ice age remains a topic of debate among scientists and researchers. While some argue that future ice ages are less likely as the Earth warms, disrupting traditional weather patterns and intensifying greenhouse gas concentrations, others focus on the role of long-term atmospheric forces due to the Milankovitch cycle.

Proponents of the orbital forcing theory believe that despite current human influences on climate, natural astronomical cycles will eventually push Earth into another ice age, albeit on a time scale of tens of thousands of years. Studies on celestial mechanics and climate change show the complex interplay of orbital parameters in modulating Earth's climate over geological timescales and emphasize the complex relationship between celestial mechanics and terrestrial climate dynamics (Abouelmagd et al., 2024).

Finally, the outlook for future ice ages is uncertain, as competing hypotheses and models offer different predictions. Continued research on past climate events, along with advances in climate modeling and observational techniques, will be necessary to elucidate the complex mechanisms governing Earth's climate change and to predict the long-term trajectory of global climate change.

Changes to the climate during the last 10,000 years

Ice ages are integral seasons of Earth's climate history, characterized by extensive glaciation and much colder temperatures compared to interglacial periods. These ice ages, defined by the expansion of the polar ice sheets and the lowering of global sea levels, have occurred repeatedly throughout Earth's existence. Scientific evidence suggests that there have been at least five or six major ice ages in the planet's geological past, interspersed with numerous smaller ice ages. Figure 1 illustrates the present-day interglacial state (a), and the Quaternary glacial state (b).

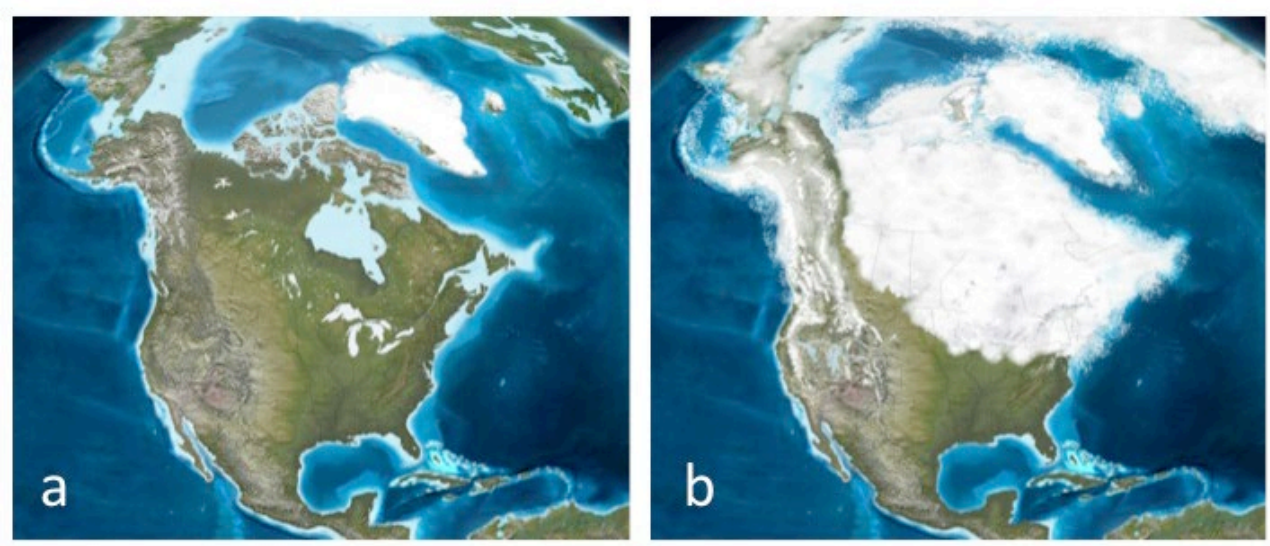

Figure 1: (a) Present-day interglacial state, (b) Quaternary glacial state (Glaciation, 2017)

Each ice age is usually followed by a warming period known as an interglacial period. Currently, Earth is experiencing one of these interglacial phases, which began approximately 10,000 years ago after the last Great Ice Age peaked about 21,000 years ago. During this interglacial period, the global temperature

gradually increased, leading to the retreat of glaciers, and creating more hospitable conditions for life. The effects of climate change since the last ice age have been manifested in many ways and are profoundly affecting natural systems and human societies.

About 13,000 to 15,000 years ago in North America, melting and receding ice formed the Great Lakes and flooded many areas in today's Washington state, Oregon, and Utah. The sea-level rose, attributed to the thermal expansion of seawater and the melting of land glaciers.

The Black Sea Flood hypothesis, proposed by William Ryan, Walter Pitman, Petko Dimitrov and colleagues in 1997, provides a convincing explanation for a major geological event about 8,400 years ago. According to this hypothesis, rising sea levels in the Mediterranean breached the natural barriers and flooded the former freshwater lake of the Black Sea about 7,600 years ago, marking a transformative moment in the region's ecological history (Figure 2). Evidence supporting this hypothesis includes sedimentary deposits and submerged archaeological sites discovered in the Black Sea Basin, which provide tangible clues to past geological and climatic dynamics. At the same time, the Persian Gulf was formed due to rising sea levels.

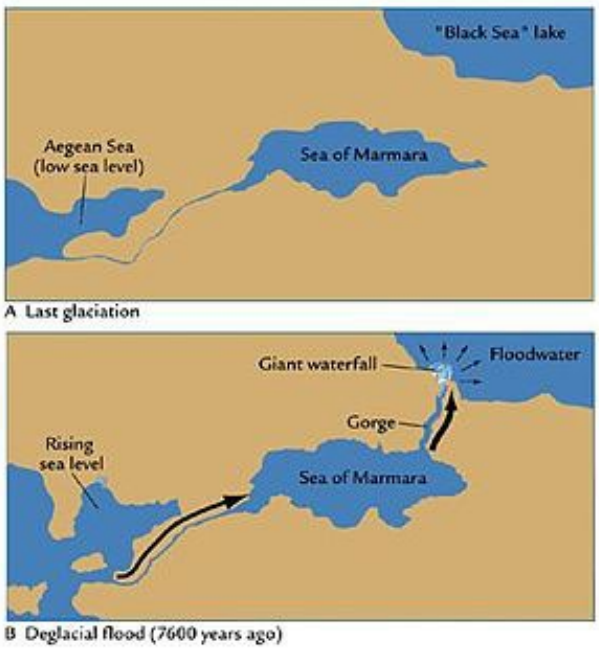

Figure 2: A vast area of the Black Sea flooded, causing sea levels to rise and coastlines to change (Fields, 2014)

Most floods generated by melting ice were catastrophic, destroying anything in their pathway. In 1996, William Pitman, a geologist, provided an illustrative catastrophic description and evidence of the Black Sea flood in his controversial theory of the Great Deluge (Glaciation, 2017):

1. By the end of the last ice age (around 12500 BC), glacial meltwater formed huge freshwater lakes, including the present-day Black Sea. Meltwater also cascaded into the world's oceans, raising sea levels by 400 feet.
2. According to the flood hypothesis, the rising Aegean Sea overran a natural barrier at the present-day Bosporus strait. Carbon dating of the shells of the first marine mollusks to arrive in the Black Sea dates the flood to 5600 BC.
3. Evidence indicates seawater rushed into the Black Sea region at a rate 200 times greater than Niagara Falls, turning the lake brackish.
4. The resulting flood would eventually have covered 60,000 square miles of land in about one year, expanding the Black Sea to its present boundaries.
5. Stone tablets inscribed with the Epic of Gilgamesh were discovered at Nineveh, 560 miles from the Black Sea. The flood story in Gilgamesh may be inspired by the Black Sea event.
6. The Genesis story of Noah, which dates to the ninth century BC, is derived from the epic of Gilgamesh, which incorporates sources as old as 2100 BC. Similar flood stories are also found in the epic literatures of Greece, India, Burma, and Borneo.

Human-induced climate changes

While natural factors such as changes in solar radiation and volcanic activity have historically played a key role in the initiation of ice ages, human-induced changes in the atmosphere, particularly increased greenhouse gas emissions, are now contributing to unprecedented changes in the dynamics of global weather.

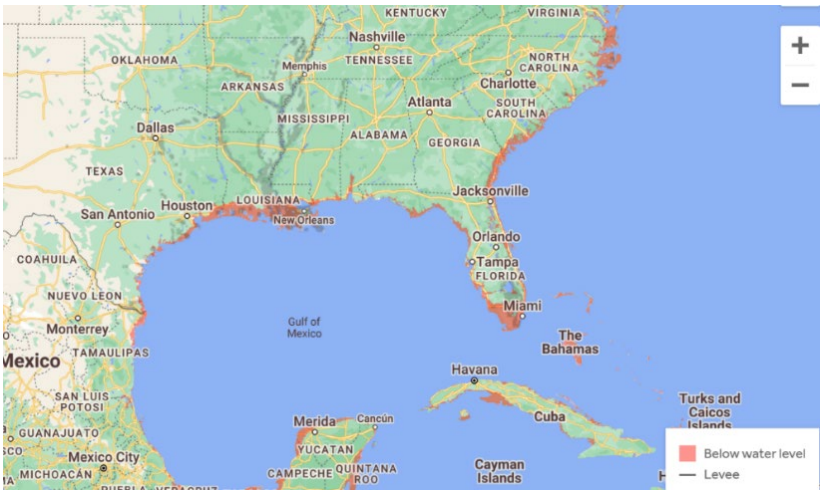

Figure 3: Gulf of Mexico coastal area simulated 5 m rise in sea level (source: Climate Central, 2024)

The effects of climate change since the last ice age have been manifested in many ways and are profoundly affecting natural systems and human societies. Sea-level rise, attributed to the thermal expansion of seawater and the melting of land ice, poses significant threats to coastal communities around the world. Global sea levels rose by an average of 8 inches (20 cm) from 1880 to 2009, according to a 2019 study published in the journal *Nature*. Forecasts indicate a rapid increase in sea level in the next few decades due to continuous melting of ice and thermal-induced water expansion. Based on NASA predictions, by the year 2500 global ocean levels may rise by 5 m, or even by 14 m in the worst-case scenario.

Climate change increases the frequency and severity of droughts, floods, and fires, and exacerbates risks to ecosystems, agriculture, water resources, and human settlements. Research published in the *Proceedings of the National Academy of Sciences (PNAS)* in 2020 identified a significant increase in the frequency of extreme precipitation events worldwide, leading to increased flood risks in many regions. Similarly, the increased incidence of extreme droughts, such as the prolonged drought documented in this study from 915 to 1025, as well as the intensification of wildfires, underscores the wide-ranging impacts of climate change on social stability and ecological resilience.

Closure criteria for tailings storage facilities

According to the Global Industry Standards on Tailings Management (GISTM) outlined by the International Council on Mining and Metals (ICMM, 2020), passive closure for all tailings facilities mandates resilience against the impact of earthquakes or floods equivalent to a 1-in-10,000-year event. But what does this entail specifically for flood design criteria? Let us delve into that in this paper.

Requirement 5.3 of the GISTM states: *"Develop, implement and maintain a water balance model and associated water management plans for the tailings facility, taking into account the knowledge base including climate change, upstream and downstream hydrological and hydrogeological basins, the mine site, mine planning and overall operations and the integrity of the tailings facility throughout its lifecycle. The water management program must be designed to protect against unintentional releases."*

From the above, the design must be resilient enough to address the following key points:

- floodwater at the site;
- floodwater originating from upstream sources;
- floodwater flowing from downstream sources;
- changes to groundwater; and
- anticipating the impacts of climate change.

Hence, for passive closure to be effective, the design must fulfill all these criteria, ensuring resilience against the extreme scenario of 1-in-10,000-year flood event.

How extreme rainfalls are estimated

How do we go about estimating a storm event that occurs only once in 10,000 years if our climate data spans less than a century, or even less than 50 years? In such situations statistical techniques are employed to extrapolate to a 1,000- or 10,000-year event. Numerous statical methods exist, with each tailored to the distribution of existing rainfall events. These methods typically aim to identify the most suitable fitting curve for the available data.

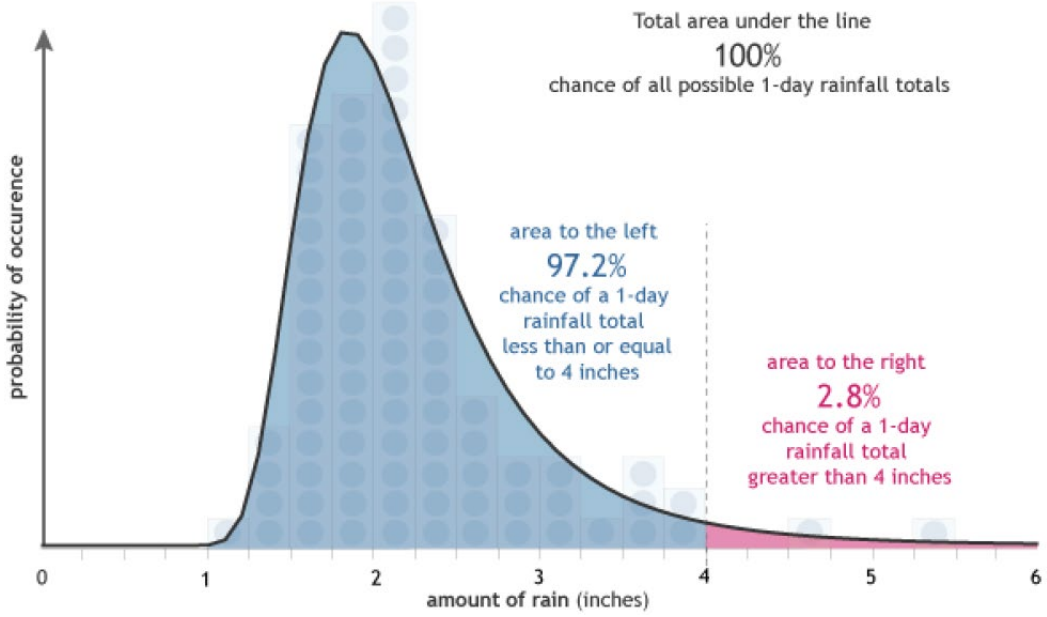

Figure 4: Statistical distribution of 1-day rainfall events. 82-year histogram of annual daily maximum precipitation totals for Beckley, West Virginia (source: Climate Central, 2024)

Figure 5 illustrates the distribution of individual recorded rainfall depicted as dots. The best fit distribution trendline (the curved line) delineates a theoretical spectrum of all potential extreme rainfall events, ensuring that the total area beneath it equals 1.0 or 100%. To determine the likelihood of a rain event exceeding a certain amount, the percentage of the total area to the right of that rainfall threshold is calculated. Conversely, the probability of a rain event falling below or equal to a specific threshold is derived by subtracting the area to the right of that threshold from 100%. Figure 4 indicates, for instance, a 2.8% chance of experiencing rainfall equal to or greater than 4 inches on any given day.

With the ability to determine the probability of a given rainfall amount, we can also ascertain which rainfall amounts correspond to specific probabilities, such as 0.1%. In other words, we can identify a rainfall threshold for events like a one-in-1,000-year event, as shown in Figure 5.

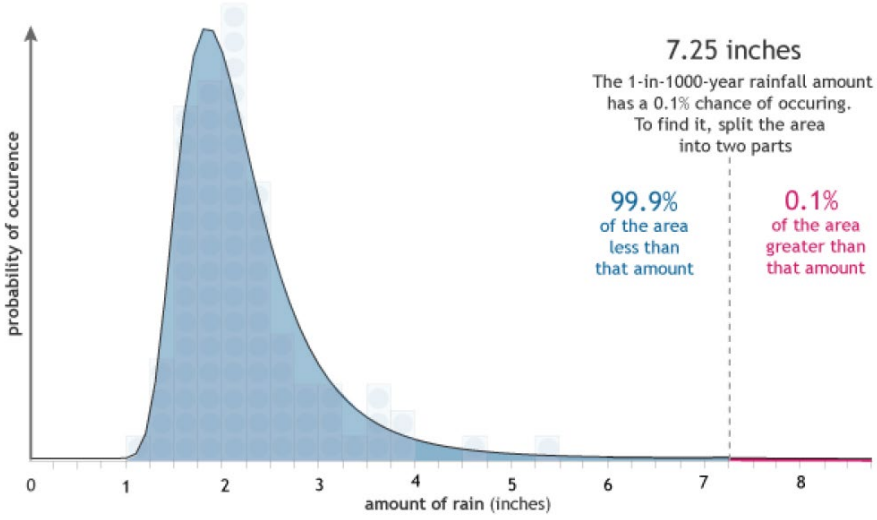

Figure 5: Determining 1-in-1,000-year rainfall, based on Figure 4 histogram

It is possible to extend the frequency analysis to estimate even more extreme events such as a 10,000-year event by extrapolating from the statistical distribution of rainfall data. However, beyond 1-in-1,000 or -2,000 events the reliability of the method is not certain, and the larger the Annual Exceedance Probability (AEP), the larger the uncertainty. It is thought that the estimated AEP for the probable maximum precipitation (PMP) events may have an estimated error in the range of two orders of magnitude (Nathan et al., 2013), as shown in Figure 6. Conversely, the estimated rainfall value for the given AEP is also uncertain and may have a wide error.

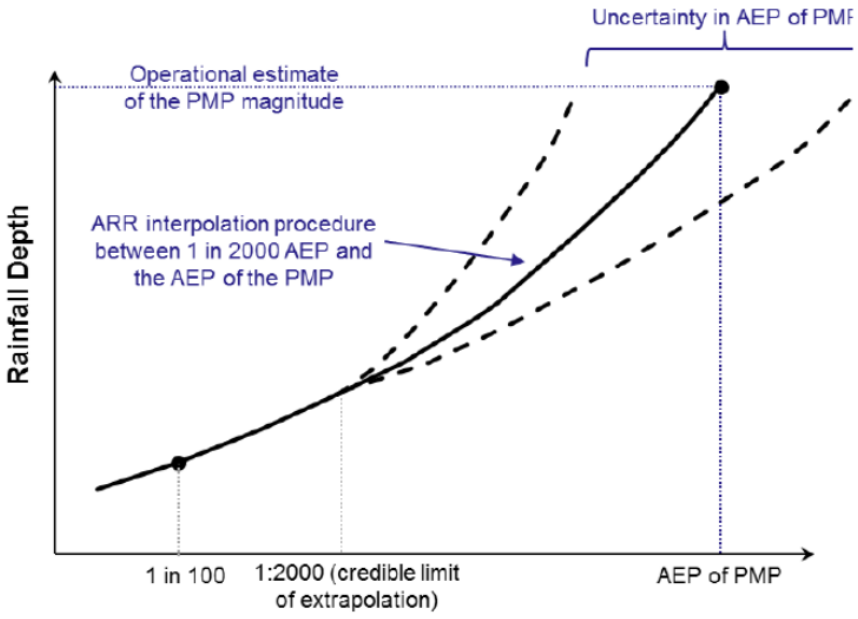

Figure 6: AEP and PMP uncertainty (source Nathan et al., 2013)

Climate change impact on rainfall frequency analyses

Can climate change impact the statistics of rainfall frequency analyses? Absolutely! Climate change significantly complicates this process. When scientists rely on past observations to understand climate patterns, they ideally seek a stable climate. A changing climate makes this task more challenging because historical data may no longer accurately represent current or future conditions. Global warming has the potential to completely shift the natural distribution of climate variables. More and more often, we observe 1-in-100 or 1-in-1,000-year rainfall events reported around the globe, and climate change is likely to increase the frequency of extreme precipitation events. What was once considered a rare occurrence, like a 1-in-20 year extreme 24-hour precipitation event, may become more common in the future, occurring with a frequency closer to 1 in 5 years. This presents a dilemma for scientists: they must assess the rarity of extreme events based on historical data, while also acknowledging that climate change is altering the likelihood of these events occurring. This will alter the statistics of flood frequency analyses and increase uncertainty regarding the estimation of extreme flood events.

In essence, climate change introduces a level of uncertainty into the analysis of past climate data and the prediction of future climate scenarios. Scientists must navigate this uncertainty to provide accurate assessments of climate-related risks and impacts. This underscores the importance of continually updating methodologies and models to account for the dynamic nature of the climate system under the influence of climate change.

Climate change modeling relies heavily on understanding the fundamental physical processes that underpin how precipitation patterns may change in a warming world. With rising temperatures, increased evaporation and surface drying can contribute to the intensification and prolongation of droughts in certain regions. However, it is essential to consider the impact of warmer air on the air's capacity to hold moisture, as described by the Clausius-Clapeyron equation. For every 1°C rise in temperature, the air can typically hold around 7% more moisture. Consequently, a world approximately 4°C warmer than the pre-industrial era would potentially have about 28% more water vapor in the atmosphere. However, this additional moisture will not be distributed uniformly across the globe. Some regions may experience heightened precipitation, while others may witness reduced rainfall due to shifting weather patterns and various influencing factors. This complex interplay of physical processes underscores the dynamic nature of climate change's impact on precipitation patterns, highlighting the importance of comprehensive and nuanced analysis in understanding regional climate variations and potential future scenarios.

Uncertain predictability of climate change

Utilizing current climate change models, scientists can project the trajectory of global climate patterns for

the next century, primarily driven by human activity-induced changes in atmospheric moisture, temperature, and rainfall distribution. These models enable the estimation of the likelihood of extreme weather events, such as rainfall with a 1-in-100-year return period. However, the precision of these projections diminishes when examining rainfall frequencies beyond the 1-in-100-year threshold, particularly for events ranging from 1-in-1,000 to 1-in-10,000 years. The uncertainty surrounding these rare events underscores the complexity of predicting long-term climate trends with absolute certainty.

In addition to anthropogenic influences, climate change stemming from natural factors like the Milankovitch cycle also plays a significant role in shaping global climate over millennia. This astronomical phenomenon, occurring on a scale of approximately 20,000 years, introduces potential cooling effects that could counteract the warming attributed to human activity. However, the compounded impact of both human-induced and Milankovitch-driven climate changes remains poorly understood. Consequently, certain regions may experience heightened precipitation, while others may face increasing aridity, leading to shifts in landscape and climate zones.

Furthermore, the melting of ice from polar regions, such as Antarctica and glaciers, poses a substantial threat by raising sea levels and inundating low-lying coastal areas. This influx of water not only alters coastal landscapes but also contributes to changes in the patterns of ocean currents, potentially intensifying storm systems and exacerbating flooding events. The resultant increase in violent storms and widespread inundation poses significant challenges for coastal communities and infrastructure resilience. There are many different climate change models, and researchers cannot agree about how climate change may go, and which areas will become wetter or drier. However, all of them agree that significant changes are coming, one way or another, by the end of this century. Figure 5 shows the results of two climate change models. The one on the left predicts hotter, drier climate and the one on the left predicts hotter, wetter climate. The truth could be somewhere in between: some areas may become drier and some areas wetter, and some areas may experience violent extremes in weather changes over a short period of time.

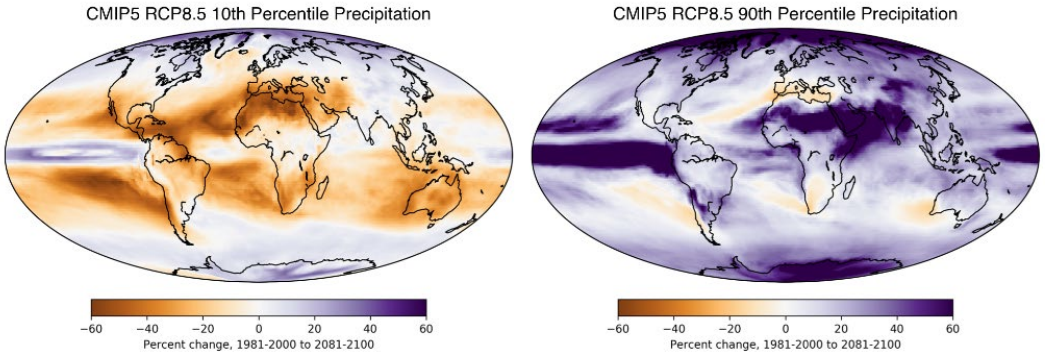

Figure 7: Two models for global climate change: 10th percentile of mean precipitation changes (left map) and 90th percentile (right map) for total precipitation (rain and snow) for each 1×1 latitude/longitude grid cell between 1981–2000 and 2081–2100 (source: Carbon Brief, 2018)

As climate zones and geographical boundaries undergo transformation, formerly arid regions may witness the emergence of lakes and rivers, while deserts may experience shifts towards more humid conditions. These changes to the natural landscape will have profound implications for ecosystems, water resource management, human settlements, and infrastructure.

Design of resilient tailings storage facilities

Consequently, the long-term implications of climate change on tailing storage facility (TSF) design criteria remain uncertain. Even TSFs designed to withstand current climate conditions may become vulnerable to the evolving climate landscape, necessitating adaptive measures to mitigate risks associated with increasingly unpredictable weather patterns. In other words, if the TSF is designed for 1-in-10,000 years based on current statistical models, it does not necessarily mean that the structure will survive 10,000 years, it simply means that the current risk of annual exceedance is 0.0001, and this risk will increase with climate change. The potential for much greater rainfall events, alterations to regional landscapes, and heightened vulnerability of existing TSFs highlight the urgent need for proactive planning and resilient design strategies in the face of ongoing climate change.

Examples of more resilient strategies for TSF disposal would include:

- Utilizing underground and in-pit disposal methods.
- For closure, preferring dry covers over wet covers.
- Implementing filtered tailings technology, which is less prone to failures and more suitable with dry covers.
- Stabilizing tailings with chemical additives such as fly ash and polymers.
- Focusing on process and metallurgy techniques that eliminate toxic compounds at the process level, ensuring the waste is non-hazardous.

Selection of each strategy should be performed based on the evaluation of multiple accounts including geological settings, topography, climate and expected changes to the environment. Paste technologies with underground disposal as well as in-pit disposal methods seem to have the least environmental footprint and are the most resilient to erosion and future climate changes. However, these methods are not always possible and economically justified. Dry stacking of filtered tailings would be the second choice for the most resilient tailings strategy. After closure, these facilities are assumed to be fully drained, and therefore the potential for failure is minimal. The slopes can be covered with erosion protection material and the slopes can be further stabilized by berms or armor for long-term stability and erosion protection. The last choice should be conventional slurry tailings disposal facilities. These structures are difficult to manage and may

entrap pore water within tailings. This is difficult to drain and may create a risk of liquefaction and failure for many years after closure.

Conclusion

The last 10,000 years of global climate history have demonstrated that radical climate shifts can occur, leading to significant changes in coastlines and landscapes. Current climate prediction models may be unreliable, as they are based on limited data and fail to consider all factors, such as the Milankovitch cycles, changing ocean levels, and currents. Compounding the effect of human-made climate change and Milankovitch cycles is not well understood. We must prepare for significant climate changes over the next 10,000 years, though the severity and geography of these changes are unpredictable. Many arid regions may become more arid or wet, while humid areas may become wetter. Numerous areas may be inundated by new rivers, lakes, or oceans. Many TSF sites, even those designed to the highest GISTM standards, could become inundated or eroded.

The potential for increased rainfall, flooding, alterations to regional landscapes, and the heightened vulnerability of existing TSFs, underscores the urgent need for proactive planning and resilient design strategies in response to ongoing climate change.

Credible Failure Modes: Considerations for Assessment and Application

Scott Martens, Teck Resources, Canada
Angela Kupper, BGC Engineering, Canada

Abstract

A core requirement of the Global Industry Standard on Tailings Management (GISTM) is to minimize risk for all credible failure modes for all phases of a tailings facility lifecycle. The intention of this requirement is to confirm that all potential failure modes are considered in the risk evaluation and that the related hazards and consequences are appropriately controlled to minimize the associated risk with all credible failure modes.

Identifying and addressing all credible failure modes is essential to support the development of robust risk management systems to prevent the hazards from causing failures. The credibility of potential failure modes is generally evaluated against a standard of negligibility, and the bar to demonstrate negligibility must be set very high. Removing potential failure modes from consideration without sufficient rigor may lead to inadequate: design oversight, construction quality control, adherence to operating requirements, or surveillance and monitoring, all of which could be seen to be unnecessary if credible failure modes are incorrectly removed from consideration. A robust failure modes assessment must consider not just the reserve capacity of the system under "extreme" loading, but also the potential for uncertainties due to insufficient site investigations, mischaracterization of materials, numerical models that do not fully capture soil or rock behavior, construction defects, computational errors, non-adherence to the operating procedures, other human errors, and the inherent uncertainties associated with geotechnical engineering.

With robust designs using multiple layers of defense based on comprehensive site investigations that adopt redundant and complementary tools and methods, rigorous construction quality control, and comprehensive performance monitoring, tailings and mine waste facilities can achieve the very high levels of safety and reliability that are required of all critical infrastructure. For this, proper identification and management of credible failure modes are essential.

Introduction

The GISTM was released in 2020 to support safe management of tailings facilities, following catastrophic tailings dam failures. A core requirement of the GISTM is to minimize risk for all credible failure modes for all phases of a tailings facility lifecycle. The GISTM and the International Council on Metals and Mining (ICMM) Tailings Management Good Practice Guide (GPG), (and other systems for responsible tailings management practice) require that all credible failure modes be identified and that robust controls be implemented to manage the hazards that could lead to a failure with unacceptable consequences. However, there has been debate on the interpretation and approach to consider credible failure modes. Although the GISTM sparked the debate for tailings facilities, the discussion in this paper is also applicable to other mine waste facilities. This paper discusses credible failure modes and the concepts and approaches to assess them, such that all potential failure modes are considered in the risk evaluation, the list of credible failure modes is comprehensive and complete, and all hazards and consequences are appropriately controlled to minimize the associated risk to a "negligible" level. The bar to demonstrate negligibility must be set very high.

There are unfortunate examples where engineering systems that were believed or assumed to have no credible failure modes have failed, or where risks have been significantly underestimated. Most of these have resulted from the lack of robustness around the identification and evaluation of potential failure modes. Not recognizing the existence and credibility of potential failure modes can lead to inadequate: design oversight, construction quality control, adherence to operating requirements, and/or surveillance, all of which could be seen to be unnecessary if there are believed to be no credible failure modes.

A structure can be very safe and still have credible failure modes, provided they are all appropriately managed to a very low risk level. There is minimal correlation between the number of credible failure modes and actual safety. This is evident from commercial aviation, where learning from past failures and adoption of a safety culture has resulted in very high levels of safety, despite there being hundreds or thousands of credible failure modes for each aircraft. Aviation safety incorporates design reviews and testing, redundant systems, personnel training (pilots and maintenance personnel among others), operational procedures including air traffic control, inspections and maintenance, and emergency planning, that together result in an exceptionally low probability of serious incidents. In 2023 there was a single fatal accident of a scheduled commercial aircraft out of 38 million flights (about 100,000 flights per day), which resulted in a fatal accident rate per flight of 3×10^{-8}, and a 5-year average from 2019 to 2023 of 1×10^{-7} (IATA, 2024). The flight fatal accident rate has consistently reduced over time through a combination of improvements in engineering, manufacturing quality, procedures and technology. Despite the differences between the tailings and aviation industries, this analogy demonstrates that it is possible for complex systems to be operated very safely when the risks of potential failure modes are controlled.

A failure modes assessment starts by developing a comprehensive catalogue of all physically possible failure modes, from which the credible failure modes are assessed, and risk treatment plans are developed. The aim of a failure modes assessment should be to identify all credible failure modes, so that the hazards and consequences can be managed appropriately. Acknowledging the reality and credibility of potential failure modes is essential to develop robust risk management systems to prevent the hazards from causing failures. Starting from a corporate safety culture that is declared and supported at the level of the Board of Directors, implemented with robust designs using redundant tools and multiple layers of defense, rigorous construction quality control, and comprehensive performance monitoring, tailings and mine waste facilities can also achieve the very high levels of safety and reliability that is required of all critical infrastructure. For this, proper identification and management of all potential failure modes is essential.

Definitions of credible failure modes

FEMA (2015) defined credible potential failure modes as: "*A potential failure mode that is considered to affect the total risk at a given dam and for which action could potentially be taken to reduce risk. A non-credible potential failure mode is a potential failure mode which is judged to have very low risks and for which a strong case can be made to that affect. Non-credible potential failure modes are often judged to represent a risk that is well below tolerable risk guidelines and orders of magnitude less than that of the more dominant potential failure modes at a given dam.*"

The GISTM (2020) definition is as follows: "*Credible Failure Mode / Scenario – Refers to technically feasible failure mechanisms given the materials present in the structure and its foundation, the properties of these materials, the configuration of the structure, drainage conditions and surface water control at the facility, throughout of its lifecycle. Credible failure modes can and do typically vary during the lifecycle of the facility as the conditions above vary. A facility that is appropriately designed and operated considers all of these credible failure modes and includes sufficient resilience against each. Different failure modes will result in different failure scenarios. Credible catastrophic failure modes do not exist for all tailings facilities. The term 'credible failure mode' is not associated with a probability of this event occurring and having credible failure modes is not a reflection of facility safety*."

The intent of the last sentence in the GISTM (2020) definition was to highlight that the existence of credible failure modes is not related to the safety of a facility since acknowledging a credible failure mode is not a statement of whether its probability is high or low. The probability of occurrence of any credible failure mode (and the safety of the facility) is associated with how that failure mode is managed. However, determining a failure mode to be a non-credible failure mode must be associated with an extremely low ("negligible") probability of occurrence as discussed further below.

FERC (2021) gave the following definition and discussion: "*Credible – A term used to indicate that a potential failure mode is considered to be physically possible and the likelihood of the potential failure mode is not considered so remote as to be negligible*." FERC notes that "*So remote as to be considered clearly negligible"* means that *"the likelihood of the potential failure mode (PFM) leading to failure is so minute so as not to be considered credible, and in quantitative terms, an annual frequency less than 1/1,000,000.*"

Threshold of negligibility

As implied by the three definitions above, there is not a single, widely accepted understanding of what conditions need to be satisfied for a failure mode to be considered non-credible (Small et al., 2023). It is common to consider that failure modes that are considered to have a "negligible" probability of occurrence are non-credible failure modes. "Negligible" is commonly defined as "*so small or unimportant as to be not worth considering*."

Some organizations have established a threshold of negligibility to be in the range of an annual probability of exceedance of 1/1,000,000 to 1/10,000,000 (10^{-6} to 10^{-7}) (FERC, 2021 and Morrison and Byler, 2022, respectively). However, we note that the threshold of what is "so small or unimportant as to be not worth considering" is dependent on the consequences. The FEMA (2015) definition referred to "risks" thus acknowledging both probability and consequence. Negligible events are commonly considered to be not only the ones that occur exceedingly infrequently (such as meteor strikes on dams) but also the ones with minor consequences. For example, a relatively high probability of getting a scratch from a tree branch while hiking in Banff could be considered a negligible event; a much lower probability of encountering a grizzly bear on the same hike would not be considered negligible, or "so small or unimportant as to be not worth considering." If the consequence is minor, an event "not worth considering" may be relatively common, whereas for a very severe consequence, even an annual probability of 10^{-6} may require further consideration. If large numbers of lives are at risk, this annual probability of occurrence would need to be even lower. This notion is honored in the As Low as Reasonably Practicable (ALARP) criteria that were originally developed by HSE (2001) and modified by others for application to dams. It is noteworthy that a fatal commercial aviation accident rate of 1/38 million would be considered negligible based only on the probability ranges above, but the aviation industry and regulators consider the failure modes to be credible and strive to further reduce the risk of these failure modes, consistent with the principles of ALARP.

It is conceptually important that the range of probabilities associated with negligibility is much lower than an "Extreme" event with an annual probability of exceedance of 10^{-4}. The annual probability of exceedance for design loading associated with Extreme consequence of failure facilities recommended by

the GISTM and other guidelines (CDA 2007; ICOLD 2022) of 10^{-4} is not meant to be an acceptable risk level or the threshold of negligibility; the system must still have a low probability of failure given the occurrence of the extreme event. For example, to meet a 10^{-6} annual probability of failure criterion, a seismic stability assessment would need to demonstrate not just that the slopes are designed to withstand seismic ground motions with an annual probability of exceedance of 10^{-4}, but also that the conditional probability of loss of containment, given the occurrence of that level of ground motion, would be no more than 1% (since 1/10,000*1/100 = 10^{-6}). This understanding assists in setting the performance expectation for seismic loading, if the failure mode is to be considered non-credible and assuming the potential consequences of a failure support 10^{-6} as an acceptable level. While it is not necessary to invoke a specific numerical threshold for negligibility, the ranges noted above provide an idea of the robustness necessary for designs such that potential failure modes meet a condition of negligibility.

These probabilities provide a conceptual indication of the threshold of negligibility; however, it is cautioned that humans are very poor at estimating low probabilities, and very frequently estimate values that are much lower than reality (Vick, 2014). NASA is widely regarded as one of the most technologically sophisticated organizations in the world, yet NASA senior management believed that the probability of a catastrophic loss of a Space Shuttle was 1/100,000 (Vick, 2002); the actual value was 1/68 (two catastrophic vehicle losses in 135 flights). It is particularly difficult to quantify the probability of failure in cases where there is only a small number of case histories for the loading event or failure occurrence (unlike for floods and seismic events where the return period can be estimated statistically).

Assessment of credible failure modes

A multi-disciplinary team should be engaged to assess potential failure modes. The team's composition would be determined for each specific case, but it could include geologists, dam designers (all relevant disciplines: soil and rock mechanics, seismic specialists, hydrology and hydraulics, modelling, etc.), construction personnel, operations personnel, the monitoring team and others. The variety of viewpoints and experiences in a multi-disciplinary team is critical to the robustness of the assessment.

The team should start by focusing on producing a comprehensive and complete list of potential failure modes. The potential failure modes assessment process can be viewed as a series of gates. First, only failure modes that are clearly not physically possible can be eliminated without additional consideration. Second, some potential failure modes may also be determined to be non-credible if sufficient evidence already exists to conclude that the probability and/or the consequences of failure are clearly negligible. Third, all other potential failure modes would be assessed in detail using investigation data and analyses to determine whether they meet criteria for negligibility, have already been managed to an acceptably low level of risk or need to be managed to an acceptable level of risk. The final result of the assessment should be a list of

all potential failure modes and the basis for determining them to be either non-credible, already at an acceptable risk level, or required to be managed to an acceptable and ALARP risk level.

A robust credible failure modes assessment must consider not just the system reserve capacity under "extreme" loading, but also the potential uncertainties due to insufficient site investigation, mischaracterization of materials, numerical models that don't fully capture soil or rock behavior, construction defects, computational errors, limitations to the current level of human knowledge in all technical disciplines, non-adherence to the operating procedures, other human errors, and as noted by Morgenstern (2024) the inherent uncertainties in geotechnical engineering. A degree of humility is required in assessing the above, in particular the ranges of uncertainty. As stated by Donald Rumsfeld in a US Department of Defense briefing in 2002 "… as we know, there are known knowns; there are things we know we know. We also know there are known unknowns; that is to say we know there are some things we do not know. But there are also unknown unknowns – the ones we don't know we don't know" (United States Department of Defense, 2002). A robust credible failure modes assessment should therefore also contemplate the potential for "unknown unknowns."

Detailed documentation of all the above should be prepared to allow independent review of the assessment and to demonstrate the thoroughness of the process. Moreover, potential and credible failure modes change with time and the assessment needs to be reviewed and revised as required. Credible failure modes may change if there are changes to the downstream condition or changes to the facility and its operations, such as additional raises, change in pond management, re-start after a long pause, etc. FERC (2021) recommends "Just because a potential failure mode is clearly negligible does not mean that it should not be re-evaluated under each subsequent PFMA (potential failure modes assessment)" and therefore should be retained in the documentation in case conditions change since the previous assessment. Detailed documentation provides a good basis for starting a reassessment of potential failure modes and the impact of changes or for reviewing the assessment after changes in staff or ownership. There are several case histories of failures caused by a poor understanding of the failure modes after a long pause in operations and/or change in ownership (Stava in Italy in 1985 killing 268 people, Jagersfontein in South Africa in 2022).

An assessment of credible failure modes must consider both primary and secondary, or dependent, failure mechanisms. For example, direct overtopping of a tailings facility may have a negligible probability if the facility is designed to store significantly more than the Probable Maximum Flood (PMF) or pass this through a spillway. However, that should not immediately lead to the conclusion that failure due to overtopping is not credible since secondary mechanisms, such as a rapid landslide into the pond that is triggered by the elevated pond water level in conjunction with heavy precipitation, could create a wave that overtops the dam. An example of this was the Vajont dam in Italy in 1963, where a large, rapid landslide

created a 250 m high wave that overtopped the dam, leading to the deaths of about 2000 people. In that case, the possibility of a landslide creating a wave that could overtop the dam had been considered, and based on model studies concluded that the effects of a wave would cause negligible damage, and that this conclusion "can be considered absolutely certain with regard to even the most foreseeable catastrophic landslide event" (Datei, 2005). In that case, the confidence on the model predictions was tragically overstated; a reminder of the need to consider uncertainties in the assessment of potential failure modes.

Table 1 is a non-exhaustive list of factors that should be considered in assessing the credibility of failure modes. The quality of the data, its representativeness and the uncertainties associated with each of the factors must be considered in evaluating credible failure modes. It is important to be aware that the level of knowledge is constantly evolving, and any current assessment will have limitations.

Table 1: Examples of factors to be considered in assessing credible failure modes

Is the spacing of boreholes sufficiently close that a geologically plausible weak material large enough to compromise the integrity of the structure could not exist between boreholes?
Are the boreholes deep enough that any weak material below the base of the boreholes could not compromise the integrity of the structure?
Are the soil properties understood well enough that there is no plausible condition where the soil strength would be less than considered in the analysis (including considerations of undrained vs. drained strength, and residual vs. peak strength)
Are the constitutive models for soil and rock behavior correct, or are there some aspects of the material behavior that may not be accurately modelled?
Do the materials vary at a scale that is not practical to replicate in analytical models (such as thin sand and silt layers in a tailings beach)?
Is material behavior well understood over the full range of stresses? Is the design outside of precedence for stress range, for the materials in the embankment and foundation?
Could there be a change in saturation in the long term due to continuous operation, infiltration and/or rise in groundwater levels, or a change in material properties due to chemical effects?
Could a gap in the construction quality control (QC) have resulted in a defect large enough to cause a failure?
Do multiple models using different approaches (analytical vs empirical, different but appropriate models of material behavior, etc.) all result in the same conclusion ("converging lines of evidence").
Could there be a landslide into the reservoir or the top of the facility?
Does the safety of the facility rely on any human action, such as operating a return water/fluid system?
Is monitoring required to identify the need for corrective action?
Could a spillway or water diversion system become blocked by debris?
Could the spillway itself fail (similar to the Oroville dam) and could this lead to retrogression into the facility or a different failure mode?
Do predictions of extreme events account for factors such as climate change?
Could internal erosion occur due to: Changes in the water table? Failure of a seepage control element, such as a drain or an internal collector pipe drain? Biological or chemical clogging of a filter or drain? Seepage through the abutment of the facility? Insufficiently compacted layers? Inconsistency of fill gradation? Defects in a geosynthetic liner? Chemical alteration or Dissolution of soluble elements in the foundation or abutments?

Validity check

A check on the validity of a conclusion that a particular failure mode is non-credible is that it should logically lead to the absence of a requirement for critical controls for that failure mode. Changes to the facility that increase the robustness through passive measures such as toe berms could render failure modes non-credible. However, any system that requires active human input or intervention to prevent a failure has credible failure modes, though a well-designed system with redundant checks and balances could render the probability of failure sufficiently low to be considered safe. For a non-credible failure mode, it should be confirmed that the full possible range of potential human error or inaction would not result in the loss of integrity of the facility. If there are no credible modes, the facility would not rely on monitoring systems to manage risk, however having monitoring systems as a redundancy is helpful to confirm system performance.

There may be situations where there are no credible failure modes during early stages of construction, when the dam section is very wide relative to its height, but where instrumentation monitoring is necessary to establish the performance for evaluation of the design assumptions and the safety at later stages of construction.

The following conditions are, on their own, insufficient to demonstrate that a failure mode is non-credible, though a combination of these could be part of the safety case, or well-reasoned argument to demonstrate that the facility meets acceptable safety standards:

- Designing to meet regulatory requirements and good industry practice. The technical quality of regulatory requirements is quite variable globally. Adherence to updated, high quality regulatory requirements and industry guidelines may provide a solid basis for managing the risk of potential failure modes, but it may not be sufficient in all cases.
- Attaining a specific factor of safety. As noted by Lupo (2018), prescriptive factor of safety criteria “do not convey any information regarding risk to the design, construction nor operation of the TSF (tailings storage facility).” This is because there are several factors that must be considered to select appropriate design factors of safety to manage risks on each project (Küpper, 2023). There are multiple instances where tailings storage facilities have failed with large calculated factors of safety, where the factor of safety was calculated on the basis of an incorrect understanding of a potential failure mechanism or the adopted design parameters were not adequate to represent the actual material behavior, such as using drained strengths for contractive, brittle materials or due to lack of data, uncertainties or errors. Examples where pre-failure factors of safety were calculated to meet or exceed the regulatory requirements but the facility failed, include: Mt. Polley at 1.5+ (B.C. Chief Inspector of Mines, 2015),

Brumadinho at 1.6 to 2.1 using drained parameters (CIAEA,2020), Wachusett Dam with a drained factor of safety of 2.4 (Reid and Fourie, 2019), and examples by Carrier (1991) and Morgenstern (2024) of dams that failed with factors of safety of 1.7 and 1.8, respectively. If incorrect or inappropriate parameters are used for the analysis, then a high calculated factor of safety is not an assurance of actual safety.

- Having the calculated capacity to withstand extreme loading (earthquake or flood). Loading estimations can have a large degree of uncertainty, calculations can be in error, failure mechanisms can be missed, and secondary failure mechanisms can occur.
- Model predictions of good performance during normal and extreme loading conditions. No models can perfectly capture all aspects of soil and rock behavior, nor the inherent material variability within a test hole, or the unknown ground variability between test holes. Models can provide valuable insights into the system behavior, and the uncertainty in the predictions can be reduced through performance-based updating, as described by Morgenstern (2018). Achieving model equivalence and calibrating the model to measured performance supports performance-based risk management. However, uncertainty is always present, and the advice of the statistician George Box remains prescient: "All models are wrong, but some models are useful."
- Good performance as demonstrated by monitoring, surveillance, or maintenance. Any potential failure mode that requires monitoring is a credible failure mode. An operator may choose, out of an abundance of caution, to continue monitoring despite the conclusion that there are no credible failure modes, however, that conclusion must not depend on the monitoring if the failure modes are to be truly non-credible.
- Previously assigned low probability of failure for a given failure mode. The results of previous risk assessments should be reviewed to check if the previous conclusions were rigorous and remain valid.

Caution on failure mode assessments

The most important caution that must be taken when conducting potential failure mode assessments is to not discount possible potential failure modes. In assessing the credibility of failure modes, the team must be aware of the potential for goal-seeking and confirmation bias. Confirmation bias (Kahneman, 2011; Vick, 2002) is the natural human tendency to seek out information that validates our pre-existing beliefs or hopes, and discounting information that would contradict these. There is an inherent desire to not have credible failure modes for tailings and mine waste facilities. However, the desire to have no credible failure modes can lead to confirmation bias. Other biases and heuristics described by Kahneman (2011) and Vick

(2002) such as the availability bias, representativeness bias, and overconfidence, can cause even experts to underestimate the level or risk and/or overestimate their ability to control the risk.

Potential failure modes and their probability change throughout the lifetime of each facility and thus the assessment must be re-done periodically, and each assessment should be considered an interim determination. The failure mode assessment should be reviewed and repeated whenever a condition occurs that would invalidate any of the premises for the previous assessment; an example could be climate change impacts on the Probable Maximum Flood that could render an older design condition no longer representative of a credible extreme. A potential failure mode and risk assessment at the design stage is helpful to check that all potential failure modes have been adequately addressed. However, there could be features that are only discovered during construction. Moreover, many engineering failures have been caused by changes in plans during construction, or inadequate construction quality assurance and quality control (QA/QC). For these reasons, a potential failure mode and risk assessment should always be re-done during and post-construction to assess if pre-construction or interim determinations remain valid and if modifications to the design are worthwhile or required to attain an appropriate level of risk management.

For new facilities, one aspect of risk management is to eliminate or mitigate as many potential failure modes as is practical in the design. An example of eliminating a failure mode would be excavating out a weak layer within the footprint of the dam as part of the foundation treatment. However, most if not all tailings and mine waste facilities will have credible failure modes that require mitigation.

There may be situations where, at the current stage of construction of a facility, a rigorous assessment of potential failure modes meets the standard to declare that there are no credible failure modes. However, future raises or expansion of the facility, or changes downstream that increase the potential consequences, may introduce credible failure modes. Construction quality control and instrumentation monitoring may be necessary to confirm the safety of the facility at later stages of construction. In that case, it may be prudent to avoid an early declaration that there are no credible failure modes, since that could cause organizational resources to be redirected to other priorities and detract from the vigilance that is needed to maintain the safety of the structure. “Regardless of non-credibility of failure modes, monitoring is most often still required to demonstrate performance and ensure that the failure mode remains non-credible with time” (LePoudre and Morrison, 2022). For “safe closure” it is generally necessary to confirm that there are not and will not be any credible catastrophic failure modes (ICMM, 2021).

Credible failure modes and risk management

The bow-tie risk management model is an example of a tool that illustrates how hazards can lead to an unwanted event, and consequences that can result from that event. In the bow-tie model (Figure 1), the hazards are on the left side of the figure, the unwanted event or incident in the middle, and the consequences

on the right. Potential failure modes can be represented by the unwanted event in the middle of the Bow-Tie. The risk management system uses controls (barriers) between the hazards and the unwanted event – these prevent or reduce the probability of the event from occurring, given the existence of the hazards. If the event should occur despite the presence of the barriers, recovery measures on the right side of the bow-tie prevent or mitigate the consequences.

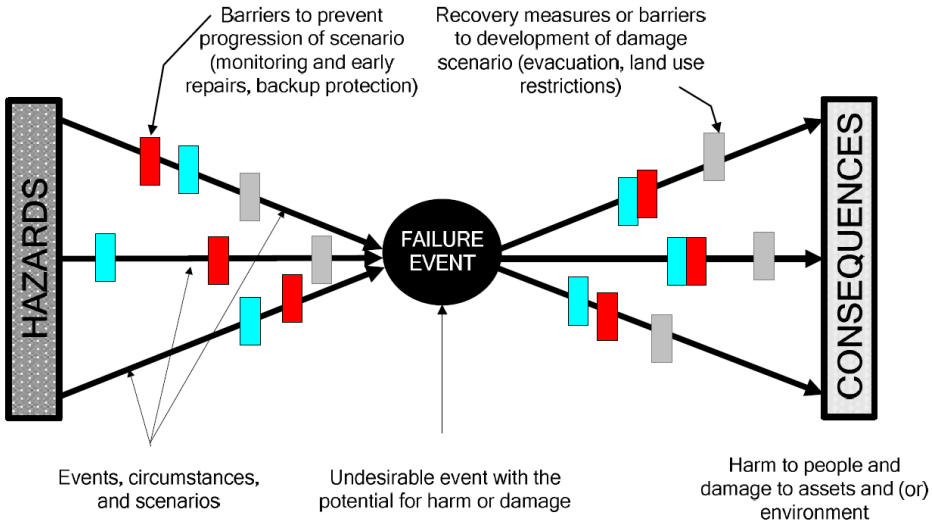

Figure 1: Bow-tie risk management model (CDA, 2007)

Acknowledgement of credible failure modes is a necessary aspect of mitigating hazards so that risks are controlled to acceptably low and ALARP levels. If potential failure modes are discounted as being non-credible without a sufficiently rigorous assessment, hazards that should be subject to controls may be left uncontrolled, increasing the risk of failures. An illustration of this is the sinking of the Titanic, with the loss of 1500 lives.

The Titanic was believed to be "unsinkable," which was effectively saying that it had no credible catastrophic failure modes. This belief drove risk taking on both sides of the bow-tie. the captain didn't slow down, and entered the iceberg field at 22 knots, which was full speed for the ship – there was no reason to slow down as a precaution, since the ship was unsinkable. The ship only held lifeboats for 50% of the people on board, and the crew were not trained and did not practice emergency deployment of the lifeboats that were carried. There was no need to since there were no credible failure modes! Had the owner, the designer, and the captain instead been realistic about the failure modes and focused on managing risk and operating safely considering the existence of credible failure modes, there could have been zero fatalities – they would have slowed down in the iceberg field to manage the risk of a collision that could catastrophically damage the ship (left-hand side of the bow-tie). furthermore, even if they didn't slow down, the 2.5 hours between hitting the iceberg and sinking was enough time to evacuate if they had enough

lifeboats and were trained to use them (right-hand side of the bow-tie). The belief that there were no credible failure modes was the direct cause of the enormous loss of life.

While the operations of the Titanic appeared to have been consistent with the international standards at the time, a robust assessment of potential failure modes would have indicated that additional risk controls were needed to reduce the risk. Inappropriately discounting the credibility of potential failure modes can take away the level of awareness and focus on the part of the dam owner and the engineer, that would otherwise contribute to a heightened diligence in risk management. The sinking of the Titanic is also a reminder that while it is important to meet international standards for each type of project, it may not be sufficient in all cases.

Acknowledgement and communication of risk

There is a perception among some groups and individuals that tailings and mine waste facilities should have zero risk. This is antithetical to existence of pervasive risk throughout society – virtually all infrastructure, from tall buildings to bridges and airplanes, have credible failure modes and hence some, typically small, risk of failure. This is also a mischaracterization of the statement "zero tolerance for human fatality" (GISTM, 2020) which does not mean zero risk – there is always risk of fatality with operating vehicles, with working underground, with working in tall office buildings. Accepting a small risk of a negative outcome doesn't mean that the outcome is tolerated. Despite the very low probability of fatal commercial aviation accidents of 1/38 million, the industry and regulators continue to work to improve safety further. The mining industry must also continually work to reduce the risk from all potential failure modes towards the goal of "zero fatalities and catastrophic events" (ICMM, 2021).

When communicating risk, it is important to understand the cultural and social context of the audience and adjust the communication accordingly. It is increasingly more common for mine owners to have developed relationships with the host communities and an understanding of the social context such that communications can be specifically tailored to work best in each situation. Sandman (2012) notes that the common perception in risk communication is that "the way to reassure people is to tell them only reassuring things." From this perspective, it would be attractive to be able to declare to stakeholders that a facility has no credible failure modes. However, Sandman (2012) further notes "Instead of convincing us that there is nothing to worry about, the conventional strategy often convinces us that you are not taking the risk seriously enough." Rather than telling people that there is nothing to be concerned about, it is generally more reassuring to confirm that we do recognize that there is a small degree of risk, which we are taking very seriously and will continue to manage. "If you tell me not to worry about anything, I will end up worrying about everything. I will worry less once I know you are worrying for me." (Sandman, 2012).

The aviation analogy is apt again. It is much more comforting to know that there is a large team of well-prepared professionals worried about the safety of the aircraft, than if those professionals said that there was no possible way for an aircraft to crash and therefore nothing to worry about.

Future considerations

This paper is not the last word on the topic. There has been significant discussion on the topic of credible failure modes and risk management, even during the preparation of this paper. It is clearly an issue that is evolving in the tailings dam safety community.

A future refinement may be to de-emphasize the assessment of the credibility of failure modes and focus on an assessment of all potential failure modes using the ALARP framework where both probabilities and consequences are considered. A failure mode that is non-credible would by definition satisfy the requirements of acceptable risks within the ALARP framework. In the future, the tailings dam safety community might reconsider the terms credible and credibility. The qualitative (and possibly subjective) nature of these terms is not helpful when facing the complexity and difficulty of assessing and quantifying the very small probabilities of occurrence of certain potential failure modes. Assessing and managing risks within the framework of ALARP may be easier to explain and support. Moreover, both the GISTM (2020) and the GPG (ICMM, 2021) require that risks be managed to ALARP so using a single framework streamlines the process. The same rigor described in this paper is required for an ALARP assessment.

Regardless of the system used to assess and manage risks, it must be done with rigor so that all risks that could result in unacceptable outcomes are identified and managed.

Conclusion

Robust risk management should aim to identify all potential failure modes and manage the associated risk. Failures of tailings and mine waste facilities are unacceptable and can have profoundly tragic consequences. Mining leaders and professionals must work to design, construct, operate and close tailings and mine waste facilities that are safe, robust, and resilient throughout all stages of their life cycle. Risk assessments are a key part of this: striving to identify all potential failure modes, appropriately controlling the hazards (the left side of the bow-tie), minimizing the consequences where possible, and enacting effective emergency response plans if a loss of control does occur (the right side of the bow-tie).

Tailings and mine waste facility risks must be managed to acceptably low levels and further reduced using the ALARP principle, so that these facilities do not meaningfully increase physical or environmental risks to the nearby populations or the environment itself. The assessment of risk using the ALARP principle or an assessment against a standard of negligibility should consider both the probability and the consequences of a potential failure.

Most safe tailings and mine waste facilities will have credible failure modes, just as bridges, tall buildings, commercial aircraft, and medical surgeries do. The presence of credible failure modes does not imply that a system is unsafe. These systems all have credible failure modes, but if the hazards are properly identified and controlled, the probability of failure can be acceptably low and consistent with the goal of zero fatalities and no catastrophic events.

Leading mining companies have adopted rigorous procedures for potential failure modes assessments and management of risks that include using the ALARP principle. Broad adoption of these principles and procedures would result in a significant improvement in tailings facility safety. The point of this paper is not to undermine the confidence in well-designed and well-constructed tailings facilities that are responsibly operated and maintained. The objective is to challenge all mining companies and professionals to a high standard of rigor in identifying and assessing potential and credible failure modes so that the risks are effectively managed to such a low level that we can demonstrate consistently safe, reliable performance of tailings and mine waste facilities. As with other critical infrastructure, where the risks are appropriately managed, the public can have confidence in the safety of these facilities.

Acknowledgements

The authors' perspectives have evolved and benefitted from many valuable discussions with colleagues, including Dr Norbert Morgenstern, Dr Roy Mayfield, Tamara Johndrow, Greg Puro, Andy Small, Chad LePoudre, Jennifer Brash, Alex Strouth and the anonymous reviewers. We hope that this paper will stimulate further discussion that will lead towards strengthened systems for safe and reliable tailings and mine waste structures.

Practical Remedies to Improve the Defenses of Tailings Structures

Jeremy Boswell, Thurber Engineering Ltd, Canada

Abstract

The high-profile failures of tailings storage facilities (TSFs) and the associated loss of life over the last decade have generated substantial volumes of new legislation and guidance and an enormous workload of validation and compliance effort in industry response. Improvements in standards and new design are noticeable, especially for facilities owned by multinational mining companies and members of the ICMM and those who have voluntarily subscribed to the principles of GISTM. However, even after all this effort, the industry has continued to witness several more failures worldwide over the past two years, some of which have involved loss of life. The primary causes of the recent Jagersfontein tailings disaster in South Africa, which failed in 2022 after publication of the above-mentioned industry responses to Brumadinho, are summarized in this paper.

The most relevant risks that have led to recent tailings dam failures have been identified and many have been well publicized: storage of water and fluid tailings behind tailings dams; tailings or foundation liquefaction; combination mechanisms of failure, such as pond overtopping followed by erosion of embankments and liquefaction flow failure; weak engineering; facility dormancy; the failure of dam management systems, and human error.

While all the effort in confirming compliance is laudable, have we become somewhat distracted? It is suggested in this paper that renewed and continued attention should be focused on the practical improvement of the defenses of tailings structures. This paper outlines several practical and operational defenses: understanding deposition history in limiting rate of rise; avoiding the banana skin of very weak layers deposited in critical areas; prioritization of subaerial beaching and maximizing beach length and beach compaction to reduce the risks of liquefaction, internal erosion or embankment failure; and vigilance in tracking leading indicators and exercising duty of care. Key defenses relating to pond size reduction and

elimination of water storage have been addressed in papers by the lead author at previous Tailings and Mine Waste conferences in Colorado.

It has been estimated that there are around 30,000 TSFs worldwide, many of which have not been fully closed over the past century but are simply dormant. The paper concludes with a call to action to recognize the risk of dormancy, to address the risks posed by facilities that are no longer operational, and to take action to ensure that our industry leaves a positive legacy for future generations.

Introduction

In November 2023 in Vancouver, delegates to the Tailings and Mine Waste 2023 conference heard an excellent keynote address by Dr Ed McRoberts (McRoberts, 2023). In his address, McRoberts pointed out afresh the grave dangers of a weak layer of fines deposited operationally near the base of a tailings storage facility (TSF). Over the years this problem layer has become known colloquially in the industry as the "banana skin." Further detail is provided later in this paper. In response to a question "How does one avoid the banana skin?" McRoberts affirmed that one does one's utmost to not build such a layer and to prevent its creation. The conference discussion provoked interest from the authors of this paper and generated momentum to list some practical remedies for the banana skin problem. Some of these remedies also address some of the other more common mechanisms and risks of failure of TSFs.

Defining the "banana skin"

Weak layers are frequently responsible for the failure of TSFs. Many authors have described in great detail the dangers of unaddressed weak foundations. The Mount Polley failure in 2014 (Morgenstern et al., 2015) and the Los Frailes failure in 1998 (Alonso and Gens, 2006) are good examples. However, the banana skin under consideration here is not a weak foundation layer: it is a weak layer on the floor of the TSF basin that is typically created by the storage of water and fines during commissioning. If not immediately removed, the fines settle and form the banana skin, which becomes most problematic for global slope stability once the structure has risen in height.

In the typical design of starter earthworks for a TSF, as shown in Figure 1, a toe drain near the starter embankment and sometimes also a blanket drain some distance from the toe are provided for drainage of the tailings and depression of the phreatic surface, to enhance stability. However, if fines are allowed to accumulate above the drain, the drain becomes blinded and is rendered impermeable and ineffective. Even more seriously, the fines if left in place serve to create a soft clay/fines layer at the base of the TSF. This is the banana skin – created by maloperation. The banana skin formed no part of the design, planning, or construction phases. For the later stage raises of the TSF, the supernatant pond is removed. However, the

banana skin is left behind. This banana skin leaves a substantially weak pathway of preferred weakness in the TSF.

Also shown in Figure 1 is the impact of the banana skin (weak layer) on global stability, and the improvement in stability if a banana skin is avoided, since the failure plane is then unlikely to pass through the same zone.

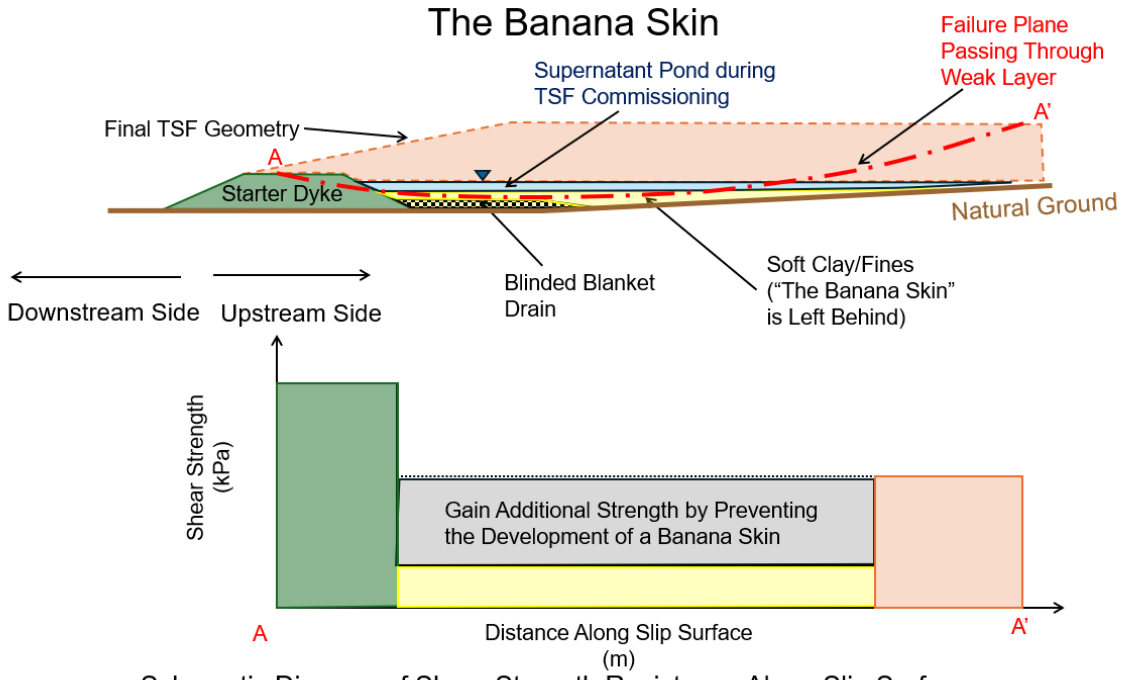

Figure 1: Defining the "banana skin"

In order to defend the TSF against the risks of the banana skin, the commissioning phase is critical. However, commissioning is not even considered by many engineers as being of any great significance, as illustrated in Figure 2. Recognition of the vital elements of the commissioning phase goes a long way towards safe TSF operation. This paper addresses several different defenses that may be employed to guard against the banana skin, especially during the commissioning phase of the TSF life cycle.

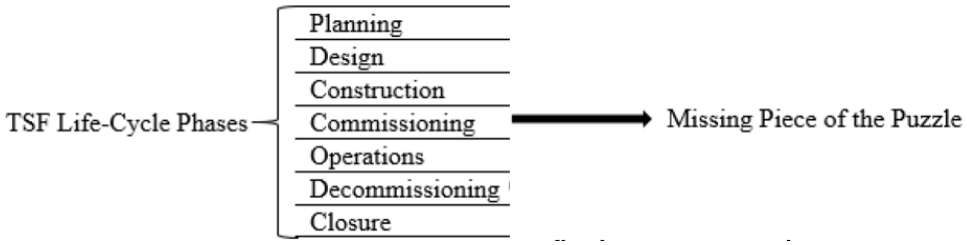

Figure 2: Life cycle of a tailings storage facility

Lefkochrysos platinum TSF case study

The erstwhile Lefkochrysos Platinum Mine (Lefkochrysos meaning "white gold") is a platinum mine which was developed in the mid-1980s near the town of Brits, South Africa, some 100 km northwest of Johannesburg. After the initial design and commissioning, the mine underwent several changes of name and ownership. As an interesting metallurgical aside, the mine was the first platinum mine to successfully mine and commercially process UG2 ore without the usual need to blend it with Merensky reef to beneficiate the ore. This opened up opportunities for other mines to successfully extract platinum group metals more directly from UG2 reef.

One of the challenges of the Lefkochrysos TSF design was that the mineralogy of the (somewhat chrome rich) processed ore and tailings was unknown prior to production, owing to the innovative nature of the mining project. Thus, the usual tailings characteristics of particle size distribution, particle specific gravity, slurry relative density, tailings mineralogy, permeability and governing rates of rise were substantially unknown and had to be assumed. In essence, the tailings design was required to be conservative and defensive, and as subsequent events were to prove, was successful. This case study of the design of the TSF shows various defenses which were employed against several operational risks, including the banana skin. The 14 defenses that the Lefkochrysos design embraced to prevent development of a banana skin are listed below and shown in Figure 3:

1. Spigoted discharge from multiple deposition points to direct and develop beaching away from the starter embankment.
2. Sufficiently large deposition areas to allow for Beach Above Water (BAW) (subaerial) deposition, managed rates of rise and associated desiccation and consolidation. Beach compaction (e.g., track packing) may also be added to accelerate consolidation and improve embankment stability.
3. Cross walls to immediately direct deposition away from the drains and prevent blinding of drains.
4. Bypass lines and cells for deposition of wastewater, flushing water and off spec or dilute tailings.
5. A constructed sacrificial beach (not shown) under the tailings to prevent accumulation of fines near the toe by introducing immediate gradient to initial beach deposition profiles.
6. Wing walls around the decants, which increase beach length, reduce beaching velocity and momentum, improve settling of fines, and prevent beach erosion and channel short-cutting.

7. Temporary decant towers (penstock inlets) to progressively remove supernatant at the point of accumulation in a timely manner, while at the same time allowing progressive and planned migration of the decant points away from outer embankments.
8. Permanent decants, with wing walls to improve beaching and settling of fines, and to prevent pond migration.

Figure 3: Lefkochrysos platinum TSF case study

9. Toe drains (not shown) below the tailings, providing immediate and early drainage of the deposit.
10. Blanket drains at natural ground level (not shown) and offset from the toe to improve drainage of the deposit and to assist with longer term phreatic surface management.
11. Finger drains that collect supernatant during deposition from areas more remote from the decants. The design intent was that in time the finger drains could be allowed to plug or be decommissioned, which was successfully accomplished.
12. Elevated drains (installed later on the beach when the TSF has undergone several raises), which improve drainage of the mature beach and prevent phreatic surface encroachment towards outer embankments. Chimney drains or vertical drains are also a critical element of

TSF design, especially for downstream and centerline construction, in controlling seepage and internal erosion. Vertical drains are seldom employed in upstream construction designs, and they were not considered for this design.

13. A silt trap, which enables rapid removal of turbid supernatant and emergency response to upset events, and allows for settling and capture of fines under controlled conditions. The silt trap was designed to be removable from the recycle water circuit, using a simple gated gravity bifurcation, thus allowing for desilting of the dam without interrupting operation of the TSF or the process plant and mine.
14. A recycle dam to prevent the storage of water on top of tailings, and to contain flood events.

These 14 defenses may be divided into four categories, as explained below.

Geotechnical and hydrotechnical design

Geotechnical and hydrotechnical remedies require foresight and anticipation of commissioning and operational issues of a TSF. These proactive measures need to be designed and specifically applied to the TSF. Cross walls direct the tailings away from drainage structures, reducing the chance of the drainage being blinded or blocked. Wing walls increase the length of the beach and improve the settling of fines to prevent beach erosion and channel short-cutting. The recycle dam is used to prevent water storage on top of tailings. The silt trap removes turbid material from the supernatant pond and allows the fines to settle under controlled conditions.

Drainage

Drainage can be implemented prior to, during and after TSF operation to manage and maintain the flow of water through and around the TSF. The construction and use of toe drains, or ground surface blanket drains, would require pre-emptive design and planning to ensure the drain is located, sized, and designed to be able to convey the design flow volumes. Finger drains collect the supernatant during deposition and may be decommissioned later. On the other hand, elevated drains are installed later when the tailings surface has been raised. Elevated drains improve the drainage of mature beaches and eliminate phreatic surface encroachment towards the outer embankment.

Buttressing with the inclusion of reverse filters can improve stability and remedy seepage and internal erosion risks. Many of these drainage elements would provide immediate drainage during the commissioning phase of the TSF, minimizing the size of the supernatant pond and removing the likelihood of fine material being deposited on top of drains or in vulnerable areas.

Slurry discharge, decant and supernatant control

Depositional cells promote the settlement of tailings material and allow water to drain into the recycle dam or a secluded area of the beach. A bypass line would redirect off-spec product, flushing of tailings lines, and additional wastewater runoff. Additional decant towers (both permanent and temporary) allow the operator and owner to better manage and maintain water levels within the TSF. Active supernatant control and removal reduces potential impacts of poor depositional management or off-spec deposition of tailings material and improves the quality of recycled water.

Beaching and deposition

Spigots, cyclones, or open-ended discharges from multiple deposition points are used to direct the beach away from the starter dam. The sacrificial beach prevents the accumulation of fine tailings material too near to the outer embankments. Off-spec cells create an area of the facility that is used for emergency deposition so that an upset condition does not impact the global stability or efficiency of the TSF. Sound beaching and deposition practice relies on a sufficiently large depositional area, controlled rates of rise, and allowing the material to be deposited above water in a sub-aerial environment rather than in a subaqueous environment. This prevents the long-term suspension of fine tailings material, promotes faster settling, and enhances tailings consolidation.

Premium on duty of care and attention to detail

The Lefkochrysos case study described above holds significant implications for tailings management:

- Owners, designers, and operators have significant responsibility to ensure that their responsibilities are discharged with the commensurate duty of care (Boswell and Sobkowicz, 2011). This applies especially to the commissioning phase.
- The defenses described above are not extremely complicated or demanding and in several cases are not even expensive. Timely and assiduous implementation of defensive measures (of which the 14 listed above are examples) will go a long way to assuring the safety of TSFs.
- Attention to detail is demanded during the implementation of defensive measures. Slipshod or partial compliance will provide no defense, since a chain is only as strong as its weakest link.

Jagersfontein tailings disaster case study

Pre-2010 history

The Jagersfontein mine in South Africa was operated by the New Jagersfontein Company from 1882 until 1932, when De Beers Consolidated Mines Ltd (De Beers) acquired the mine. Large-scale commercial mining by De Beers commenced in 1949 (Lochner et al., 2024), operating as an underground mine until

1972. Following the South African transition to democracy in 1994, the new Mineral and Petroleum Resources Development Act (MPRDA) came into force and the Minerals Act of 1991 was repealed. Under the new act, the Jagersfontein tailings facility was reclassified as an ordinary dam in 2002 and had no need to comply with mining legislation (Lochner et al., 2024). This enabled large-scale re-mining activities to proceed where conventional mining regulations did not apply.

Superkolong Consortium, a broad-based black economic empowerment (BEE) holding company, acquired the mine from De Beers in 2010 (Writer, 2022) to reprocess the legacy coarse reject kimberlite dumps and reopen the TSF after almost 40 years of dormancy. Jagersfontein Development Ltd, a partnership between Reinet Investments S.C.A. (Reinet) and Sonop Diamond Mining Ltd, acquired shares in Superkolong in 2011 (Brown and van Wyk, 2022). In April 2022, Reinet sold its consortium share to Stargems Group, a Dubai-based diamond trading company, just months before the tailings disaster.

Jagersfontein TSF operational history after 2010

In 2010, after the onset of coarse reject mine waste dump reprocessing, the original TSF was expanded to the west and almost doubled in size by 2013 (Torres-Cruz and O'Donovan, 2023). Construction of the east TSF extension was underway in 2015 and completed by 2017. Tailings deposition from the west expansion eventually allowed tailings to flow from the west extension to the original TSF and east extension via two furrows in an internal wall. Continued eastward migration of tailings eventually completely buried the furrows and internal wall. In 2019, erosion gullies and slope instability were observed in the downstream southeastern wall, and buttressing efforts commenced to increase the wall thickness in this area.

The tailings facility was shut down in 2020 by the provincial government as the facility exceeded authorized water levels (Banya, 2022). Operations were allowed to continue under a new license in June 2021. An inspection of the TSF by engineers in July 2022 found that the water volumes were within limits and that the dam was safe (Banya, 2022). On September 11, 2022, the TSF failed, causing at least one loss of life, destroying several homes and causing significant environmental damage. About 5 million cubic meters of tailings material (Rivet, 2023) were released, creating a downstream tailings plume about 8.5 km long and 1.5 km wide (Petley, 2022). Tailings continued to flow along approximately 56 km of streams and rivers.

Contributing factors

Investigations of the failure concluded that several operational practices contributed to the breach of the Jagersfontein TSF, including:

- Too much slurry was pumped into the TSF, resulting in a full supernatant pond with water right up to the perimeter wall.

- There was tailings deposition from only one discharge location on the west dam wall of the TSF. The lack of perimeter tailings deposition prevented the development of beach freeboard.
- The absence of beach freeboard and lack of capacity did not leave available storage to manage extreme precipitation events.

Figure 4: Aerial photographs of the Jagersfontein tailings facility in 2010, 2021, and September 2022 (photographs courtesy of Google Earth)

- Ponding of surface water at the downstream toe of the southwest dam wall, likely from seepage through the TSF foundation or the dam wall, contributed to slope instability.
- There was a lack of toe drainage or seepage control measures around the perimeter of the TSF.
- There was a lack of compartmentalization.
- There had been many changes in ownership, and therefore there was a lack of continuity of the TSF operating staff.
- There was a lack of regulatory oversight during the years of the TSF dormancy.

- There was a change in regulatory jurisdiction and a re-classification of the Jagersfontein tailings dam as an ordinary dam, which enabled re-mining activities to proceed outside of regular mining regulations.
- There was human error, including:
    - Failure to recognize warning signs, such as the development of seepage and erosion gullies in the area of the breach in 2019 (Torres-Cruz and O'Donovan, 2023).
    - Failure of the operator to listen to workers' concerns about overfilling of the TSF.
    - Dismissal of calls from residents about "rumbling sounds" hours prior to the failure (Brown and Van Wyk, 2022).

Some lesser known but valuable facility management defenses

Whistleblower policy

As discussed in the Jagersfontein case study, employees are often the first to realize if there is something seriously wrong with the TSF. However, it is not easy to speak up about this concern in front of their hierarchies, as it may lead to subsequent discrimination or disadvantage later on. Some people are also afraid of harassment and victimization. This will lead them not to report their concerns.

The Mining Association of Canada (MAC) and other statutory and vocational bodies and guidance (such as GISTM, 2020 – also embracing the principle of Free Prior and Informed Consent), encourage whistleblower policy and practice to enable employees and communities to raise serious concerns without fear. Moreover, this promotes openness, honesty, and accountability.

Change management procedures

Change management procedures are a key component of the operation and surveillance of a TSF. Any significant changes to ownership, regulatory oversight, operations, personnel, monitoring, or design require a change management procedure. Change management systems, processes, and procedures are specified in several sections of GISTM 2020 and ICMM 2021.

Significant risks are associated with the TSF when changing key personnel (e.g., Engineer of Record, Responsible Tailings and Facility Engineer, etc.). Apart from this, a procedure should be developed for mine ownership and production changes. The Jagersfontein disaster showed the tragic consequences of not having these change management procedures in place.

Compartmentalization as an operational defense

The TSF that consists of a single compartment does not present options for continued tailings operation in the event of a substantial malfunction with the TSF containment (i.e., overtopping failure, internal erosion,

etc., of an individual embankment). Multiple compartments would assist in an emergency. One hates to repeat the cliché "Don't put all your eggs in one basket" – however, it was never truer than in this case.

Documented and detailed contingency planning

No tailings management plan should be without early and comprehensive contingency planning. Contingency measures for tailings deposition are considered an essential feature of tailings planning, without which the operator is left with little defense in the case of an operational upset, site incident, flood event, or other extreme situation. The greater the risk of upset events or conditions, the more effort should be applied to contingency planning.

Some example components of contingency planning include:

- Hard and soft copies of maps, the Emergency Preparedness and Response Plan (EPRP), Operation Maintenance and Surveillance (OMS) documents, the Design Basis Report (DBR), Risk assessment documents, and other emergency documents should be available and easily accessible at the TSF. With these emergency documents, a "war room" must be prepared for an emergency situation when digital records may be inaccessible.
- A secondary power source, availability of mobile plant, heavy equipment, and emergency materials should be on standby for the TSF to tackle emergency situations.
- A backup of human resources for emergency situations is required, especially for key operational personnel.
- Communication procedures with the downstream population and emergency services should be developed. An early warning system and a formal flood notification procedure should be in place to warn anyone located downstream. This should also include table-top and on-site practical drills and rehearsals.

Specialist training for key operations personnel

Successful commissioning of a tailings facility is a key foundational aspect of a stable and well-maintained TSF. By establishing and communicating clear design, construction, and commission-staged goals, the personnel involved in the TSF can understand and operate in the best interests of facility performance.

Additional precautions

When commissioning a TSF, there is a heightened requirement for foresight so that design engineers, owners, and operators can understand and implement the best methods to mitigate the creation and impact of a banana skin or fine silt layer. Accordingly, a few further precautions are emphasized below:

- Ensure that the tailings material has been comprehensively characterized and accounted for in the facility design. In the absence of such characterization, the design must be developed with an abundance of caution and precaution in mind.
- Ensure that the initial depositional volumes during commissioning are monitored and surveyed for quality assurance/control studies to confirm the design engineers' assumptions, especially in regard to production tonnages, water volumes, tailings PSD, slurry density, and beach slope.
- Manage deposition so as to reduce the likelihood of poor-quality material eroding and damaging facility defenses. Examples include the use of wing walls, buttresses, sacrificial beaches, swales, and bypass lines.
- Ensure the area of beach is large enough, and available soon enough, to accommodate rate of rise limitations and maintain minimum beach lengths. The beach is also used to control pond location, limit migration of the supernatant pond, prevent overtopping and, under normal operating conditions, to create and maintain above-water tailings deposition.
- Ensure drainage measures and design features are well established and protected through commissioning and operational phases.
- Practice careful vigilance in regard to the development and application of change management procedures.

Conclusion

The Jagersfontein tailings failure in 2022, and more recent heap leach failures at Çöpler Mine in Turkey in February 2024 in which nine lives were lost, and at Eagle Gold Mine in Yukon in June 2024, are unfortunately showing that our defenses continue to need substantial improvement. It may be argued that TSF owners who are members of or subscribe to the ICMM Tailings Practice Standard (ICMM 2021) and GISTM (2020) and other newly revised jurisdictional regulations have upped their game considerably, and that standards in this sector have improved significantly. However, this represents less than 5% of all the TSFs worldwide. As an industry we clearly still have a long way to go, to get to zero harm.

This paper has listed several practical remedies to improve the defenses of tailings structures. At the same time, there has to be a concomitant shift in dam safety culture towards duty of care and attention to detail in many areas, including change management procedures, contingency planning, operator training, and community and employee awareness.

While several mine owners have embarked on the arduous journey to true closure of tailings structures, far too many dormant structures have simply been abandoned. Stronger action is needed to ensure that our industry leaves a positive legacy for future generations.

Acknowledgments

The authors wish to express our thanks to our clients, our associates in the industry, and our colleagues at Thurber Engineering for their support, collaboration and insight, which contributed to this paper.

Update on GISTM Implementation at BHP – Lessons Learned on the Journey

Chad LePoudre, BHP Group Ltd, Canada
Tenaya Brown, BHP Group Ltd, USA
Justin Willis, BHP Group Ltd, Australia
Chris Sonntag, BHP Group Ltd, USA

Abstract

BHP Group Limited (BHP) is a multinational mining and metals company headquartered in Melbourne, Australia, and a founding member of the International Council on Mining and Metals (ICMM). This paper summarizes BHP's journey and lessons learned through implementation of the Global Industry Standard on Tailings Management (GISTM) across a global portfolio of multiple operating and legacy assets. BHP self-declared conformance with GISTM for its 22 very high and extreme consequence tailings storage facilities (priority TSFs) in August 2023, and is working towards conformance for the remaining TSFs by August 2025. BHP is also currently progressing the independent validation component of GISTM conformance for the priority TSFs.

Three broad topics are included in this paper: (1) BHP's GISTM journey, including internal and external work; (2) challenges and lessons learned from technical and non-technical perspectives; and (3) summary of findings and next steps.

This paper highlights the complex and iterative nature of GISTM implementation across the organization and highlights the importance of ongoing support and continuous improvement initiatives. An emphasis on lessons learned and practical solutions to technical and non-technical challenges faced by BHP is intended to contribute to the industry knowledge base around good tailings management practices.

Introduction

The Global Industry Standard (the standard) on Tailings Management (GTR, 2020) was publicly released in August of 2020 by the Global Tailings Review (GTR) panel, co-convened by the International Council of Mining and Metals (ICMM), the United Nations Environment Programme (UNEP), and Principals for Responsible Investment (PRI) (GTR, 2020). As a founding member of ICMM, BHP is committed to demonstrating alignment with GISTM across our global portfolio of tailings facilities.

BHP operates a portfolio of 74 tailings storage facilities (TSFs) including 22 very high and extreme consequence TSFs (referred to as priority TSFs). BHP self-declared conformance with GISTM for its very high and extreme consequence TSFs in August 2023, and is working towards conformance for the remaining TSFs by August 2025. This paper highlights the GISTM implementation approached adopted by BHP and describes the alignment framework, internal and external workstreams, challenges and lessons learned from technical and non-technical perspectives, summary of findings, and opportunities for next steps. BHP is on a journey of continuous improvement in tailings management, including GISTM implementation and conformance. The intent of this paper is to contribute to the industry knowledge base around good tailings management practices and share the learnings and potential opportunities for continuous improvement identified though BHP's experience with GISTM implementation.

Overview of BHP's GISTM journey

Background

Preparation for implementation of GISTM within BHP began before GISTM was published. First, as an ICMM member, BHP had the privilege to participate in the review of various versions of the GISTM drafts. For each version of the drafts, internal Subject Matter Experts (SMEs) reviewed and provided comment on components of the standard respective to their expertise. These comments were collated and provided to an ICMM coordinator who, in turn, collated all comments received from ICMM members and then submitted these comments to the GTR panel. It was important to BHP to participate in this process so that we had an early opportunity to understand the content, could participate in advancing good tailings practice, and to help ensure that the standard was also practically achievable. The achievable portion was important to BHP for our own facilities, but we also recognized early the importance of achievability in not discouraging non-ICMM members from GISTM uptake. BHP was also among ICMM members that began working on documents to support GISTM implementation, namely the Tailings Management Good Practice Guide (ICMM, 2021a) and Global Industry Standard on Tailings Management Conformance Protocols (ICMM, 2021b) (more discussion below).

BHP's approach

BHP operates in accordance with the three-lines assurance process (IIA, 2020). BHP's operating model places a large degree of autonomy on the individual asset (first line), supported by group level functional teams such as the centralized tailings excellence (TEx) team (second line), with occasional reviews by an internal audit team with accountability to the board (third line). Figure 1 describes the types of roles and responsibilities typically associated with each line (BHP, 2022).

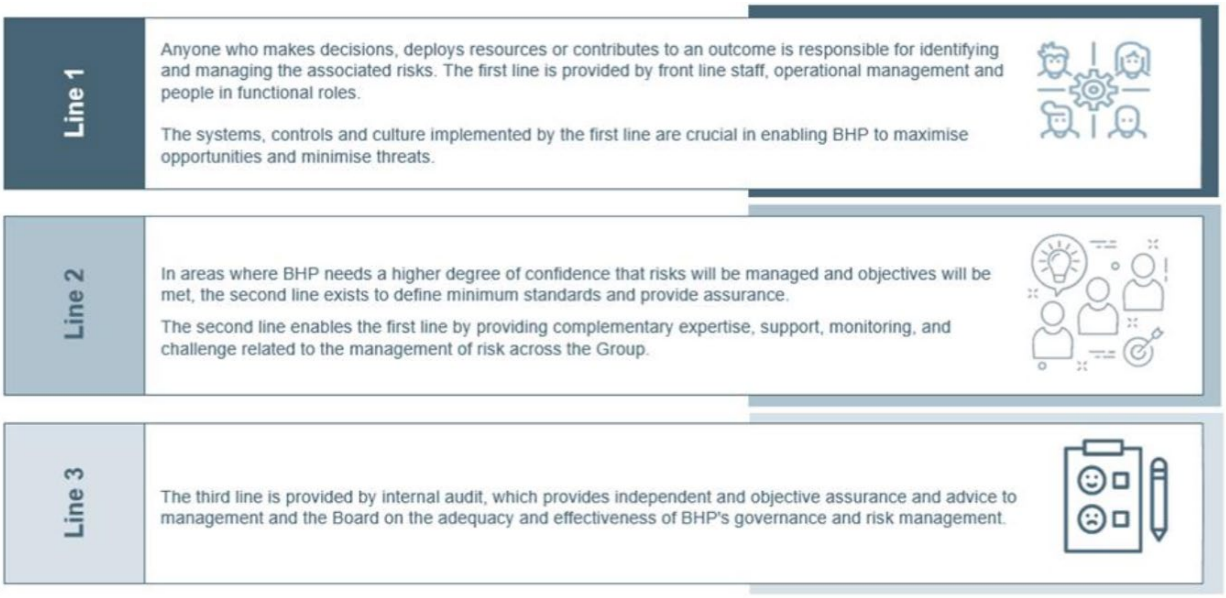

Figure 1: BHP three lines model (BHP, 2022)

For GISTM each asset was responsible for conformance themselves, as they own the work within the first line. The central TEx team provided support, coordination, and guidance, and collected and summarized implementation progress for reporting to BHP management. BHP's approach to GISTM alignment began with the creation of a board-endorsed tailings management policy and revision to our internal Global Standard for tailings, specifying the need to conform with GISTM. The TEx team prepared and updated guidance documents, prepared a GISTM "Mapping Tool," and consulted with internal stakeholders on the rollout and conformance as part of defined second line activities. The mapping tool was a table that included each of the requirements, conformance protocols, examples of evidence for conformance, and multi-disciplinary resources (internal and external) to assist the asset with implementation of each of the GISTM.

BHP assessed conformance to GISTM based on a number of principles, described in full in our Public disclosure document (BHP, 2023), and summarized below:

- Conformance is based on evidence that demonstrates that the understood intent of the GISTM requirement criteria have been met with underlying systems, processes, and practices in place to meet the requirements.
- Requirements may be assessed as not applicable in specific situations.
- Major engineering works required to meet a GISTM requirement scheduled for completion beyond the ICMM timeframe are considered acceptable with a suitably detailed and prioritized work plan.
- For requirements that reflect on-going processes (for example requirements 1.2, 1.3, 3.1, 5.8, 6.1, 6.2, 9.3, 13.4, 14.2 – 14.5, 15.2 and 15.3), a "Meets with a plan" level of conformance is acceptable

when can be demonstrated that the work has been substantially progressed and is supported by systems and processes. Additionally, in the event of a tailings facility failure, there should be no realistic prospect that claiming conformance for these requirements could be considered as a potential cause of failure. Where processes are in a cycle of review and updated in accordance with BHP's regular business practices, evidence that reflects that current practices and demonstrates systems and processes are in place that meet the intent of the requirement, will be taken as conformance.

For sites with very high or extreme consequence classifications (Prioritized Sites), BHP set internal conformance deadlines leading up to the August 2023 deadline. These internal deadlines provided time for internal review and verification of the self-assessment outcomes and provided evidence. Sites with high or lower consequence classifications are now in the process of being brought into alignment with GISTM requirements, with an internal target date of December 2024. To facilitate learnings across assets, a GISTM champions group was established with regular routines for the sharing of experiences and approaches between the asset teams.

Internal work

The conformance push leveraged internally developed mapping and self-assessment tools that were informed by the Tailings Management Good Practice Guide (ICMM, 2021a) and Global Industry Standard on Tailings Management Conformance Protocols (ICMM, 2021b). The tools were utilized to conduct gap assessments and identify work streams for each tailings facility to achieve conformance. Identified work streams were either completed by site teams or contracted to external parties. The internal work focused on updating and developing documentation and driving further integration between the tailings team and other functional groups within the organization, including Health, Safety and Environment, Corporate Affairs, Tailings Excellence, and the Accountable Executive. Externally contracted work focused on production of documents such as the DAR, DBR, etc.

The TEx team coordinated regular meetings (approximately every two weeks) with asset representatives that had accountability for GISTM conformance. These representatives were referred to as the "GISTM Champions." The meetings covered a wide range of topics, but were nearly always focused on various technical issues and challenges associated with GISTM implementation. This forum also allowed for the sharing of lessons learned between assets, where some assets had advanced various portions of GISTM already. Needs of the assets were discussed, such as resourcing support or additional guidance needed, and the TEx team would work to help facilitate solutions.

During the conformance push, a quarterly self-assessment and audit readiness review was conducted by each asset. The review enabled the asset teams to track progress towards conformance and capture any

lessons learned or guidance from the organization. It also facilitated benchmarking from a quality perspective and effective resource allocation to ensure sufficient progress was being accomplished across the portfolio.

External work

BHP was also among ICMM members that began working on documents to support industry GISTM implementation, namely the Tailings Management Good Practice Guide (ICMM, 2021a) and the Global Industry Standard on Tailings Management Conformance Protocols (ICMM, 2021b). The Tailings Working Group of ICMM facilitated a series of meetings between member companies to conduct knowledge shares on technical subjects related to GISTM. Further, ICMM prepared training materials, including videos of voiceover presentations to support the Good Practice Guide. It may be noted that the Good Practice Guide, the Conformance Materials, and the training materials were made available, free of charge to anyone, on the ICMM website.

A key component of the GISTM conformance push for many assets was further defining the scope of support required from the Engineer of Record (EOR) and Independent Tailings Review Board (ITRB). While much of this understanding and capacity was already developed, some asset teams had to appoint and empower new resources to achieve conformance. In several instances, GISTM requirements required substantial increases in external resource utilization to generate and/or consolidate the necessary technical information in an auditable format.

While the preparation for GISTM was focused on preparing for external independent conformance validation, BHP's August 2023 conformance declaration was based on self-assessment results. To provide confidence in the self-assessment results, BHP ran a verification program using an external auditing team that reviewed a sample of evidence across the GISTM requirements and high priority TSFs. This verification was completed toward the end of 2022, with several technical and non-technical lessons learned from this verification program. These items will be discussed in the following sections.

Challenges and lessons learned

Throughout BHP's GISTM journey, there have been many challenges and lessons learned ranging from detailed technical aspects to non-technical items such as approvals processes. This section presents the technical and non-technical challenges and lessons learned, compiled from the authors' personal experiences and the results of a detailed questionnaire sent out from TEx to the priority TSF teams after GISTM declaration.

GISTM survey results

Following completion of the GISTM self-assessed conformance declaration, TEx solicited feedback from

the assets through a survey, with responses received from three assets. The survey questions and feedback are summarized in Table 1.

Table 1: Survey results

Questions	Survey response summary
What was the one, most challenging part of GISTM implementation from your perspective?	Three consistent challenges were noted across assets. (1) ALARP, (2) definition of conformance, (3) internal reporting requirements.
Were the ICMM conformance protocols useful, did you refer to them at all or often?	Yes. The conformance protocols became a key element of demonstrating conformance rather than achieving compliance. Particularly during external verification.
Was the ICMM Good Practice Guide helpful?	Yes. However, not to the extent of the conformance protocols. Served as more of a reference guide than a driver for work.
Was the BHP mapping tool helpful? What changes would have helped?	Yes. However, several improvement opportunities were noted. These opportunities led to some updates to the mapping tool and other available resources.
Did you find that BHP OR, standards and/or guidance notes were helpful with implementation of GISTM? Please provide comments.	The guidance documents were found to be useful, but often not released sufficiently early. In some cases, changes to guidance documentation caused re-work.
Did you get adequate support from asset leadership with conformance?	Yes. However, several assets noted that coordination and communication was challenging due to changes in leadership positions over the period.
Would additional communication from TEx to asset leadership be helpful? Suggestions?	Assets requested continual support around GISTM effort rather than a one-off, as well as additional guidance on how to communicate the ALARP journey to senior management and the Accountable Executive.
Was support from TEX helpful, and/or what additional support from TEx or other functions would have been helpful?	Several assets suggested that sharing examples of "what good looks like" for various requirements could be helpful and improve practices across the organization.
The Public Disclosure details will need to be verified every year. How did you find the process this time? What would you suggest could be done to improve it?	Development of a routine with long lead times and a consistent approach were identified as key improvements. Some challenges were noted around the requirements changing through implementation.
Were you given sufficient opportunity to review and comment on the public disclosure?	The assets had mixed results but indicated that more time may have been needed if major changes to the public disclosure had been required.
An audit readiness review is now needed to internally verify conformance, prior to external and public auditing (such as GTMI). Do you have suggestions for this review?	Clarity around scope and timing was requested and emphasis was placed on communicating BHP's understanding of current conformance.
What would you do differently for GISTM conformance next time?	Two primary items were noted: (1) Improve efficiency to gain approvals and sign-offs with asset leadership teams and Accountable Executive, (2) ensuring timely guidance and resourcing based on asset needs.

Questions	Survey response summary
What went well with the GISTM conformance process?	Substantial organizational support for GISTM conformance push, starting early on key scopes, approvals, and processes.
Please rank difficulty (low, medium, high) and provide comments regarding the 15 principles of the GISTM	A relatively wide variety of responses were recorded. Principles found to present a **high** level of difficulty were: **Principle 3: Design, Construction, Operation and Monitoring of the Tailings Facility.** This presented a challenge at some sites due to the level of engagement required with the Accountable Executive. **Principle 15: Publicly disclose and provide access to information about the tailings facility to support public accountability.** This was difficult because of the number of reviews, changing templates, and multiple iterations for each disclosure. Principles found to present a **medium** level of difficulty were: **Principle 1: Respect the rights of project-affected people and meaningfully engage them at all phases of the tailings facility lifecycle, including closure.** This was identified as an early struggle before appropriate SMEs and functional groups were brought in to support the efforts. All other Principles were either found to require **low** effort or were not commented on by the assets.

Technical challenges and lessons learned

Technical challenges to achieving GISTM conformance were primarily related to interpretation of the requirements and understanding what level is considered sufficient to meet the intent. While the Conformance Protocols and Good Practices guides were useful references, in practice they provided sufficient flexibility for organizations to incorporate their own risk frameworks and operating standards, which meant that different interpretations and views of conformance could exist. At BHP this flexibility was leveraged to update existing processes, systems, and documents to make them suitable for GISTM, rather than wholesale creation of new systems and documents. This reduced the workload on the asset teams, while ensuring sustainability of the GISTM implementation. Using existing systems, process and documents did present a number of challenges though, specifically with the Deviance Accountability Reports (DAR) and ALARP. Design Basis Reports (DBR) also presented challenges at some legacy TSFs, where construction design basis and documentation are often limited. These challenges and lessons learned are discussed in more detail below.

Definition of conformance

There was challenge within BHP, and the mining industry, regarding the definition of conformance. For

example, there are different interpretations and intent behind the words "compliance" and "conformance," or "verification" and "validation." For many of the requirements of GISTM, it is difficult to meet the higher standard associated with "compliance" and "verification" as compared to "conformance" and "validation." For example, Requirement 2.2 pertains to site characterization, but all persons associated with tailings management will understand that site characterization is almost never complete (perhaps only in some instances of passive closure). Similar challenges exist with many other requirements. Therefore, BHP's position regarding conformance was based on the principle of "where work is substantially progressed and supported by systems and processes."

Using Requirement 2.2 again, if it was demonstrated that a site characterization was substantially progressed in accordance with the requirement, and there was an effective governance and assurance system in place (EoR responsible for the site characterization, ITRB periodically reviewing the site characterization and assessing gaps, Dam Safety Reviews conducted on schedule, etc.), then the Requirement would most likely satisfy the "meets" threshold. Therefore, an asset could conform with the requirement where they could demonstrate good practice, even if there was work in progress to address potential gaps in knowledge identified through the aforementioned processes and systems. Further, independent validation could be conducted using the same criteria.

There were some who disagreed with this approach, both within and external to BHP, creating one of the significant challenges experienced and even becoming the topic of some discussion at ICMM Tailings Working Group meetings. Persons who dealt with other sustainability commitments were more accustomed to the compliance model. However, other sustainability initiatives tend to apply to a more policy-oriented approach, with questions such as "does a human rights policy exist?" where GISTM requires companies to "conduct human rights due diligence to inform management decisions throughout the tailings facility lifecycle and address the human rights risks of tailings facility credible failure scenarios." Since management decisions are ongoing and credible failure scenarios are constantly being reviewed and revised, BHPs position was that evaluation of conformance with the requirement is more appropriate than compliance.

The independent validation process is the quality control on this approach to conformance. BHP is now going through the process of independent validation of conformance using independent consultants, in accordance with the ICMM Conformance Protocols. The evidence for each requirement is reviewed and those independent reviewers provide feedback to BHP on whether the criteria for conformance has been met.

Interpretation of GISTM requirements

The BHP guidance documents to support GISTM interpretation sought to provide sufficient guidance so

that GISTM was interpreted and implemented consistently across the assets, and was aligned with BHP's overarching risk and governance frameworks without introducing rework, while also providing enough flexibility to be implemented leveraging asset specific systems, processes, and documents. In practice this was a tight balancing act that was difficult to get correct, with some guidance ending up being too broad, while the more specific guidance did not cover every situation present in BHP. As noted in the survey feedback, the guidance was sometimes not issued in a timely manner, and a number of opportunities for improvement have been identified that are currently being addressed. While developing guidance documents is not necessary to achieve GISTM compliance, guidance and support from the second line enables adoption of a consistent approach to GISTM across an organization, more efficient use of existing systems and process, and alignment with overarching BHP frameworks.

Legacy TSFs

Demonstrating conformance for legacy TSFs presented a significant technical challenge as many of the facilities are between 50 to100 years old and/or were never operated by BHP. Many supporting technical documents met the intent of GISTM but were not in a state that enabled easy verification or auditing. Characterization studies and reports, design documents, and construction records and details were often limited in scope, partially complete, or unavailable. While legacy TSFs did have sufficient detail within the knowledge base to make a determination on the TSFs integrity, the data was not in the formats specified in GISTM such as the DBR, DAR, CDIV, etc. When considering the evidence needed to demonstrate conformance, it became necessary to make judgement calls on if/when to conduct additional characterization data, complete additional engineering studies and when necessary, remediation projects, all the while considering resource availability.

Additionally, many communities and first responders located near legacy assets had a limited history of engagement with the sites. "Principle 1: Respect the rights of project-affected people and meaningfully engage them at all phases of the tailings facility lifecycle, including closure" (GTR, 2020) required tailings SMEs for legacy TSFs to generate alignment with Corporate Affairs on the best approach to GISTM as external discussions around tailings and their potential impacts should proceed on the shoulder of established relationships with communities and first responders.

Design basis reports (DBR)

DBRs for operating facilities were generally already developed and met the intent of GISTM. However, at many legacy sites, the basis of design was not documented, and documentation to support a design basis was found across a variety of different documents. Further, in many cases, documenting the design basis required additional geotechnical and environmental characterization and analysis to fill gaps in the existing knowledge base. One of the approaches adopted by BHP was to implement a Knowledge Base Report

(KBR) in lieu of the DBR at some sites. The KBR compiles references to relevant historical documentation, including available as-built and characterization documentation, operational history and design or assessment criteria. It is structured similarly to a DBR but focuses on leveraging existing documentation and ensuring that is categorized and available in a manner that meets the intent of the DBR, rather than summarizing the information found in each report across a long operational history. This practice was found to be effective and supported demonstration of conformance with several other GISTM requirements.

As Low as Reasonably Practicable (ALARP)

From a technical perspective, the demonstration of ALARP was, and continues to be a key challenge across assets along the GISTM journey. The ALARP concept involves highly subjective terms, and there are a number of ways to demonstrate that risks have been reduced to ALARP. For BHP, the desire was to use existing site and BHP wide systems and process as much as possible, while also aligning with BHP's risk management framework, reflected in the guidance developed by the TEx team. After an approach had been developed each TSF needed to be considered to assess if the risks could be demonstrated as being at ALARP or not. Key to demonstrating ALARP is an assessment of risk reduction options and a decision on whether to proceed or not with these options. This required extensive internal communication and engagement, including with asset leadership and the Accountable Executive. Prompt and proactive planning and communication regarding risk and risk status are considered key to successfully meeting Requirement 5.7 of GISTM.

Non-technical challenges and lessons learned

Throughout the GISTM journey, multiple non-technical challenges and lessons learned were identified. These consisted of managing the large volume of evidence, obtaining management support and buy-in on our GISTM journey, generating required approvals from the Accountable Executive and delegates, developing consistent approach across BHP, managing workloads for EoRs and internal teams and reporting status of implementation. These are discussed in detail below.

Evidence management system

To demonstrate conformance to GISTM, many pieces of evidence need to be prepared, compiled, reviewed, approved, and ultimately issued for external validation. BHP elected to use an internal web-based tool for managing evidence for the assortment of external standards that BHP has committed to comply with. This tool, called the Sustainability Standards Portal (SSP), while not exclusively for GISTM, was under development concurrently with assets working towards priority TSF conformance, with the GISTM evidence a trial use of the tool.

Three key challenges arose during implementation. (1) Addressing issues and bugs with the new tool as the evidence was being uploaded; (2) rolling the tool out to assets; and (3) providing user training on the tool. After rollout, assets provided feedback on the system and were able to identify several improvements that have positively influenced efficiency and usability of the tool. Key improvements included updates to the Quick Reference Guide, development of SSP training videos for new and existing personnel, allowing for bulk processing and downloading of documents and data, and changes to some of the validation and comments functions to improve user experience. While the tool provides improved long-term documentation and auditability, additional resources and time were needed for uploading, verifying, and approving conformance documentation that put a strain on several assets.

Management support and buy-in

Obtaining asset leadership support and buy-in around GISTM presented a challenge, particularly at operating assets. For example, in one instance an asset asked, "Who do you think you are and why do you think you can make us do this?" In these cases, asset leadership was primarily concerned with costs, potential impact to production, and complexity from changes or improvements to operating systems and procedures. Tailings SMEs consistently found that communicating the "why" behind many of the new requirements was necessary. Early and proactive communication was determined to be the most effective approach to generating buy-in. Buy-in was also achieved through being able to clearly and accurately demonstrate how GISTM conformance activities impacted cost, production, and risk outlook at the site. However, it was also necessary to have established commitment to GISTM from BHP executives in writing to demonstrate to assets that this was not an optional exercise. It was also noted that some "healthy tension" between management and technical SMEs was a good thing as it pushed asset leadership to improve understanding and support for good tailings management practices, while also motivating technical SMEs to be efficient and well thought-through in their approach.

Approvals – accountable executive and asset management

Developing a clear, consistent mechanism for asset management and Accountable Executive approvals required substantial coordination and communication from TEx and tailings SMEs. Three primary challenges were encountered when obtaining AE and management approvals. (1) Upward communication and acceptance of the role and responsibilities of the accountable executive; (2) defining the delegations and approvals framework and process; and (3) obtaining signoff on required documents in a timely manner.

Once the delegations and approvals framework has been developed, the most influential and effective approach to obtaining approval/signoff was the generation of a single signoff package rather than obtaining approval on each required deliverable separately. As the Accountable Executives spanned multiple assets, the signoff packages needed to be relatively consistent across each asset and need to have a structure that

enabled key site-specific information to be communicated succinctly. In addition, practitioners needed to be prepared when engaging directly with the AE and senior leadership to answer questions or concerns in a format specified by management.

Developing consistent approach across BHP

BHP's asset lead GISTM approach was accompanied by the risk that each asset would interpret the requirements differently, resulting in different standards across BHP. As noted above, this risk was managed by the development of guidelines, and a verification program run by a third party. As this was the first time implementing the standard, the internal guidance was not able to address all scenarios and required updating, which resulted in re-work for some assets. The verification program identified areas of inconsistency that required re-work also, and the timing of these updates resulted in short timeframes for updating ahead of the GISTM implementation deadline. The journey to achieve a consistent standard across BHP continues, and additional planning for the non-priority TSFs is underway in an attempt to avoid repeating the same level of re-work.

Managing workloads

Throughout the GISTM journey, challenges with tailings team workload were encountered, due in part to the limited availability of experienced tailings practitioners within both operations and consulting functions. A balance needed to be found between managing the projects and technical studies that would improve tailings facility safety and mitigate risks, and preparing evidence to support implementation and report GISTM progress. Simplifying and improving internal tracking and reporting systems to enable the site teams to focus on TSF integrity was a key lesson, while making sure that the validation team has suitable experience to assess implementation as opposed to simply box ticking. As noted by the ICMM conformance protocols, this reduces the need for "bullet proof" evidence.

To achieve conformance two of BHP's assets created specific GISTM positions or teams, while the remainder managed the workload within existing teams. Where the workload was managed within existing teams, this was often accompanied by greater use of the EOR and external consultants.

For the GISTM requirements requiring support from the EoR or other external consultants, deliverable timeliness and quality became a challenge in many instances due to the sheer quantity of work and the need to prioritize work, resulting in short turnaround times on certain work scopes. It was found that in an era of high workloads for experienced consulting support, early planning, communication, and prioritization of work leads to better outcomes.

Summary of findings and next steps

This section summarizes the TEx survey results, technical and non-technical challenges and lessons learned

as discussed in the sections above and the next steps identified within BHP. The survey was conducted across varying assets and teams and showed that technical guidance and resources related to the GISTM conformance push were generally appropriate and available. However, the survey also indicated that ALARP, demonstration of conformance, and internal reporting requirements were often challenging to implement. Principles 3, 14, and 15 were found to be the most difficult with a rating of "high" and Principle 1 was rated the next most difficult with a rating of "Medium." All other Principles were rated as "low" difficulty or not commented on by the assets.

Several technical and non-technical challenges and lessons learned were identified along the GISTM journey. Technical challenges primarily consisted of interpretation of GISTM requirements, developing DBRs, demonstration of conformance at legacy TSFs, and ALARP. In many instances, these challenges were interconnected and interdisciplinary in nature, which required extensive coordination and collaboration between the business, SMEs, and internal and external stakeholders. Technical lessons learned were to focus on obtaining early and thorough technical guidance, using benchmarking across sites to determine what "good" looks like, and setting up clear routines/cadence for updates and review of documentation.

From a non-technical perspective, challenges primarily consisted of developing and implementing an evidence management system, obtaining management support and buy-in, clarity on the approvals process with senior management and the accountable executive, developing a consistent GISTM conformance approach across the organization, and managing workloads. Lessons learned focused on early and proactive communication around GISTM, and the importance and necessity of defining routines, expectations, and lead times that are reasonable and achievable. Further, it is important to continue to integrate GISTM alignment as it is a continuous process rather than a destination and one-time conformance push. A key portion of the lessons learned was also the ability and advantage of leveraging experience from the 2023 conformance push for high priority sites to the 2025 conformance push for lower priority sites.

As BHP moves towards conformance for all TSFs by August 2025, we are updating all relevant guidance, maintaining routines for sharing lessons, tracking progress of conformance, and scheduling out key engagements and internal deadlines considering the lessons gained from the priority TSFs.

Conclusion

Throughout the GISTM journey, BHP personnel committed to an immense amount of internal effort and external coordination to achieve conformance for the high priority sites by 2023. As part of the continuous improvement process, the lessons learned along the way have been incorporated into the conformance push for low priority sites that is currently underway. Three topics were included in the paper: (1) BHP's GISTM journey, including internal and external work; (2) challenges and lessons learned from technical and non-

technical perspectives; and (3) summary of findings and next steps.

This paper details the complex and iterative nature of GISTM implementation across the organization and emphasizes the importance of ongoing support and continuous improvement initiatives. The findings further herein illustrated the importance and benefits of maintaining a robust and integrated three lines of defense model that is supported at the highest levels of the organization. The emphasis on lessons learned and practical solutions to technical and non-technical challenges faced by BHP is intended to contribute to the industry knowledge base around good tailings management practices.

Acknowledgements

First and foremost, the authors would like to acknowledge everyone within BHP who has contributed their valuable time and effort to the GISTM journey. Without their tremendous effort and commitment, achieving GISTM conformance at all would not have been possible. The authors also acknowledge the thoughtful survey responses from various SMEs across the organization that are discussed in this paper. Their responses demonstrate an unbroken commitment to continuous improvement of tailings management practices. Lastly, the authors would like to acknowledge the support of BHP leadership along the GISTM journey. Their commitment to GISTM aligns with our core values of "doing what's right," "seeking better ways," and "making a difference" and has resulted in a strong and robust safety culture across the organization.

Meteorological Inputs to Tailings Storage Facility Assessments and Risk Assessments – Experience and Lessons Learned

Bill Kappel, Applied Weather Associates, USA

Abstract

As a result of the issuance of the Global Industry Standard on Tailings Management (GISTM) in 2020, the International Council on Mining and Metals Tailings Management Good Practice Guide (ICMM GPG), and ICOLD's Bulletin 194, Tailings Dam Safety, there is a drive to designing tailings storage facilities (TSFs) to handle the Probable Maximum Flood (PMF) during closure and, in many cases, during operations. Quantifying the effects of extreme precipitation and changing meteorological conditions on the safety of tailings storage facilities during operations and closure is critically important. This paper provides guidance with respect to the PMP and how climate change should be accounted for in the PMP estimate. Additionally, guidance is provided on how to couple wind speeds during extreme precipitation events to determine suitable freeboard.

Applied Weather Associates (AWA) has completed hundreds of site-specific PMP, precipitation frequency, and climate change assessments around the world; many for large dams and complex mining operations. These studies have included both deterministic and probabilistic evaluations. For TSFs with ponds, the results have been used to determine spillway adequacy and freeboard requirements, to understand water balance, to evaluate extreme precipitation depths and seasonality, and to provide input for evaluation of hydrologic runoff responses. These studies are also applicable for cover designs and designing erosion protection systems.

AWA develops the PMP following the storm-based approach, which provides deterministic values that are commonly used for evaluation of spillway adequacy and design. Until recently, these deterministically derived values did not have a probability associated with them, and therefore quantifying where those values fell within the risk spectrum was not possible. For nearly ten years now, AWA has applied a regional Lmoments process along with a stochastic storm transposition process to quantify the probability of the PMP depths. This also provides unique outputs that include several recurrence intervals,

including the 10,000-year event. This combination of deterministic and probabilistic outcomes is very valuable for assessing risks associated with a TSF.

Over the last few years, AWA has also included climate change projections specifically related to extreme rainfall and PMP. This presentation will provide details on PMP development, the application of probability assessments, and how climate change assessments are applied to those outcomes. These will be discussed with specific examples related to tailings storage facility safety. Several locations around the world will be considered. This analysis is very important for informing likelihoods in risk assessments.

AWA also has provided input to estimating the required freeboard that is required to protect from overtopping of tailings dams during extreme precipitation events. Proper consideration of extreme meteorological events (precipitation and wind) are key data inputs to assist designers and owners on how to best allocate funding for ongoing safe operations and closure.

The GISTM and ICMM GPG introduced the concept of credible failure modes, a key component of which is understanding if a potential failure mode is physically possible. This paper will provide input to physically impossible thresholds related to extreme precipitation events.

Introduction

Understanding and quantifying the hazards from meteorological and climatological events that can affect tailings storage facilities (TSFs) is critical to ensuring safety and reducing risk. Many of the meteorological and climatological inputs include a large amount of uncertainty and subjective judgement. It is very important that these analyses are completed by experienced and qualified experts in this field. Another critical aspect is communication of development process, areas of uncertainty, and how those affect results to the practitioners and regulators. Discussions in this paper will describe several of the key meteorological processes that are used for design inputs for TSFs. These include Probable Maximum Precipitation (PMP), precipitation frequency, climate change assessments, and wind speed assessments.

Probable Maximum Precipitation development

Probable Maximum Precipitation (PMP) is a critical input for estimating the Probable Maximum Flood (PMF) with a rainfall-runoff relationship, which is an input to hydrologic design. However, a deterministically derived PMP represents the theoretical upper limit of rainfall (WMO, 2009) which is based on subjective storm adjustments, uncertain storm analyses, and other meteorological judgements. Further, deterministically derived PMP depths have not included any probability or frequency of occurrence. Therefore, although PMP is often provided as a specific depth representing the best estimate for various durations for a given area size or location, it must be recognized that there is uncertainty around that value. Therefore, it is important to quantify areas of uncertainty in the PMP development process, determine the

effect of those uncertainties, communicate those uncertainties, and work with the engineering team to ensure reasonable application is completed. To further complicate the issue, climate change projections should also be evaluated to determine if they predict changes that are outside of the bounds of uncertainty and natural variability already accounted for in the PMP development process.

Since the early 2000s, Applied Weather Associates (AWA) has continued to refine the deterministically derived PMP depths to quantify uncertainty and reduce risk. Part of this process includes quantifying the amount of uncertainty associated with each major input parameter. These include selection of storms, storm transposition limits, storm adjustment factors, quantification of rainfall accumulation in time, space, and magnitude, and other key parameters. The range of variance of each of these can be evaluated and combined to provide a total amount of uncertainty around the best estimated PMP depths (Mikovic et al., 2015; Kappel et al., 2020; Kappel et al., 2023).

Another recent advancement AWA has refined to provide a probabilistic estimation of PMP is the process to calculate annual exceedance probabilities (AEP) for various durations out to 10^{-10}. This is completed by applying the regional Lmoments process and stochastic storm transpositioning process to develop statistically robust data sets from which to derive the required recurrence intervals with confidence bounds (Kappel et al., 2024). Deterministically derived PMP depths can then be plotted or compared to the AEP output to understand the rarity of the PMP depths. This provides a valuable sensitivity of the PMP depths, which can support risk assessments.

These processes are, of course, dependent on the amount, spatial coverage, and quality of data available. The more data available both spatially and temporally, the more accurate the results will be. This relates to the storm analyses, storm adjustments, precipitation frequency development, temporal characteristics, and spatial patterns.

The final piece of the puzzle is to test climate change projections related to extreme rainfall against the range of uncertainty that has been calculated using deterministic and probabilistic methods. AWA has completed nearly a hundred such studies globally using regionally downscaled models (RCM) derived from the suite of global climate models (GCM) available from the various Intergovernmental Panel on Climate Change (IPCC, 2017) outputs. Initial work used the 5th generation of models, CMIP5 (2017) and now uses CMIP6 (2021). This suite of climate change projections provides daily temperature, precipitation, atmospheric moisture, and other meteorological parameters needed to understand the amount and rate of change through 2100 that are important for PMP development. These projections can then be compared against the information derived from observational data and the baseline climatology of a given location. Recommendations related to the most likely outcome can then be developed and provided for evaluation and sensitivity analyses.

Example of deterministic PMP development

PMP depths are used in the computation of the Probable Maximum Flood (PMF) for relatively small catchments, generally for the design of high-consequence structures, such as TSFs. PMP depths developed in the example below were focused on the area size of the contributing basin to a TSF at a mine site in Utah (1.23-mi^2) as shown in Figure 1.1. AWA used our database of storm analysis and PMP information from adjacent studies that are specifically relevant to this location (Figure 1.1). PMP depth estimates calculated for this location were evaluated against the previous studies and regional work.

Methods used to derive PMP values included consideration of numerous extreme rainfall events that have been appropriately adjusted to the basin and representing each PMP storm type important for this location, local and general storms. Storm lists that have been previously applied and reviewed in detail by several independent review boards in adjacent studies were considered to develop the initial list of storms. These were evaluated in detail to determine which could potentially be important for PMP development for this particular basin (Figure 2). The large number of storm events covering a large spatial region and long period of record provided enough data from which to derive the PMP depths within an acceptable amount of uncertainty.

The process of combining maximized storm events by storm type into a hypothetical PMP design storm resulted in a reliable PMP estimation by combining the worst-case combination of meteorological factors which represent a PMP design storm that is physically possible over of the basin considered. The method assumed that a sufficient period of record was available to identify extreme storm events within the region and that at least a few of those storms attained or came close to attaining the maximum storm efficiency possible for converting atmospheric moisture to rainfall. In essence, the process is trading time for space to capture PMP processes.

The PMP development process assumes that if additional atmospheric moisture had been available, an individual extreme storm would have maintained the same efficiency for converting atmospheric moisture to rainfall. The amount of moisture is represented by available precipitable water in the atmosphere and is calculated by assuming a saturated atmospheric column based on observed dew points. Therefore, the ratio of the maximized rainfall amounts to the actual rainfall amounts would be the same as the ratio of the precipitable water observed versus the climatological maximum in the atmosphere associated with each storm.

It is important to remember that the methods used to derive PMP and the hydrological procedures which transform PMP depths into runoff need to adhere to the requirement of being “physically possible.” In other words, various levels of conservatism and/or extreme aspects of storms that could not physically occur in a PMP storm environment should not be used to produce combinations of storm characteristics that are not physically consistent in determining PMP depths or for the associated hydrologic applications.

Although the term "probable" is included in the PMP term, this does not relate to probability. Instead, it refers to the physical possible element associated with the design storm. Any PMP event is considered to be extremely rare and represent a physical upper limit of rainfall potential.

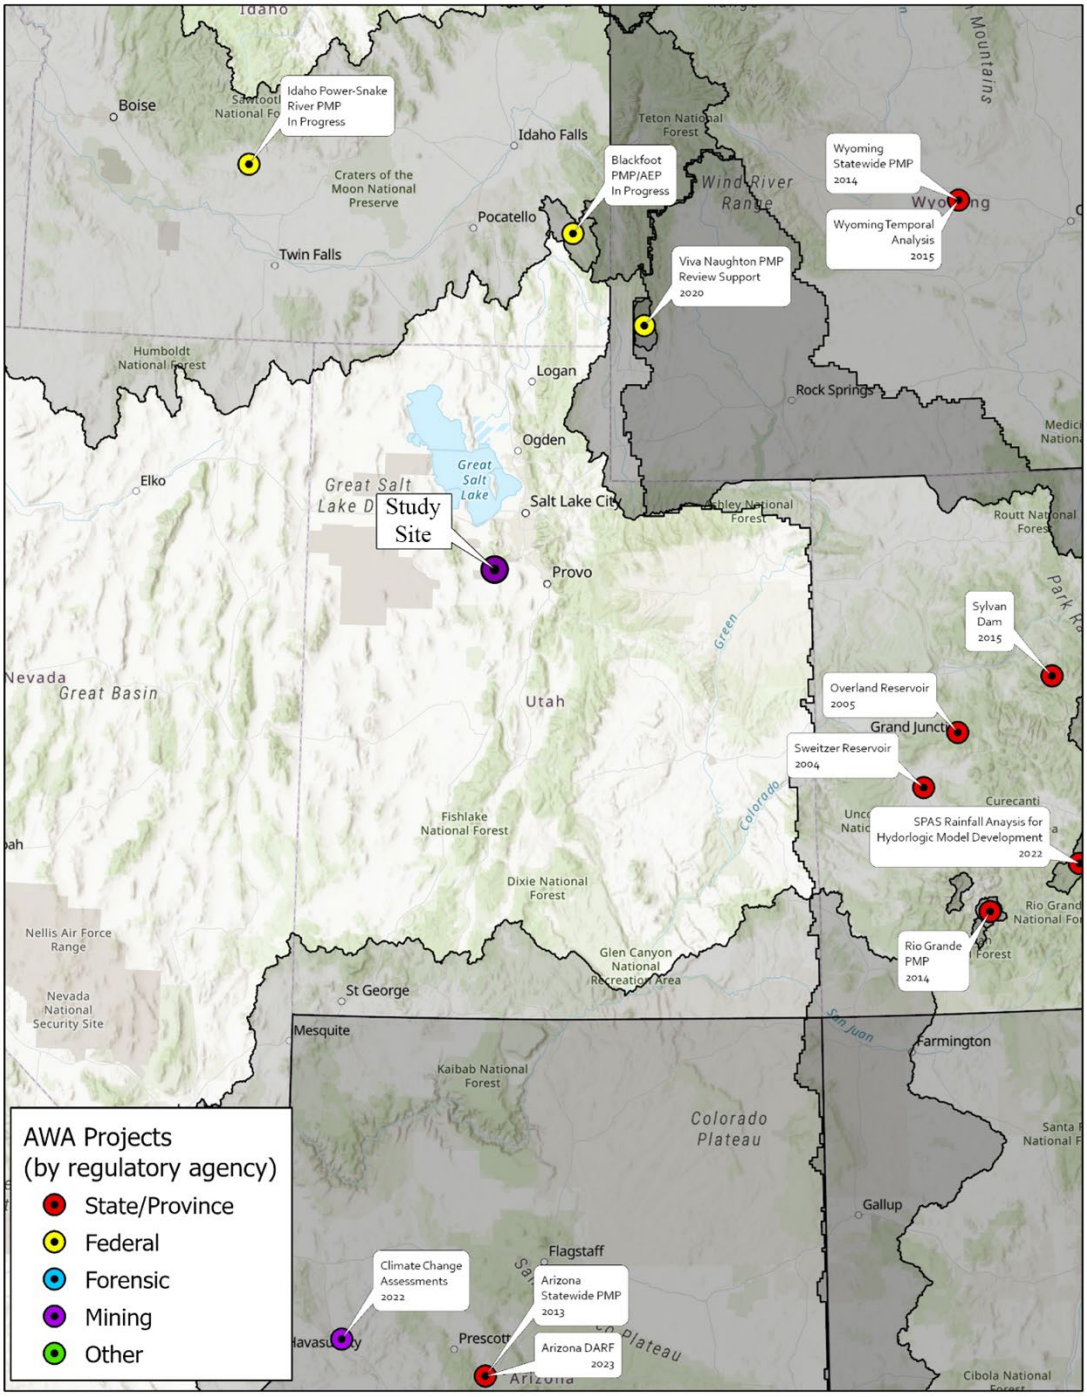

Figure 1: Probable Maximum Precipitation study location and surrounding studies that were evaluated for data

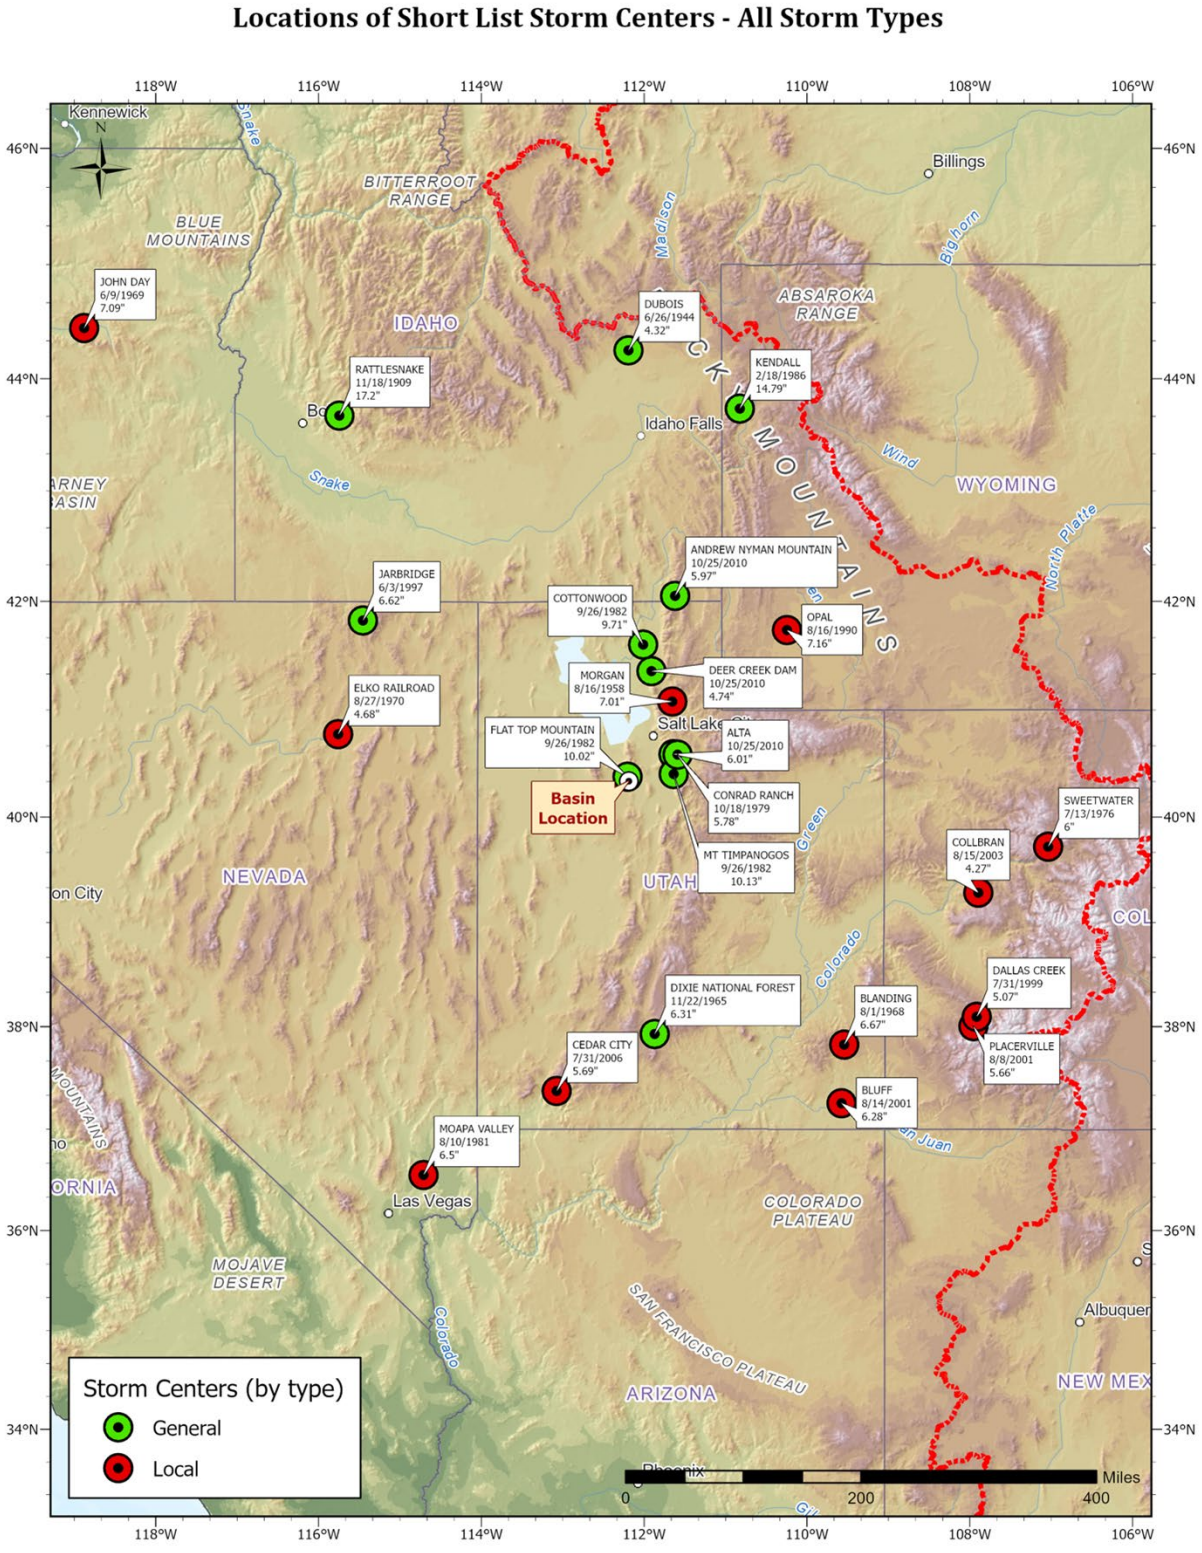

Figure 2: Locations of storm centers used for PMP development in relation to the basin location

To calculate the PMP, the Total Adjustment Factor (TAF) for each storm must be applied to the rainfall depths calculated using the Storm Precipitation Analysis System (SPAS) analyzed depth-area-duration (DAD) value for the area size and duration of interest to yield a total adjusted rainfall value. The storm's total adjusted rainfall value is then compared with the other total adjusted rainfall depths of every storm considered transposable to the basin location. The largest adjusted rainfall depth becomes the PMP for that point at a given duration. This process must be repeated for each applicable duration and storm type.

This study provides basin-specific PMP depths based on the area-size of the basin and the durations most relevant for PMF evaluations. Depth-duration charts plotting the adjusted rainfall depths for both storm types are provided in Figure 3 and Figure 4. The controlling storm for each duration can be determined from the depth-duration charts and it is important to note that several storms control PMP as the duration changes and there are generally a good number of storms supporting the controlling storm PMP depths.

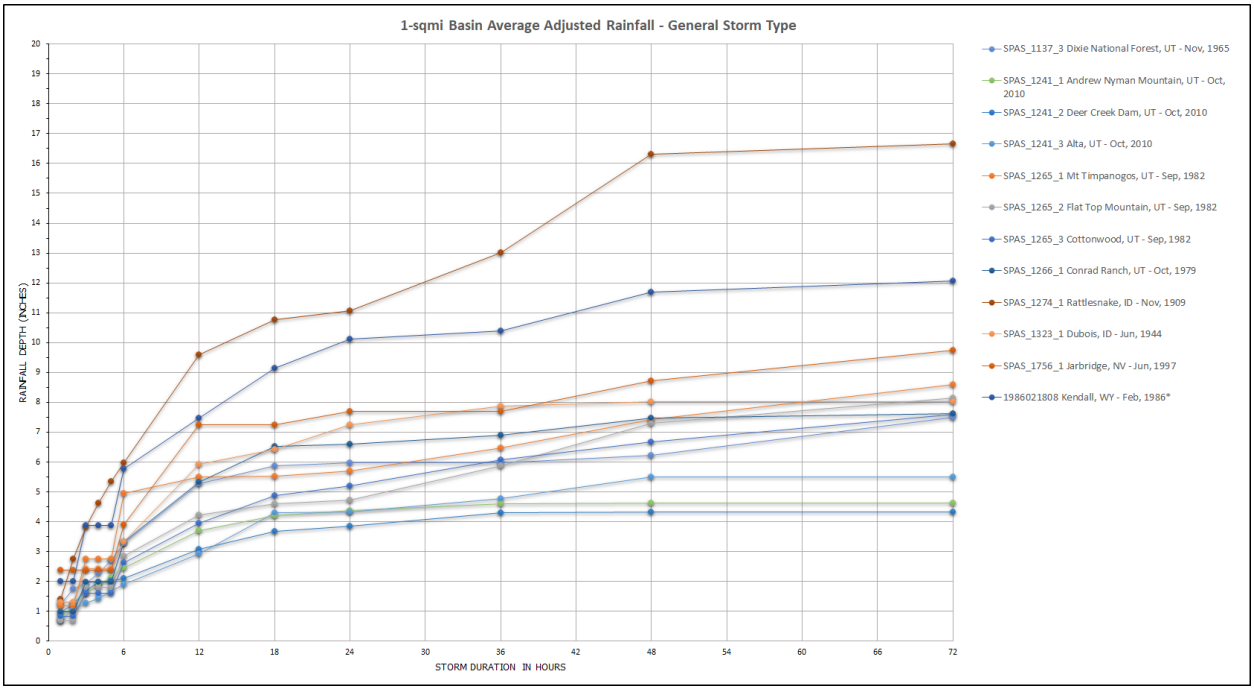

Figure 3: General storm PMP depth-area chart

It is important to note that a very specific combination of atmospheric parameters is required to produce a PMP event or similar rare precipitation frequency. After an extreme event occurs (e.g. 100-year, 1,000-year, or PMP type storm) the atmosphere needs time to recharge and reset. The time for that reset increases depending on the rarity of the event. Therefore, it is not reasonable to expect back-to-back PMP events. There is limited guidance on this for several reasons. One is that we have not observed many PMP

level events from which to determine this timeframe. Next, this would vary by storm type and location. For example, it is much more likely that tropical systems could affect a similar region within a few days of each other. This is partially because those storms are moving in from a location outside of a particular location and therefore the atmospheric parameters that develop those storms are not directly affected by the previous storm until reaching the location. Conversely, a severe local storm required high levels of local instability and moisture inflow. If severe storms were to occur in a given location, it would affect the atmospheric conditions around that region. This would lower the instability and sap the moisture from the atmosphere. Therefore, it would likely take several days to weeks before another storm would happen in the same location.

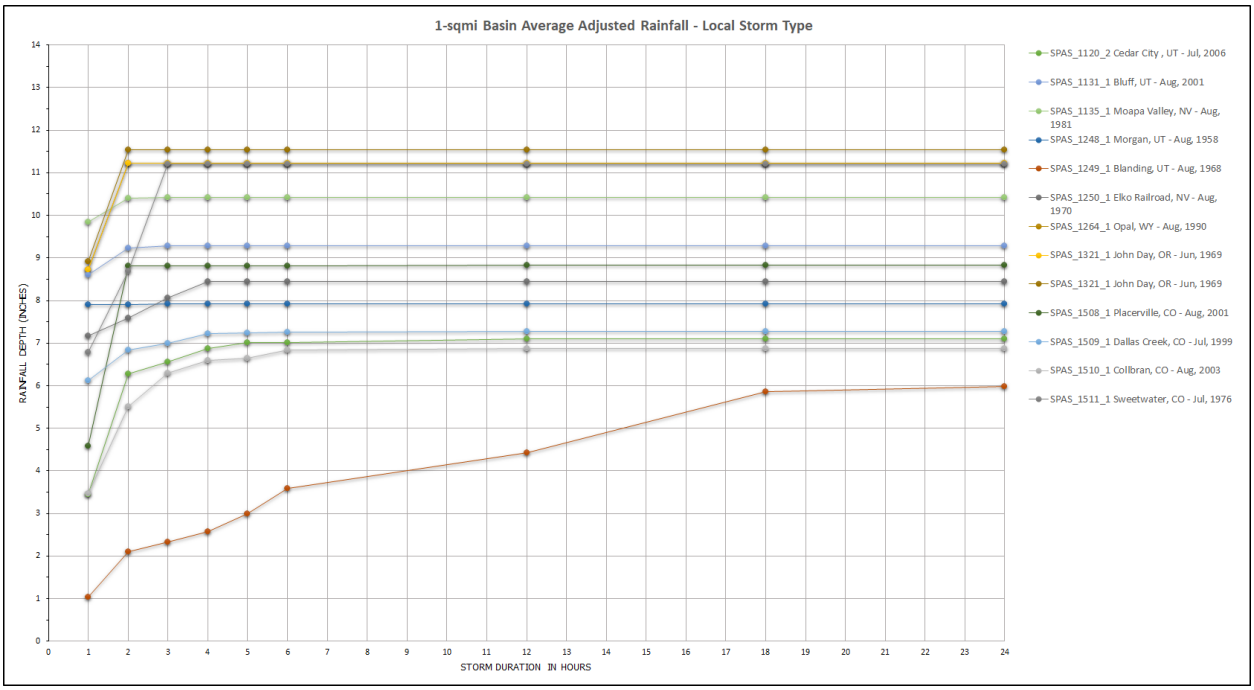

Figure 4: Local storm PMP depth-area chart

There is general guidance from some agencies related to the timeframe between major events. For example, the Federal Energy Regulatory Commission (FERC) recommends a 100-year rainfall three days prior to the PMP with dry conditions in between. The nuclear Regulatory Commission also provides guidance. However, in both cases, the guidance is somewhat arbitrary, and more work needs to be completed to better define these antecedent conditions. As the timeframe after a given event extends, the possibility of another event increases, but this should be considered weeks at a minimum depending on the storm type and seasonality as a given location.

These discussions are only related to the precipitation aspects. Consideration also needs to be given to the hydrologic assumptions and the rarity of each of those assumptions and how they could occur prior to and between PMP events.

This is very important for analyzing the reasonableness of the PMP depths and ensuring appropriate envelopment and consistency through time. The PMP depths should be utilized for subsequent PMF development. These represent depths that incorporate the current state-of-the-science methods for PMP development along with an updated storm database.

Example of Annual Exceedance Probability development

In this example study, AWA analyzed precipitation-frequency relationships to derive the Annual Exceedance Probabilities (AEP) for 24-hour and 72-hour precipitation for the location. A regional L-moment analysis based on methods described in Hosking and Wallis (1997) and utilizing the R-statistical software packages lmom and lmomRFA developed by Hosking (2015a; 2015b) was followed.

A regional frequency analysis approach utilizes L-moment statistics instead of product moment statistics, which decreases the uncertainty of rainfall frequency estimates for more rare events and dampens the influence of outlier precipitation amounts from extreme storms (Hosking and Wallis, 1997). The basis of a regional frequency analysis is that data from sites within a homogeneous region can be pooled to improve the reliability of the magnitude-frequency estimates for all sites. A homogeneous region may be a geographic area delineated by meteorological climatologies or may be a collection of sites having similar characteristics pertinent to the phenomenon being investigated. The data methods used are listed in the following sub-sections.

Precipitation data and annual maximum series data

For this study locations, a search to identify individual stations in the region was conducted using precipitation data sources from official National Weather Service (NWS) stations, Remote Automated Weather Stations (RAWS), US Geological Survey (USGS), and other meteorological networks. Each station's period of record (POR) was evaluated to determine which stations were appropriate for use in the final regional analysis.

The term "annual maximum" refers to a single 24-hour and 72-hour precipitation maximum being selected for each precipitation gauge for each year of record. Several procedures were required for assembly of the precipitation annual maximum series (AMS) dataset. Figure 5 shows the extent of the study area and the stations used in the analysis after the completion of these procedures and all subsequent quality checks. Regional L-moment statistics (Hosking and Wallis, 1997) were computed for the annual maximum data for

stations shown in Figure 5. Detailed methods and examples of the Lmoments precipitation development are provided in several references (e.g., Kappel et al., 2024).

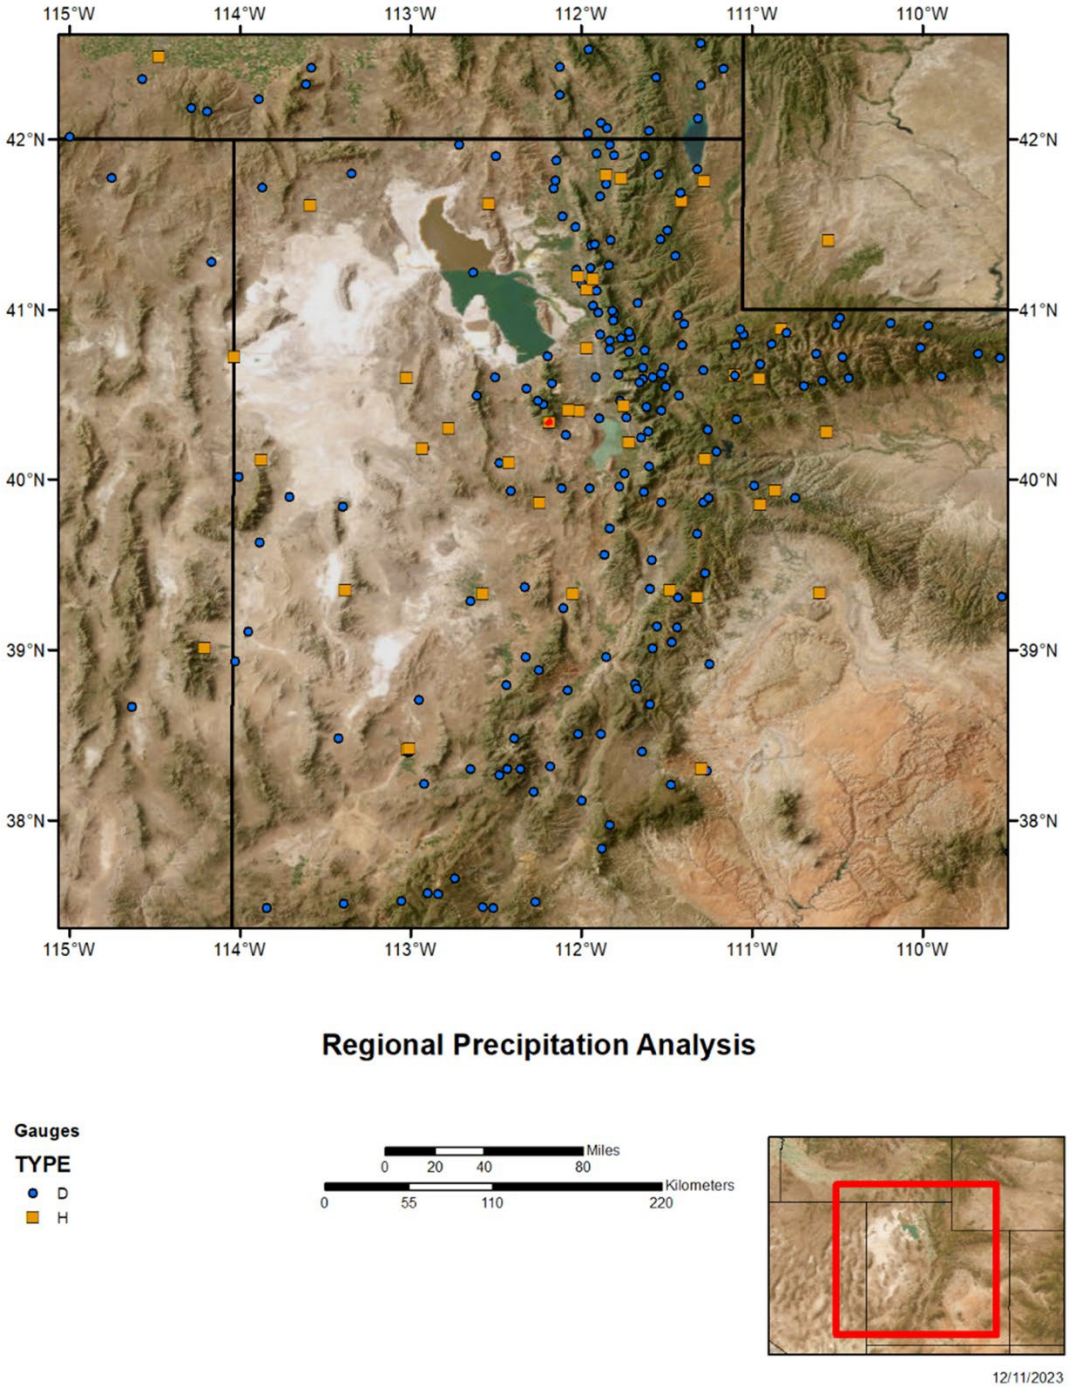

Figure 5: Locations of stations used for regional frequency analysis. The red outline is the basin, orange squares are hourly stations and blue circles are daily stations used for the 24- and 72-hour analysis

The output from this process is a series of gridded datasets that produce the at-site mean annual maximum (MAM) statistics described in the above sections and were used to scale the GEV distribution regional curve for each duration on a grid-cell by grid-cell basis. This allowed spatial mapping of precipitation-frequency estimates for selected recurrence intervals for the durations of 24-hours and 72-hours. Eighteen average recurrence interval (ARI) grids per duration were prepared from this information for point precipitation maxima for 1, 2, 5, 10, 25, 50, 100, 200, 500, 1,000, 5,000, 10,000, 100,000, 1,000,000, 10,000,000, 100,000,000, 1,000,000,000, and 10,000,000,000 years. The final 24-hour 100-year ARI and 72-hour 100-year ARI are shown in Figure 6 and Figure 7.

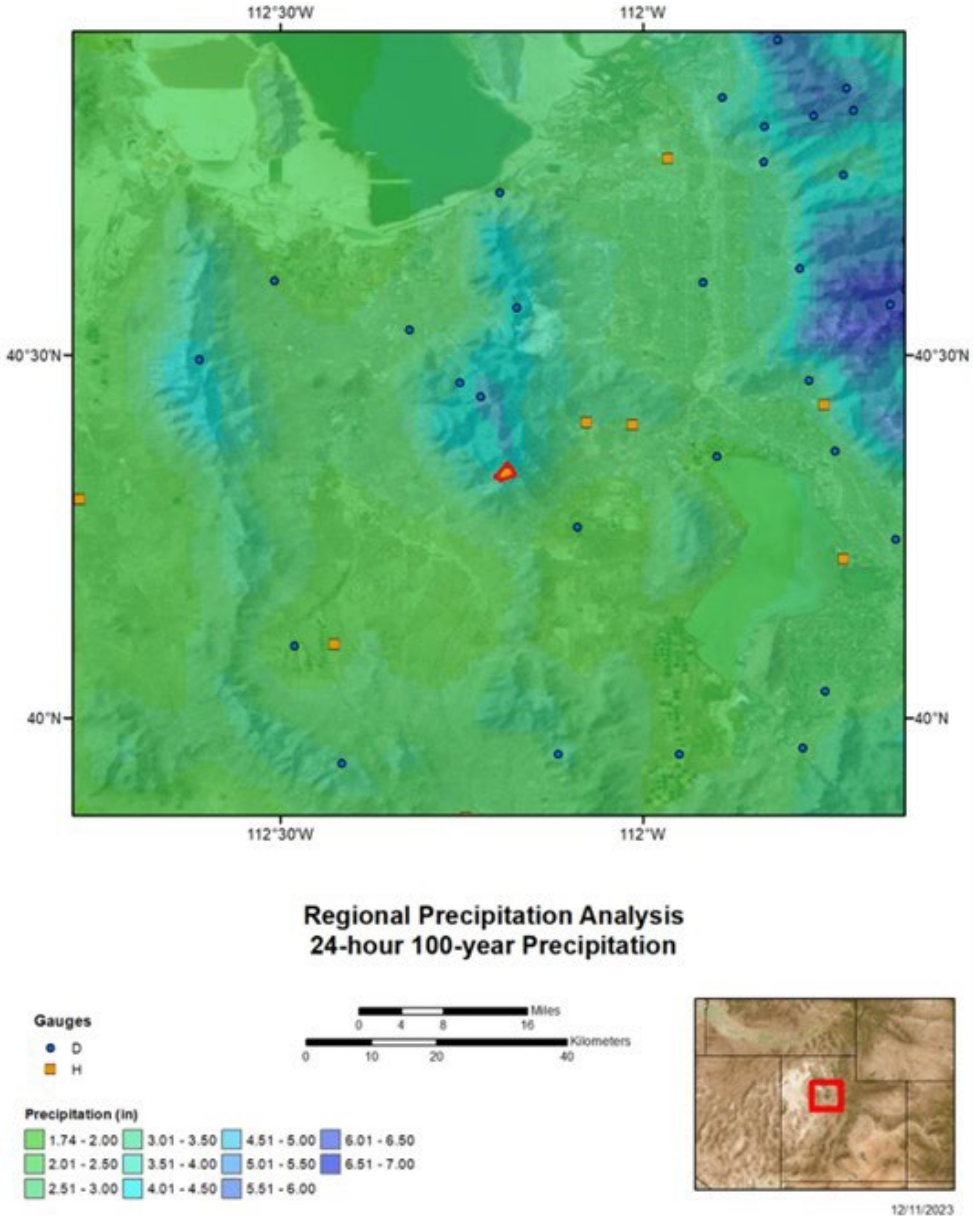

Figure 6: Spatially mapped 24-hour 100-year precipitation

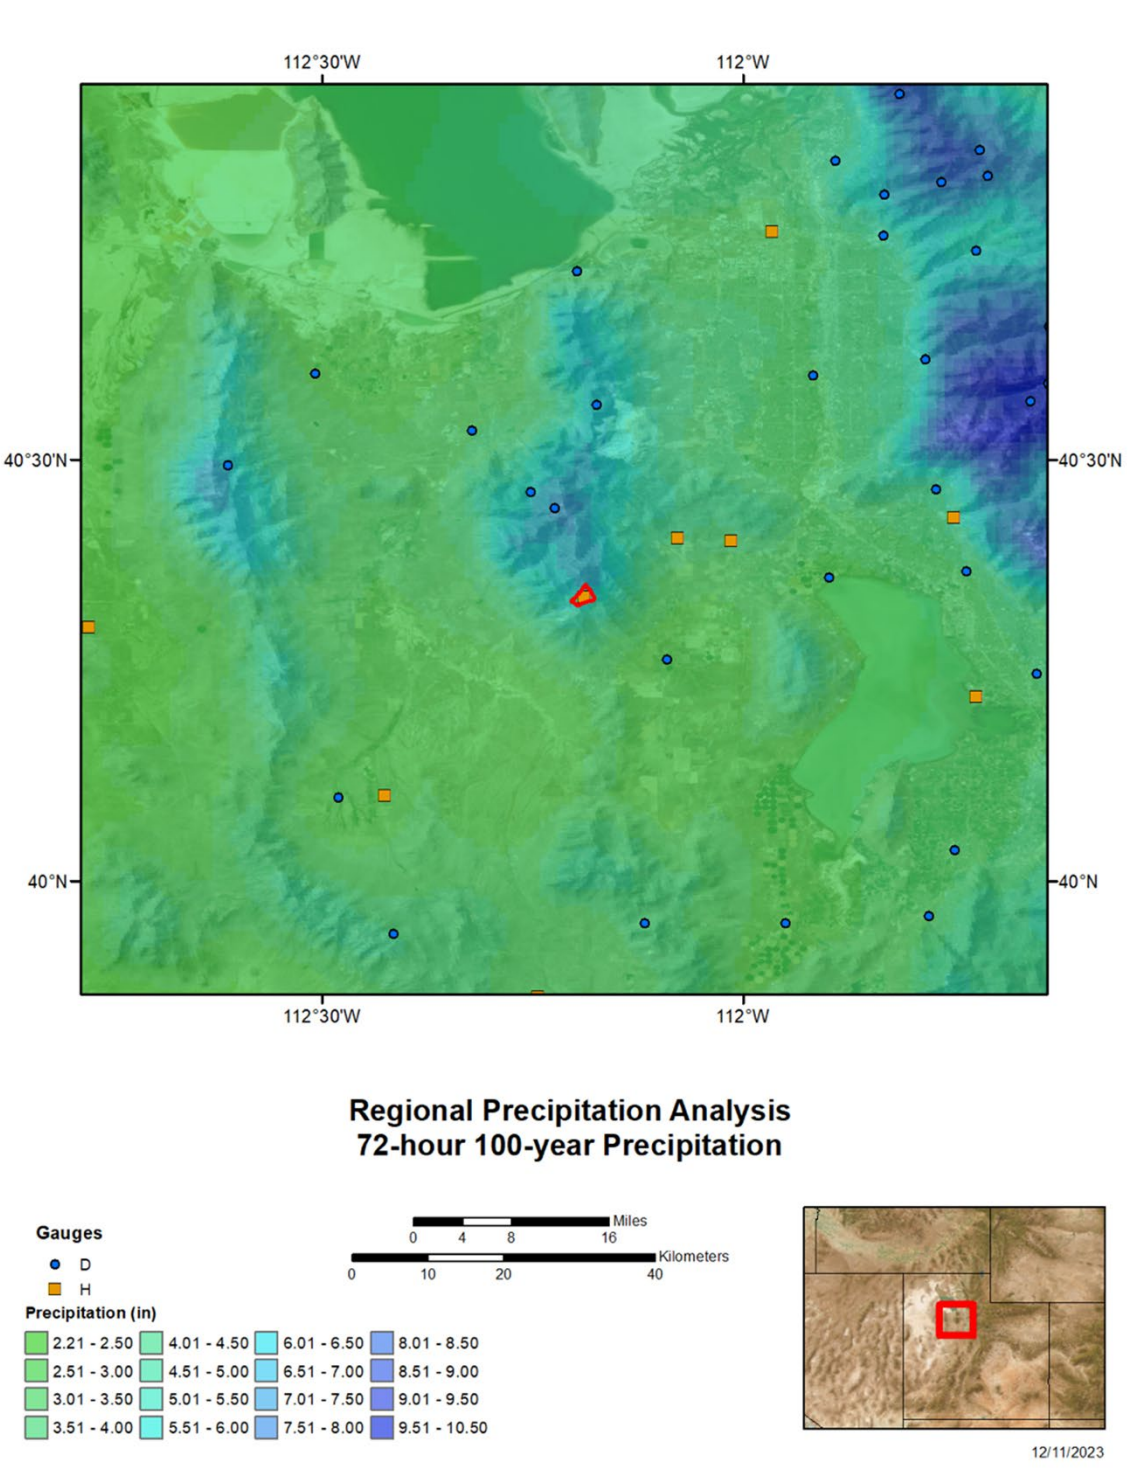

Figure 7: Spatially mapped 72-hour 100-year precipitation

Annual Exceedance Probability (AEP) grids for the 24-hour and 72-hour were used to extract the basin average AEPs. The 24-hour and 72-hour basin average AEP values are provided in Table 1 and illustrated in Figure 8 and Figure 9.

Table 1: 24- and 72-hour AEP values in inches. The 50% data represent the best estimate of precipitation magnitudes, while the 5% and 95% data represent the upper and lower bounds

Study Site		24-hour			72-hour

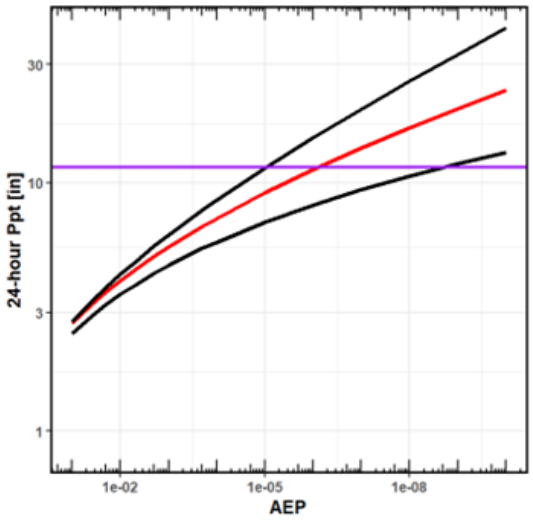

Figure 8: 24-hour regional L-moment frequency curve and uncertainty bounds representing the 5% and 95% confidence intervals. The purple line represents the estimated basin 24-hour PMP

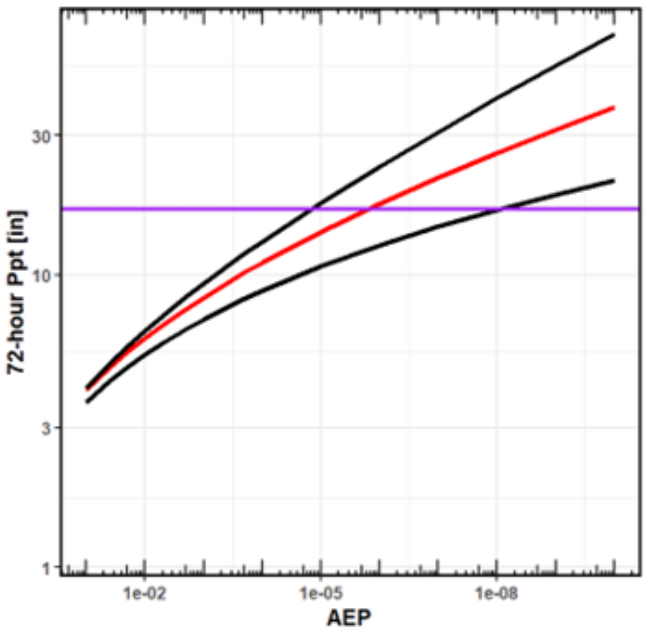

Figure 9: 72-hour regional L-moment frequency curve and uncertainty bounds representing the 5% and 95% confidence intervals. Purple line represents the estimated basin 72-hour PMP

Annual Exceedance Probability (AEP) for the 24-hour (11.5-inches) and 72-hour (16.74-inches) PMP were estimated. The 24-hour PMP has an AEP of 10^{-7} (Table 2) and the 72-hour PMP has an AEP of 10^{-6} (Table 2). It is important to note that there is significant uncertainty at these very low AEP ranges. Uncertainty bounds are provided for reference. However, even with the extreme uncertainty at very rare AEPs, this still provides valuable information and sensitivity inputs for risk analyses and probability assessments.

Table 2: AEP for 24-hour and 72-hour PMP

Basin	PMP (24 hr, 72 hr)		AEP (24 hr, 72 hr)		AEP Upper (24 hr, 72 hr)		AEP Lower (24 hr, 72 hr)	
Study site	11.5	16.7	10^{-7}	10^{-6}	10^{-6}	10^{-5}	10^{-9}	10^{-9}

Climate change assessments

Climate is changing, always has been changing, and always will change as long as the energy received from the sun across the Earth's surface and atmosphere is not distributed evenly. Accounting for future changes in climate is important to reduce risk and develop resiliency to potential future changes. The magnitude and rate of change at any given location for important meteorological parameters often must be modeled. However, we currently have an incomplete understanding of the Earth's climate system and future estimates of atmospheric composition. Therefore, model projections of the Earth's climate system and how that

climate system responds to greenhouse gases are applied using global climate models (GCMs), which are computationally intensive and are therefore run at low resolution both in time and space. The GCMs are developed by various governmental, academic, and research agencies around the world in coordination with the Intergovernmental Panel on Climate Change (IPCC). For detailed analysis at a given site, the resolution of the GCMs is inadequate to capture the spatial variations. To overcome this, projections from GCMs are downscaled using a statistical process into regional downscaled model projections (Regional Climate Models, or RCMs) through the CORDEX interface. The RCM process can provide projections of future climate conditions on a much smaller scale (e.g., 25-km by 25-km) supporting more detailed site-specific information allowing for adaptation assessment and planning (Figure 10).

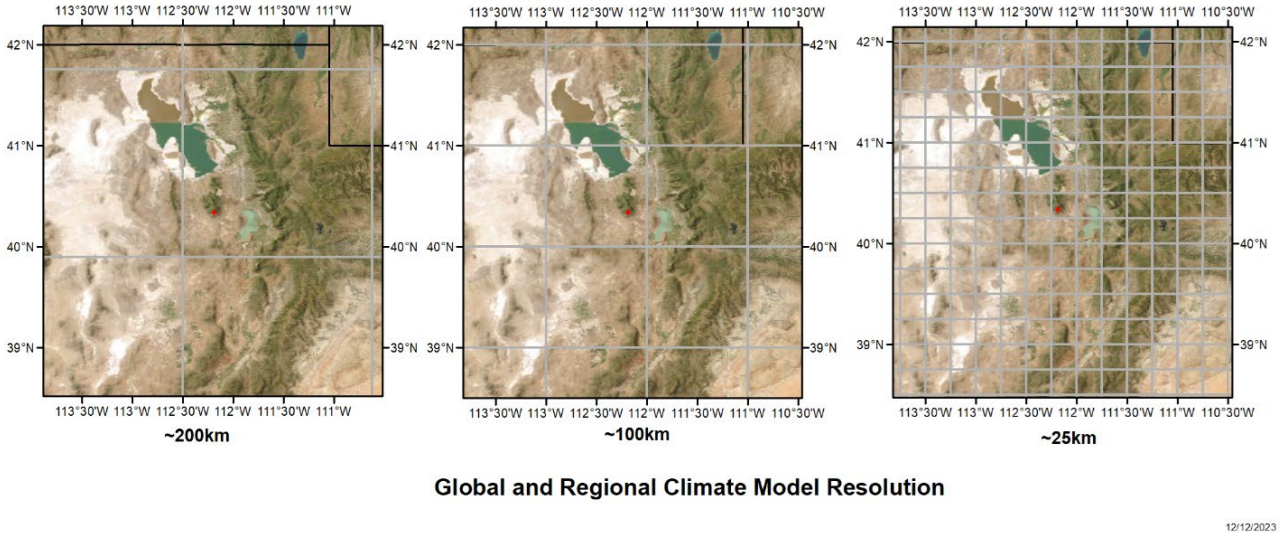

Figure 10: Climate change analysis region showing grids from GCM and RCMs

From these RCM projections, the potential effects of climate change on meteorological characterization within the study region were assessed. Various emissions scenarios that are used to force the GCMs are described by Shared Socioeconomic Pathways (SSPs). SSPs are scenarios of projected socioeconomic global changes and greenhouse gas concentration trajectory that are considered possible in the future (Figure 11).

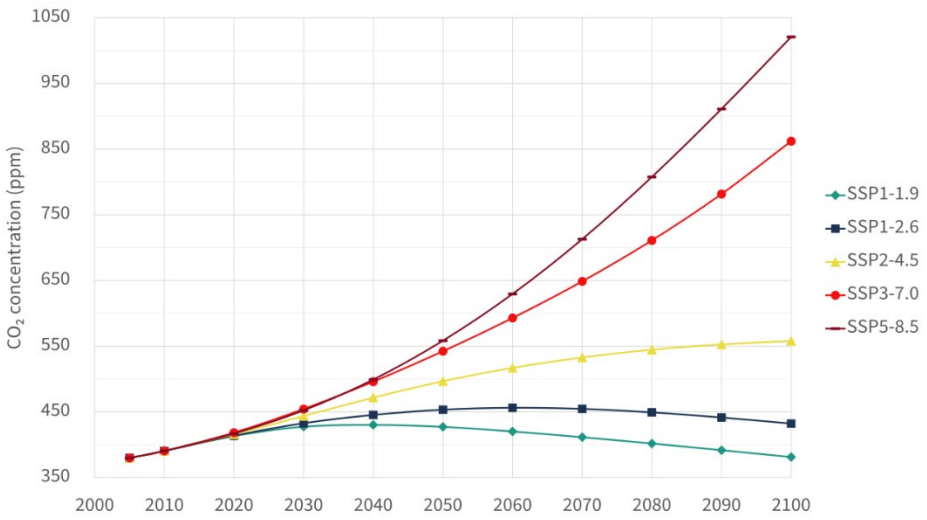

Figure 11: Shared Socioeconomic Pathways (SSP) trajectories. Reproduced from IPCC (2021)

The key climate model parameters used in this analysis were precipitation (Ppt), air temperature (Ta), dew point temperature (Td), wind speed (Ws), solar radiation (Srad), and evaporation (Evap). The parameters of relative humidity (RH) and Ta were used to derive the estimates of dew point (Td). Twenty-six RCM projections had the parameters needed for the climate change analysis. The climate projections historical period is based on daily data from 1950 through 2014, and the future periods are based on daily data from 2015 through 2100. The projections are evaluated using several methodologies. This helps inform the range of outcomes and uncertainty in the projections and produce a more reliable estimation.

Climate change projection analysis methods

Trend analysis

Mann-Kendall trend analysis (Mann, 1945; Hipel and McLeod, 2005) was performed on three climate stations located near the mine site for 1-day, 3-day, and annual durations. Results of these station-based trend analysis are shown in Table 3. The climate station trend results were used to assess the historic model projections.

Table 3: Climate stations used for trend analysis, evaluated at the 0.05 significant level

	Precipitation			Temperature
	1-day	**3-day**	**Annual**	**1-day**
Station 1	no trend	no trend	no trend	no trend
Station 2	no trend	decrease	no trend	decrease
Station 3	no trend	no trend	N/A	no trend

In addition, Mann-Kendall trend analysis (Mann, 1945; Hipel and McLeod, 2005) was performed on twenty-six climate model projections using the three scenarios (historic, SSP4.5, SSP8.5) for durations of 1-day, 3-day, 30-day, 90-day, and annual. Results for all climate model projection trend analyses are summarized in Table 4.

Table 4: Climate stations used for trend analysis, evaluated at the 0.05 significant level

Precipitation frequency analysis

Methods to account for non-stationarity in projections were not addressed, the projections were applied assuming stationarity. For the precipitation frequency analysis, AWA utilized the daily climate model projections to perform frequency analysis on the 1-day, 3-day, 30-day, 90-day, and annual durations.

AWA evaluates the climate change projections for the entire period available from 2015 through 2100. However, because the projections are provided on a daily time step, other evaluation periods can be considered applying a rate of change through time. For example, one may evaluate the projections through the year 2050 and then do a separate analysis for the years 2050–2100. This may result in slightly different outcomes depending on the climate change projections amount of change through time.

AWA identified, extracted, and quality controlled maximum daily precipitation projections for the twenty-six models and three projection scenarios. Annual Maximum Series (AMS) were then subjected to the frequency analysis methods described earlier in the AEP section. Example results from this analysis are shown in Figure 12 and separated by season for the 1-hour duration. Figure 13 provides example results of the summaries of climate change assessments that can be applied for evaluation. For most high hazard structures, the median of the SSP4.5 is recommended for application.

Wind-wave run up

Another aspect that is critical for TSF and dam design is the need to properly quantify the potential of wave

action on top of a PMP/PMF event. In many studies reviewed by AWA, the wind wave run up analysis have been inadequate and not representative of the wind patterns that could occur during and immediately following a PMP/PMF event. As part of the wind wave run up analysis, wind speed and direction analysis are completed for various durations and directions. The critical timeframe for wind wave set up and the critical fetch(s) given the design of the TSF pond or reservoir must be evaluated. The analysis can be completed using a frequency analysis based on observed data at the site and within similar regions.

However, the main issue that is often found and corrected by AWA site-specific studies is related to understanding of the unique synoptic meteorological conditions that would be associated with the PMP event and the wind fields that would be generated during these events over the location of interest. During the PMP design storm, significant wind would only occur within a specific range of directions as a PMP event develops, matures, and moves through based on the synoptic patterns associated with the storm environment as well as the local topographic and exposure conditions.

The specific characteristics that occur with the PMP design storm and the site location must be considered. And the specific wind direction(s) that could occur should during the storms must be accurately considered when developing the wind speed and direction inputs for wind wave run up. In other words, if the wind with the PMP design storm could only come from the northwest yet the critical direction for the fetch of the location is from the southwest, then the maximum wind speeds only from the northwest should be used. Winds from other directions (e.g. southwest) should not be used as they are not critical for the wave development over the TSF. For locations that are affected by tropical systems, the wind direction will change through time as the storm progresses through the region. During the course of the storm, wind directions may shift from each direction of the wind rose. In these situations, the frequency analysis and development of wind speed climatologies should only be done for the direction(s) that are along the fetch and would result in the maximum wind wave set up. Conversely the wind speeds from the other directions should not influence the wind speed climatologies. Therefore, applying the worst-case wind speed and wind direction outputs without proper consideration for how these parameters would develop during a PMP design storm is not correct and should not be applied.

It is important to note that the storm characteristics vary by location and storm type. For example, along the west coast of the North America, wind is associated with low pressure systems moving off the Pacific Ocean generally from northwest through southwest and PMP events would not occur with winds from the northeast through southeast. In this region, many reservoirs drain from the east to the west following the river systems and topography. Therefore, the critical fetch for many of these locations does not align with the most critical wind direction and the wind wave run up analysis should only consider the critical directions. This would likely result in smaller wave set up and less freeboard requirements.

In central regions of North America, low pressure systems often form on the lee side of the Rocky Mountains. In these areas winds from the north through the east through the south are most common during heavy rainfall events as low pressure move through the region. However, most reservoirs drain orthogonal to these directions as they drain from west to east from the higher to lower elevations. However, in these regions, the strongest winds often occur associated with strong upper-level winds crossing the mountains and down sloping off the mountains towards the adjacent plains. These are sometimes termed “Chinook” winds. In these situations, the weather pattern is dry, but the winds can be sustained well over 100mph for several hours. In addition, these are often occurring in a direction that represents the worst-case fetch of a given reservoir. In cases where the PMP/PMF has recently occurred and the reservoir is still relatively full, this event could occur at a timeframe when the strongest winds and high-water surface elevations co-occur.

Another example would be the eastern Atlantic coast of North America where tropical system s affect the region. In these areas this type of storm moves in from the south through the east. However, these storms are associated with a closed circulation until they transition to an extra tropical storm. Therefore, wind from these vents can come from any direction depending on the path of the storm in relation to the given TSF or reservoir. However, the wind speed from the different directions varies significantly during the lifetime of the storm. In this example, the strongest winds are associated with the right front quadrant of the storm and if this quadrant of the storm could not affect a given location, only the wind speed form the appropriate quadrants should be used. Again, many of the reservoir systems in this region flow from west to east or south to north and the reservoirs also follow these directions. Therefore, the wind speed associated with the right front quadrant would in the opposite direction of the critical fetch of these reservoir examples. Instead, the wind direction associated with the direction of the critical fetch would be evaluated, for example the left front quadrant or northwest to west wind speed associated with the tropical system.

The goal of this discussion is to be sure the analysis is specifically reflective of the local characteristics of the TSF or reservoir site, the direction and distance related to the fetch, and how those relate to the meteorological patterns that would produce strong winds during a PMP design storm event.

Conclusion

The development and application of important meteorological input parameters for TSF design and evaluation was discussed, with examples provided of deterministic PMP and probability assessments. Comments were provided on the proper pairing of extreme mereological events and wind and how those should be applied based on the site-specific location. In addition, the application of climate change assessments and how those affect these outputs was shown. It is important to note that unrealistic combinations of outcomes and overly conservative applications should not be applied. For dam safety assessments and design the key messages are as follows:

- Do not combine PMP back-to-back. The timing between events should reflect the physical conditions of the location, atmosphere, and storm type.
- Quantifying the probability of extreme events, including PMP, is very useful for risk assessments and risk informed decision making process, and to ensure your design is appropriately rare.
- Consideration of climate change should be assessed to determine how changes may affect extreme events for a given location and how to ensure resiliency of design.
- Site specific evaluation of extreme wind conditions that could occur in relation to the PMP storm event and the topography/exposure of your site should be completed to ensure inappropriate combinations of extreme parameters are not combined.

GISTM – Effective Implementation

Lis Boczek, South32, Australia
Richard Zayler, South32, Australia
Gideon Steyl, South32, Australia

Abstract

The Global Industry Standard on Tailings Management (GISTM) is an important standard for mining companies to implement for both investors and insurers. GISTM focuses on the importance of social, environmental and engineering aspects to ensure the safety of tailings storage facilities (TSFs) and the communities that may be affected by mining operations and their associated structures. A key aspect in obtaining value from GISTM alignment is breaking down the silos that exist within the operations and corporate functions of a mining company. GISTM cannot be successfully implemented if it is solely focused on being compliance driven. It requires structural changes in the organization to achieve the intent on a continual basis during the life of the TSF. Prior to the standard, interaction of the groups required to implement and sustain GISTM would only occur to achieve regulatory outcomes, and the relationship would not continue into the operational space once the TSF was built.

The implementation journey of GISTM within South32 has highlighted two components that influence successful implementation: collaboration and improved operational practices.

This paper attempts to provide a response to the question: "Can GISTM drive the change needed to achieve improved operational performance to increase the safety of the TSF?" We will outline the journey taken by South32 to implement GISTM across our operations and the benefits obtained from the process. In addition, the paper aims to highlight the lessons learnt and improvements undertaken to implement GISTM for not just compliance, but to improve the overall safety, social performance, and environmental outcomes associated with our TSFs.

Introduction

The Global Industry Standard on Tailings Management (GISTM) was developed following the 2019 catastrophic failure of a tailings storage facility (TSF) at Córrego do Feijão mine in Brumadinho, where 272 people lost their lives and there were significant impacts to local flora and fauna. An integrated approach to tailings management with transparency, accountability, and safeguards for the rights of project-

affected people were key pillars of the GISTM implementation. ICMM member companies committed to implement the standard for Very High and Extreme facilities by August 2023 and all remaining TSFs by August 2025. The ICMM drafted conformance protocols to support implementation of the 77 GISTM requirements and these protocols are used as a basis by many mining companies, including South32, to assess conformance to GISTM.

Several GISTM papers have been published since it was introduced in 2020 and it continues to be a source of discussion. There are many ideas on how to implement GISTM within companies. Consultants have made numerous interpretations of each of the Principles and the best way to implement these in a mining environment. It is well understood that to implement GISTM effectively, collaboration across the different disciplines within a mining company is required. Due to the expanding literature support on GISTM, the industry is evolving in its understanding through collaboration and shared learnings within the ICMM member companies.

This paper discusses the journey undertaken by South32 on the path to GISTM conformance, and how this conformance can influence the safety of our TSFs.

South32's journey

Roles and accountabilities

The GISTM implementation at South32 began as a centrally managed project with each operation being responsible for the implementation. Each operation was initially given the freedom to implement GISTM for TSFs with guidance on the minimum requirements to meet conformance by South32's Tailings Dams Governance group, prior to the publishing of the ICMM protocols.

An initial gap assessment was completed at each operation to inform the budget and timeline to achieve GISTM implementation. Accountable Executives (AE) were appointed based on geographical region and a Responsible Tailings Facility Engineers (RTFE) for each operation was employed. The RTFE mandate was to achieve GISTM conformance at their respective operation. Subsequently, Engineers of Record (EOR), Independent Tailings Review Board (ITRB) Members and Independent Technical Reviewers (IRs) were shortlisted for each operation and appointed to their roles by the AE.

The hardest role to fill in all operations was the RTFE. The minimum qualification requirements were defined by the Tailings Dams Governance group and our operations endeavored to recruit appropriately qualified RTFEs. This proved a significant challenge as the experience and qualifications defined were in high demand across the whole industry. The parallel implementation of GISTM among all ICMM members resulted in a chronic shortage of candidates.

Most operations employed a project manager to facilitate the implementation, which led to a compliance mindset around commissioning and completing documentation. At some operations, the GISTM implementation commenced prior to appointment of the RTFE role.

The ITRB/IRs conducted site visits to all operations and channels were set up between our RTFEs, EORs, and ITRB/IRs to allow for regular communication and feedback.

Development of documentation

To achieve ICMM GISTM conformance, modification of existing documentation and in some cases new reports to fill in the gaps identified were required. The development of engineering documentation, retrospective construction documentation, and potentially long lead items were identified as priorities for our RTFEs and EORs to address. The finished documents generally met the GISTM requirements; however, when internal technical reviews were undertaken, gaps were identified where the whole requirement, or the intent of the requirement, was not being met.

Three key questions arose regarding the documentation being produced. Firstly, was it fit for purpose? Secondly, was it sufficient to fit the risk classification of the facility? Finally, was it suitable for the available resources and experience of personnel at the operation? This was especially relevant in the case of our Tailings Management Plans (TMP), Water Management Plans (WMP) and Operation Maintenance and Surveillance Manuals (OMS), where the documentation must be appropriate for the end user to implement.

To ensure all information was available in a centralized location for all our operations and functions, an internal Microsoft SharePoint site for GISTM documentation was created.

Engagement with stakeholders (internal and external)

One of the key pillars of GISTM is meaningful engagement with project-affected and Indigenous peoples. Our operations already had systems in place to engage with our local communities and Indigenous populations on a variety of issues, and we leveraged those existing systems to start engagement specifically on our TSFs. A key learning from the TSF specific stakeholder engagement is the significance to communities of environmental impacts on waterways and land areas. When these are not heritage sites, they would not have been identified during desktop reviews. Historically, consequence classification assessments were undertaken by consultants without engagement across all groups to inform them of all impacts. Whild engagement cannot be retrospectively implemented for existing facilities, modifications can be made to the future design and closure of the facility that may provide a better outcome for those impacted.

Internal stakeholder engagement included cross-functional and operational teams. In South32 we identified very early on that our Environmental and External Affairs teams are key players to achieve meaningful conformance to GISTM. We also recognized that GISTM conformance would not be achieved in an effective manner without improving the profile of our TSFs and our facility performance within the

greater South32 business. Site visits, workshops, and virtual meetings were conducted across all South32 functions to promote awareness of our TSFs. Furthermore, educational and tailings related materials were updated for our operations to help raise the perceived importance of our TSFs. The increase in profile significantly helped our cross-functional teams to achieve conformance for our environment and community-focused requirements.

Cross-functional meetings at various levels, implemented initially to promote GISTM conformance, have continued and evolved into more informal information sharing between functions within the business. This has helped maintain collaboration and relationships with stakeholders, and ensures that the importance of our TSFs is not lost among the wider business.

How did we measure conformance?

What does GISTM conformance look like?

To enable measuring of GISTM conformance, companies score themselves as "meets," "partially meets," and "does not meet" against each of the GISTMs 77 requirements. Meeting with a plan has also been accepted by the industry for some requirements where conformance will take longer due to additional works, etc. This is particularly evident in relation to as low as reasonably practical (ALARP) risk reduction measures.

Understanding what is required to meet conformance may sound simple but interpretation can vary, and the requirements of conformance can also vary depending on the type of TSF, size, consequence classification, and construction methodology. To define the minimum requirements, the first step taken by South32 was to review the consequence classification of each TSF, confirm whether all TSFs met the definition of a TSF under GISTM, and identify existing facilities that should be excluded. This step was important, as the definition of a TSF for the purpose of an internal standard and/or stewardship activity often includes other waste types/facilities that do not strictly meet the industry definition for tailings.

Conformance criteria

ICMM GISTM conformance protocols set out guidance for measuring conformance, and an initial gap assessment of implementation works to date was conducted in early 2021 by South32 Tailings Dams Governance group.

The criteria used for self-assessment were those presented in the ICMM Conformance Protocols; however, for better quantification/precision for the "partially meets" criteria, South32 adopted three different levels of conformance achievement (25%, 50% and 75%), considering sufficiency status as evidence for meeting the requirement as per Table 1. Conformance to GISTM was measured across each operation as a percentage compliance.

Table 1: GISTM requirement assessment criteria

Criteria	Adherence
Does Not Meet – No information as evidence	0%
Partially Meets – Information exists but is insufficient and actions/purchase order are not in place	25%
Partially Meets – Information exists but is insufficient and actions/purchase order do not cover whole requirement	50%
Partially Meets – Information exists but is insufficient and actions/purchase order covers whole requirement	75%
Meets – Information exists as evidence	100%
Not Applicable – This specific requirement is not applicable in the context of the asset and does not participate in the calculation of the average	N/A

All the operations' self-assessments were collated into a Monthly Report that was issued to key internal stakeholders. Internal validation of the operations' self-assessments was undertaken by South32 Tailings Dams Governance group and third-party KPMG for our FY23 disclosure.

Addressing the safety of our facilities

Conformance to GISTM alone, while it provides a deeper understanding of the condition of our TSFs, does not fully address the safety of the TSF. Without good operational systems and practices, the safety of our TSFs can be compromised. Thus, a significant focus has been placed on ensuring that our documentation is fit for purpose; our people are well trained; and the risks to the TSFs are well understood and communicated from an operational perspective.

One of the keys to the safety of our TSFs is ensuring that risks around water management are well understood. The role that water plays in increasing the risk of failure and the impact of failure has been made clear to our operations. Our South32 Dam Management Standard mandates that all decant pond sizes should be less than 10% of the operational area in a TSF, unless designed to be greater and approved in writing by the EOR. Secondly, the design storm must be removed within 30 days by available infrastructure to ensure the safe operation of the TSF and promote maximum in-situ tailings density.

Monthly reporting by our RTFEs within the business includes GISTM conformance and TSF performance metrics such as:

- decant pond size;
- trigger action response plan (TARP) condition;
- instrumentation condition;
- inspection reports;

- maintenance status;
- survey reports (LiDAR, InSAR, monuments); and
- status of critical controls.

South32 also implemented a centralized monitoring platform to allow for real-time oversight of the physical performance of each of our TSFs, which includes the above performance metrics.

Moving from conformance to effective implementation

At the beginning of South32's journey, the mindset of the business was around compliance to GISTM, with targets set to achieve 100% conformance by the implementation timelines. This focus led to a mindset of ticking boxes rather than using the GISTM to change our operations to embed it. Through internal review processes, it became evident that the dialogue needed to shift from pure GISTM compliance and focus more on changing the way we operate while achieving conformance to the GISTM.

South32 achieved compliance to GISTM for their very high consequence classified facilities by August 2023 and are well on the way to achieving full compliance for all other facilities by August 2025. As a business we are committed to maintaining conformance with GISTM. If we unpack what a sustained conformance to GISTM looks like at an operational level, it requires a change from work undertaken to achieve and maintain conformance, to work required to embed GISTM into the way we operate. Although a subtle difference, the embedment of GISTM requires all areas of the organization at both an operational level and a corporate level to work together and think with a proactive and engaged mindset that is driven by improvements in how we operate. It requires sustained ownership and commitment to facilitate the embedment of GISTM.

As we mature in our journey and we move closer to achieving GISTM conformance across our business, we have shifted from making GISTM conformance the goal, to making sure GISTM becomes part of the way we operate. This involves ensuring those cross-functional relationships are maintained and strengthened with systems to support and ensure that we have ongoing communication and that we meet our commitments within South32. It also includes ensuring that any documentation related to the operation of the TSF aligns with actions undertaken especially around the OMS, water management plan, trigger, action and response plan, and emergency response plans. The outcome of this supports South32's guarantee that we all go home safe and well and is an integrated part of how we operate.

Learnings and outcomes

Learnings

The implementation of the GISTM within South32 had, and still has, some challenges and learnings. These include:

- GISTM being viewed as a Project to be implemented and once completed we are compliant in the long term. There is and has been significant effort made to promote and educate stakeholders to understand that ongoing commitment to GISTM requires a sustained effort to maintain conformance going forward.
- Maintaining momentum throughout the GISTM implementation at each operation as it approached full conformance. It is challenging, as the last 5% to reach 100% conformance required 50% of the effort, and ongoing education was needed as stakeholders changed over the journey.
- External engagement was left to the latter half of the implementation, but this engagement would have benefited from early education on our TSFs, or from being gradually introduced to our TSFs from the start, using our existing external engagement systems.
- The deliverables for the GISTM varied greatly across the operations. This was in part due to the initial momentum of the implementation with different RTFEs, EORs, and consultants involved. Effort was made to standardize key documentation and reporting requirements, but in hindsight, this would have benefited from a slower initial implementation that was phased in to align with set goals for South32.
- Starting implementation before the ICMM conformance protocols were published and fully understood. South32 started implementation in December 2020 with gap assessments and actions to fill the identified gaps completed in February 2021. RTFEs and EORs had commenced actions, and it was not until mid- to late-2021 that the conformance protocols were reviewed against the actions, resulting in additional gaps identified, which caused delays and required rework.
- TSF Projects in late Feasibility Study and Execution phases were impacted by South32s commitment to implement GISTM, as these projects could not be delayed due to their business sustaining nature and have been treated as “existing facilities” under GISTM. This led to stakeholder engagement and requirements being retroactively applied.
- Management plans and documentation produced to conform with GISTM requirements was not always used effectively by the operation to enhance our TSF knowledge base or support improvements in operational safety.
- Effective change management and early intervention in the change management process to enable continued implementation of GISTM. Due to the continued changing structure in the operational environment, effective handovers between staff required management to allow for sufficient knowledge transfer between individuals and familiarization with systems.

Positive outcomes

There have been many positive outcomes for our business with the implementation of GISTM. These include:

- Centralizing our Tailings Knowledge Base to allow for easy access to all documentation related to our TSFs. This allows for information to be viewed by all areas of the organization (not just at the operation).
- Promotion of our TSFs and people has allowed for a higher level of TSF awareness across the business and at the operation.
- Greater understanding of the risk of our TSFs and improvements in how we manage those risks.
- More detailed and live monitoring of our TSFs, with regular reporting to a larger group of stakeholders on TSF status.
- Collaboration between stakeholders with inclusion of tailings team members at an early stage in projects and working groups.
- Operational integration of the tailings team in the wider team to help maintain relationships and improve decision-making processes.
- Improved water management at our operations through enhanced understanding of the role water plays in managing the risks associated with a TSF and the potential impact of failure.
- Identification of areas that require additional attention moving forward, and where we can continue to improve our operations to reduce TSF-related risks.

Conclusion

South32 is still progressing on the learning journey to bring all areas of the operations and functions together to achieve embedment of, and maintain conformance to, GISTM. Conformance at face value can be achieved without collaboration, but ongoing maintenance and effectiveness cannot. South32 still has a road to travel to achieve the level of collaboration and density of communication to provide for a business-as-usual mindset, but with progressive integration into the South32 operating system it is achievable. In addition, a focus on moving forward to maintain effective implementation is ensuring that documentation produced is fit for purpose and, where gaps still exist, working to improve these areas to ensure alignment. While a standardized approach is preferred for ease of governance and alignment across the business, implementation of the GISTM needs to be specific to each operation, and conditions of the TSF and cannot be a one-size-fits-all approach.

A Case Study on ALARP for Safety Management of Tailings Storage Facilities

Theo Gerritsen, Rio Tinto, Australia
Yi Zhu, Rio Tinto, USA

Abstract

ALARP – *As Low as Reasonably Practicable* – refers to the principle of testing risk reduction against the cost of the corresponding risk reduction effort. The principle of societal risk acknowledges that there is no absolute safety (zero risk) from engineered systems, and neither society nor a company have infinite resources to spend on managing risks. However, it requires risk management to reduce risks to *"As Low as Reasonably Practicable."* ALARP is built into requirements under the Global Industry Standard on Tailings Management (GISTM, 2020). Rio Tinto presented its ALARP roadmap for demonstrating dam safety to an ALARP requirement in relation to tailings storage facilities during the 2023 Tailings and Mine Waste Conference in Vancouver (Zhu and Pascoe, 2023). This paper presents the details of when one of its active tailings storage facilities followed that roadmap for ALARP demonstration.

Introduction

ALARP – *As Low as Reasonably Practicable* – refers to the principle of testing risk reduction against the cost or sacrifice of the corresponding risk reduction effort. The ALARP principle is referenced across multiple Rio Tinto Standards and Group Procedures. Rio Tinto's risk management standard and HSE management system standard both require that health and safety risks are managed to ALARP. To facilitate Rio Tinto's commitment to the implementation of GISTM for its tailings storage facilities (TSFs), Rio Tinto has developed a process (roadmap) to demonstrate ALARP related requirements in the GISTM (Zhu and Pascoe, 2023). This paper presents a short summary on that roadmap and the details when the roadmap was followed for ALARP demonstration by its Oyu Tolgoi mine tailings storage facility (OT TSF).

The Oyu Tolgoi copper-gold mine (OT) is located in the southern Gobi Desert region of Mongolia, approximately 550 km south of the Mongolia capital, Ulaanbaatar, and 80 km north from the border with China. OT operates a multi-cell paddock type TSF, as shown in Figure 1. TC1 of the TSF was active and TC2 was undergoing its stage 1 (initial) construction (during the ALARP demonstration exercise presented in this paper). The OT TSF supports a nominal ore processing rate of approximately 110,000 tonnes per

day (for an annual tailings production of approximately 40 million tonnes). It receives thickened tailings slurry with an average solids content (by weight) of about 60%.

TC1 is a roughly-2km square ring-dike facility constructed with containment embankments raised in the downstream direction. Construction of TC1 started in February 2011 and tailings deposition commenced in March 2012. The embankments are raised each year and are scheduled to reach the final height of approximately 70 m to provide about 240 million m^3 of storage volume for storing about 360 million tonnes (Mt) of tailings solids.

Figure 1: OT TSF

TC2 was constructed to the north of TC1, with the northern embankment of TC1 forming the southern embankment of TC2. TC2 has a total footprint area of approximately 480 hectares in a sub-pentagonal shape. The adopted design footprint of TC2 is moderately larger than the 400 hectares of TC1 and this has led to a larger design storage volume of 282 Mm^3 for TC2 than TC1 of 240 Mm^3. TC2 design has largely followed the same for TC1 but has incorporated the operational experience and lessons learned from TC1.

Rio Tinto ALARP roadmap for dam safety

As presented in Figure 2, the Rio Tinto ALARP roadmap for dam safety requires both good practice demonstration and ALARP demonstration.

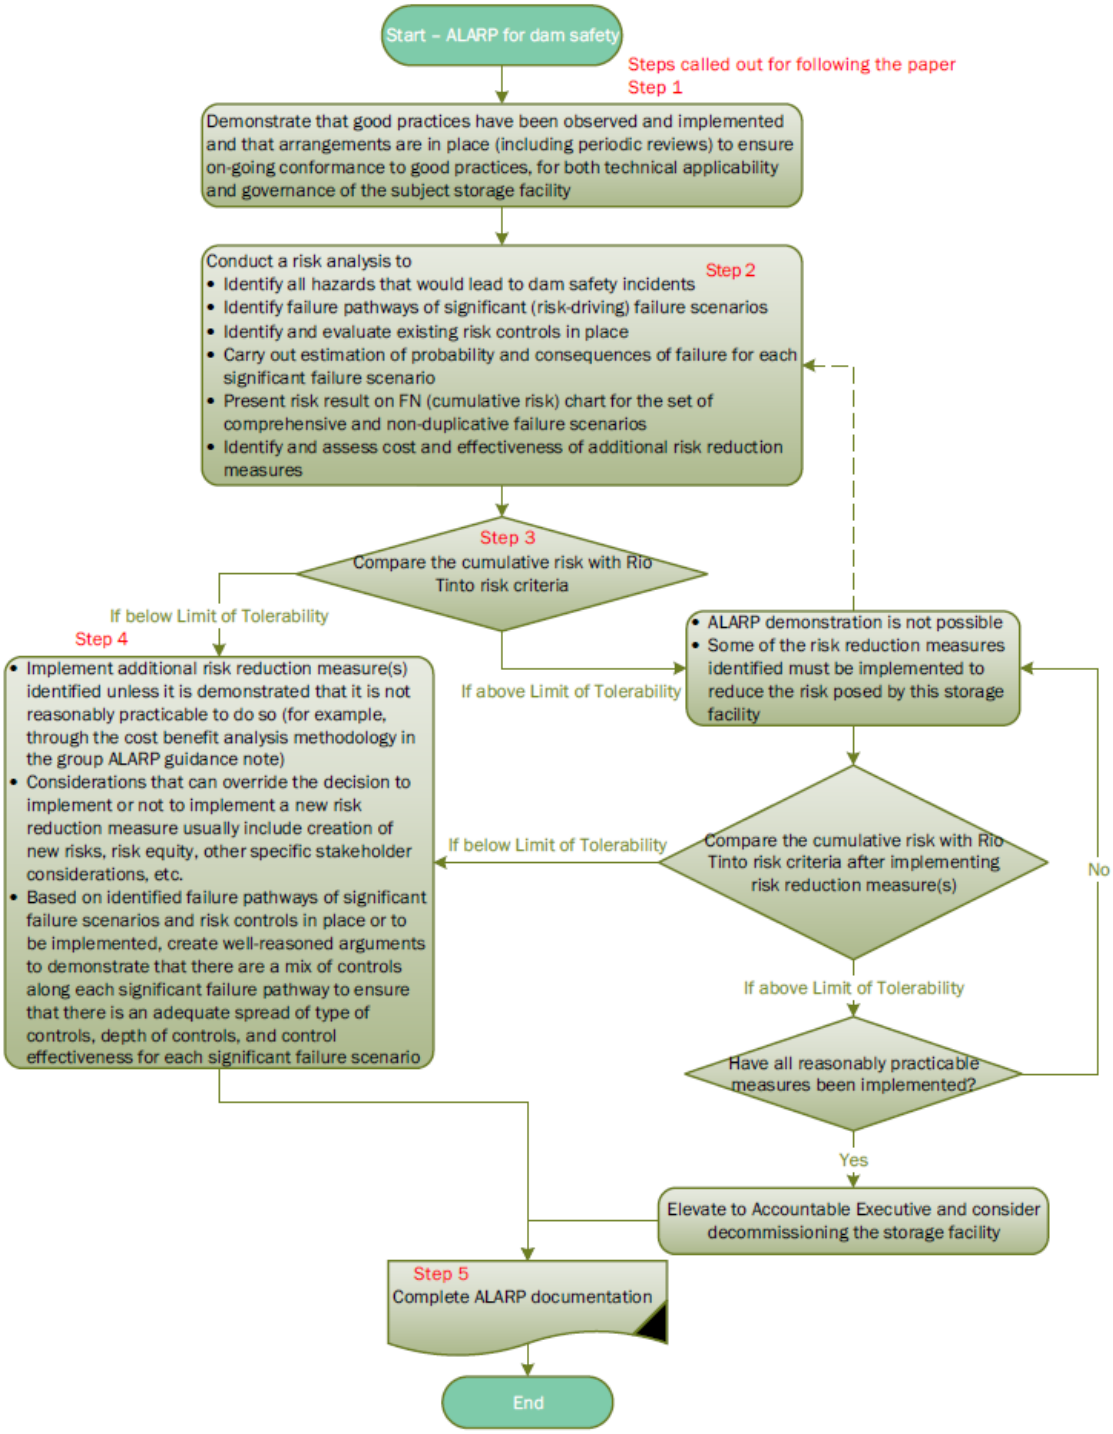

Figure 2: Rio Tinto ALARP roadmap for dam safety

Good practice demonstration (Step 1 in Figure 2)

To the extent possible, Rio Tinto requires an examination of the implementation of specific applicable good practice to each of its TSFs, from both engineering and governance points of view. This is done before the quantitative risk analysis based ALARP demonstration.

For OT TSF, the good practice demonstration includes a detailed examination on the implementation of the Tailings Management System (TMS) at OT and the state-of-practices followed by the engineering and operations for the TSF.

Implementation of TMS for the OT TSF

The specific implementation of the TMS for the OT TSF is embodied by the following:

1. A clear understanding of the responsibilities and accountabilities for roles related to the tailings management. OT has established both internal roles and external roles for its tailings management, including the Accountable Executive, Nominated Manager, Qualified Site Representative, and Responsible Dam Engineer. OT has a qualified Engineer of Record (EoR) and deputy EoR, an ITRB, and independent operational and design reviewers.
2. Regular reviews of both short- and long-range tailings management plans to ensure adequate funding/planning for tailings management.
3. Following the processes (in Rio Tinto D5 safety standard on tailings storage and GISTM) to deliver quality designs or design changes.
4. Following the processes (in D5 and GISTM) to deliver constructions that meet the design intent.
5. Maintaining an effective Operations Maintenance and Surveillance (OMS) manual and conducting proper TSF operations, TSF maintenance, and TSF surveillance activities, accordingly, including:
    - maintaining a defined operational freeboard;
    - maintaining a defined size of reclaim pond;
    - maintaining an effective TSF monitoring system with the trigger action response plan (TARP) defined and regularly reviewed; and
    - conducting regular planning and maintaining a mature level of preparedness for upset and emergency scenarios.
6. Maintaining an effective tailings response plan (for loss of containment dam failure scenarios) and conducting regular response drills.
7. Following the Rio Tinto 3-lines-of-defense assurance delivery model:
    - First line of activities by OT site-based team and the Rio Tinto Copper technical team for a proper implementation of D5 and GISTM.
    - Second line of activities by the Rio Tinto Group Technical Major Hazards team.

Good practices for engineering and operations

OT TSF is a modern tailings storage facility with a thoroughly documented development history. Engineering study started in the 2000's and over almost 20 years Knight Piésold, KCB, Golder, and ATC Williams have amassed engineering data and reports for the OT TSF. The cumulative understanding of the site condition is thorough and up to date through several programs of site investigation and laboratory testing. The current engineering assessment methodology is at the state-of-practice, for material characterization, pore pressure response behavior characterization, and geotechnical analyses including liquefaction evaluation, slope stability, and seismic deformation. The adopted dam raising methodology for the TSF is to raise the containment embankments in the downstream direction. A review board was established earlier in the TSF development process. For the current TC2 initial construction, the EoR has full time supervision onsite led by an experienced construction engineer.

The TSF is founded on Cretaceous clay and the potential geotechnical (in)stability associated with it remains to be the most visible risk-driving failure mode (leading to a potential loss of containment of tailings and water). This was confirmed through a recent (October 2022) hybrid risk analysis (HBRA) presented later in this paper.

While clayey foundation is of general concern for its undrained behavior during shearing and its potential to reach a residual strength condition, the current adopted shear strength characterization of the clay for OT TSF design is appropriate, and this conclusion is based on significant number of efforts including carrying out multiple comprehensive field and laboratory investigation programs, employing state-of-the-art geotechnical analyzing techniques, and conducting multiple reviews. OT continues its working with the EoR on recommendations from the ITRB to further improve the confidence on and verify/confirm the appropriateness of the shear strength characterization of the clay for design.

A weakness of engineering during TC1 initial construction in 2011 was the decision not to install a purposely designed seepage collection (drainage) system; this decision, compounded with a few other chains of events, has led to the high salinity incident officially registered in November 2021. However, TC2 has clearly rectified this engineering weakness.

An internal review in 2019 raised its concerns on limited appreciation of the regional hydrogeological setting and the potential interaction between TSF seepage and the surface/groundwater system. Since then, significant works have been completed by Piteau Associates on the subject, including hydrogeologic well testing, site hydrogeological characterization, and numerical modeling on seepage and water chemistry. This work has informed the TC2 design on seepage management.

A comprehensive TSF OMS manual was last updated in August 2022. The OMS includes the full scope from tailings delivery, tailings deposition, water returns, and embankment performance monitoring with proper TARPs defined. The tailings depositional practice has refined over the years and has since early

2019 been performing well in terms of encouraging proper tailings beach development and tailings consolidation, minimizing water loss through evaporation, and maintaining the operating freeboard and size of the reclaim water pond.

OT maintains a system of comprehensive geotechnical instrumentations on telemetry (on Tableau system) to monitor pore pressures and displacements, with well-defined/reviewed TARPs. Multiple daily inspections are conducted by several TSF related teams. Deformation remote monitoring by InSAR is included in the system as well. Continuous evaluation on the currency and adequacy of dam instrumentations is evident. EoR team is well connected with activities onsite and independent operational reviews are carried out per a defined schedule.

The monitoring of the growth of the TSF basin at OT with bathymetric surveys can be improved. Although the state of tailings does not control stability of the TSF, an improved understanding on the overall in-placed dry density of the stored tailings mass and its spatial distribution enhances tailings response planning, refines the TSF life (duration) estimates, and leads to a more efficient closure design.

Tailings response plan, included in the OMS manual, was last updated in August 2022. The OMS includes TARPs to trigger the tailings response plan. The response plan is based on failure impact scenarios simulated in the dam break studies. OT carried out a drill for tailings response in 2019 during which OT was able to contact potential population to be impacted within one hour. Another drill was carried out in 2023.

ALARP demonstration

Rio Tinto has designed a risk analysis (HBRA) to be conducted to support the ALARP demonstration. The HBRA largely follows what is practiced by the Bureau of Reclamation of US Department of the Interior and US Army Corps of Engineers (BOR and USACE, 2019) and US Federal Energy Regulatory Commission (FERC, 2021) as quantitative risk analysis (QRA) for dam safety. The state-of-practice of risk characterization for dam safety relies in part on subjective probability estimates (quantification of expert judgment). Such a risk analysis was carried out for OT TSF in October 2022 (Step 2 in Figure 2) and formed the basis for its ALARP demonstration exercise presented in this paper.

Societal risk tolerability (Steps 2 and 3 in Figure 2)

The risk analysis identified eight risk-driving failure scenarios for the OT TSF:

1. Failure of TC1 embankment in the area of the northwestern corner due to rising pore pressures at toe resulting from sealing of foundation pore pressure relief wells.
2. Failure of TC1 embankment in the area of the northwestern corner due to design with nonconservative parameters adopted for the foundation.

3. Failure of TC1 embankment in the area of the northwestern corner under normal static condition.
4. Failure of TC1 embankment in the area of the northwestern corner under seismic loading condition.
5. Failure of TC1 embankment in the area of the northeastern corner under normal static condition.
6. Failure of TC1 embankment in the area of the northeastern corner under seismic loading condition.
7. Failure of TC1 embankment in the area of the northeastern corner due to foundation liquefaction or strain softening caused by rapid loading (fast rise of water level in the reclaim pond).
8. Failure of TC1 west embankment under seismic loading condition.

It is noted that all the above failure scenarios are the so-called geotechnical instability failure mode which is about the static and seismic instability of the embankment-foundation system (the structural containment system). During the risk analysis, there was consensus that any overtopping or internal erosion-based failure mode is not significant (or risk-driving) for the OT TSF due to the rigorous design and construction of the TSF. The risk characterization from the risk analysis led to Figure 3 presenting the risk level posed by the TSF.

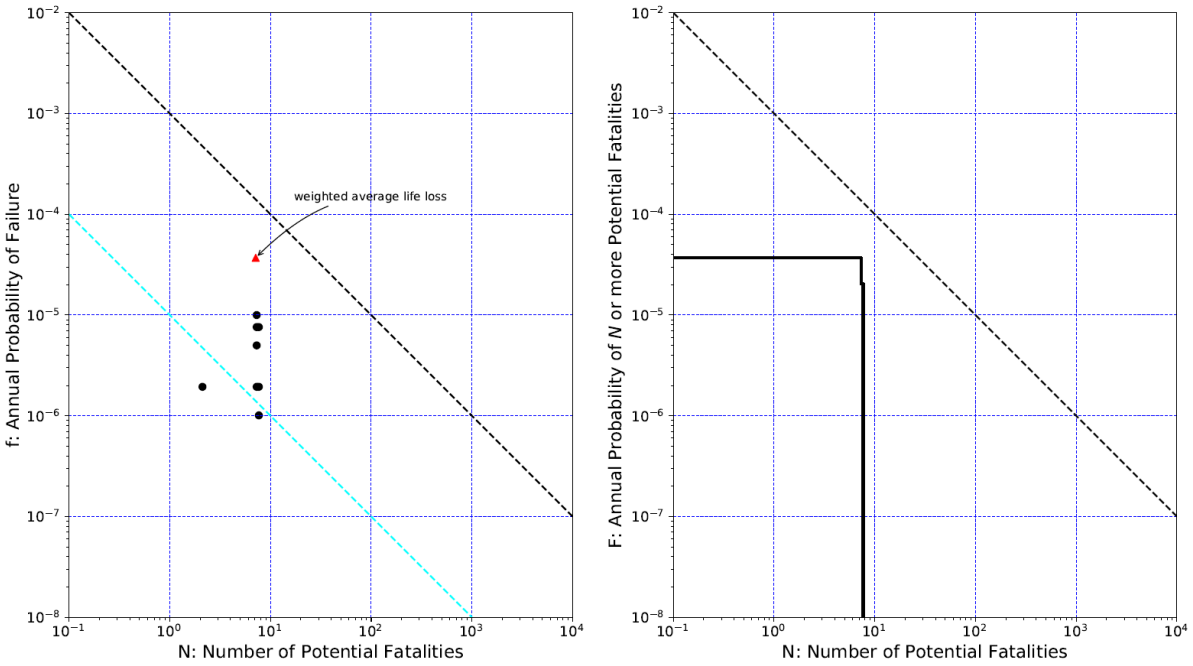

Figure 3: Existing risk posed by OT TSF (based on risk analysis in October 2022)

The *F*-*N* chart (Figure 3) presents cumulative (combined) risk effect required for societal risk (public safety) evaluations. *F*-*N* is the relation between the estimated number of fatalities (*N*) and the estimated annual probability of failure of the dam (*F*) causing loss of life ≥ *N*. As detailed in Zhu and Pascoe (2023), risks falling within the ALARP region (such as shown in Figure 3) are not considered to be tolerable until after assessing continuous risk reduction measures. These are risks that we do not regard as negligible but rather something we need to keep under review and reduce further if we can. The Rio Tinto ALARP

roadmap for dam safety does not involve the concept of "broadly acceptable risk" that is at normally two orders of magnitude lower than the Limit of Tolerability (LoT). Good dam safety management practice requires continuous risk monitoring and reviews even for risks at two orders of magnitude lower than the LoT. The Rio Tinto ALARP roadmap requires assessing continuous risk reduction measures for all risk levels; by doing so, it maintains a downward thrust on an already low risk level.

Continuing risk reduction measures (Steps 2 and 4 in Figure 2)

For the OT TSF, during the risk analysis in October 2022 (Step 2 in Figure 2) the following further risk reduction/mitigation measures were identified and assessed:

- Risk reduction measure (RRM) #1: Undertake study to assess pore pressure impacts on stability performance related to sealing off foundation pressure relief wells along the north embankment of TC1.
- Risk reduction measure (RRM) #2: Assess the extent and orientation of clay fissuring within the clay foundation and update material properties used with the stability models to reflect the outcomes of the study.

Both RRM #1 and RRM #2 are about characterization of the foundation for the TSF. The Rio Tinto ALARP process considers such efforts as part of good engineering practice, as such, these efforts should be carried out *regardless of cost or time*. The consensus during the risk analysis is that, once these studies are completed, the perceived risk would be lower, as presented in Figure 4.

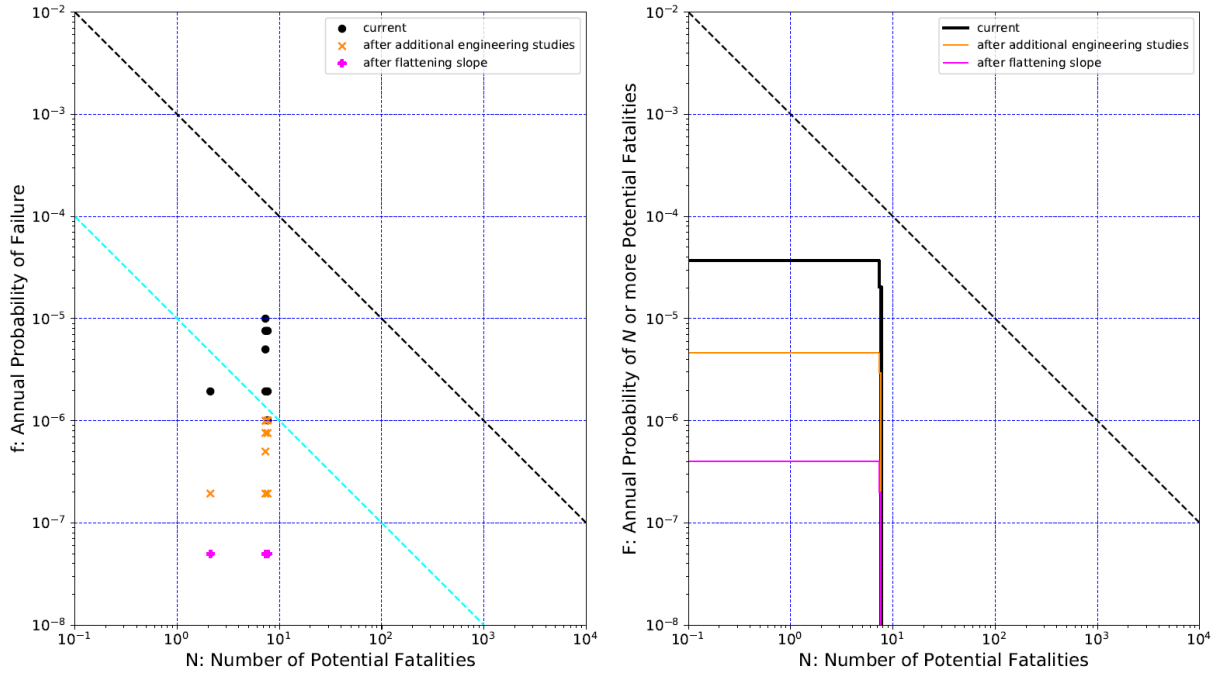

Figure 4: Summary of risks posed by OT TSF

The risk analysis (Step 2 in Figure 2) did not identify other risk reduction measures due to the robustness of the OT TSF (as briefly summarized above in the Section on *good practices for engineering and operations* as part of Step 1 on *good practice demonstration*). However, for the purpose of demonstrating ALARP regarding the benefit of further risk reduction versus the additional effort (sacrifice) required, Figure 4 also includes a hypothetical risk level after further flattening the downstream slopes. Following the Rio Tinto group ALARP guidance, Table 1 presents the cost benefit evaluation for this risk reduction measure of flattening the downstream slopes, based on the following inputs:

- Current existing risk (the expected value of annual life loss) = 2.78×10^{-4} (this is the area under black lines on the FN chart in Figure 3 or Figure 4).
- Flattening the existing downstream slopes would achieve a risk reduction of 2.75×10^{-4} that would lead to a residual risk of 2.99×10^{-6} (indicated by the magenta lines on the FN chart in Figure 4).
- The cost of such measure is US$5M capital spending. In reality, any type of flattening the current 4H:1V downstream slopes would incur a cost much higher (hence leading to an even higher disproportion factor in Table 1).

Table 1 indicates that it is *not reasonably practicable* to implement such a risk reduction measure.

Table 1: Cost benefit evaluation for flattening the downstream slopes

Description of the proposed Risk Reduction Option:		*flattening downstream slope*	
Base Data			
Value for preventing a single fatality (VPF)	12,000,000	*USD*	**See ALARP Guidance note*
Disproportion factor (PF)	10		**See ALARP Guidance note*
Scenario Data			
Existing risk (base case)	2.78E-04	*pa*	**Taken from relevant quantitative risk annalysis. This is the cumulative individual risk calculated or the expected value of annual life loss (calculated with FN curves, based on 'stationary stochastic process' assumption)*
Risk with implemented risk reduction option	2.99E-06	*pa*	
Risk reduction offered	2.75E-04		
Cost to implement solution			*The 'cost' and 'value' should be in common Net Present Value (NPV) terms.*
Capital cost	5,000,000	*USD*	**Cost estimate to implement solution*
Life of facility until closure	15	*years*	**expected life of facility until closure*
Operational expenditure per year	0	*USD*	**Ongoing yearly operational cost*
Yearly cost	333,333		
Cost for preventing a fatality (CPF)	1,214,053,986	*USD*	
Disproportion Factor (PF)	101.2		
Conclusion on Risk Reduction option	Don't implement risk reduction option		

Effectiveness and sufficiency of risk controls (Steps 2 and 4 in Figure 2 continued)

The Rio Tinto ALARP roadmap for dam safety lastly requires a review of the effectiveness and sufficiency of risk controls. This review leads to well-reasoned arguments demonstrating that there are a mix of controls

along each significant potential failure development pathway to ensure that there is an adequate spread of type of controls, depth of controls, and control effectiveness for each significant failure scenario.

For OT TSF the risk analysis in October 2022 (Step 2 in Figure 2) identified the following risk controls including both preventive and mitigative controls:

- Proper engineering designs, including:
  - A qualified design consultant for providing the design.
  - Adequate site and laboratory investigation programs to properly characterize the subsurface conditions, the dam construction materials, and the tailings material.
  - Proper seismic hazard study.
- Proper hydrogeological study on the regional groundwater system overall and pore pressure regime in the TSF foundation in particular.
- Proper hydrological study and adequate surface water management (upstream diversion) to minimize recharge into the groundwater system directly underneath the TSF.
- Proper independent reviews.
- Proper TSF constructions, and construction QCQA.
- Proper water balance study and modeling to guide the operation of the supernatant pond and monitoring of the water level of the supernatant pond.
- Sufficient monitoring of the growth of the TSF basin with bathymetric surveys, and proper planning and execution of tailings deposition.
- Adequate and sufficient TSF monitoring with TARPs defined and reviewed regularly and implemented with the monitoring and mitigation plans defined with the TARP levels.
- Preparedness and response planning for upset and emergency scenarios.
- Specifically for the risk of environmental impact (by seepage from TSF), controls include a properly designed and constructed seepage management system (drainage, cutoff, seepage collection and a pump back system when required to capture seepage leaving the compliance boundary), proper seepage monitoring, and water compliance monitoring.
- Failure impact assessment based on proper dam break studies and a proper tailings response plan with periodic mock exercises.

These risk controls are mapped out against the potential development of a failure pathway leading to downstream consequences. This detailed mapping of risk controls shows that there is an adequate spread of type of controls, depth of controls, and control effectiveness for each significant failure scenario analyzed during the October 2022 risk analysis (Step 2 in Figure 2). These detailed mappings are also well-reasoned arguments that there are effective risk controls in place to keep the risk posed by the OT TSF low. Due to

page limitations this paper is unable to include these detailed mappings of risk controls for OT TSF. Interested readers are encouraged to contact the paper authors.

ALARP documentation (Step 5 in Figure 2)

Deciding whether a risk is reduced to ALARP is a deliberate and separate exercise from seeking continuous improvement of dam safety management. The result of an ALARP assessment could be one of the following (Zhu and Pascoe, 2023):

- Existing risk is confirmed to be ALARP.
- Risk would be ALARP after implementing action(s).
- The confidence level for the risk characterization is low so that additional studies are required before an ALARP conclusion.
- ALARP is not possible, and other actions are required, e.g. the removal of the storage facility should be considered.

This deliberate ALARP assessment exercise should be properly documented (Step 5 in Figure 2). For the case presented in this paper, a document was prepared to support the assessment result that the risk posed by the OT TSF was reduced to ALARP based on the four pillars of evidence (Zhu and Pascoe, 2023). This document was approved by AE and became one of the integrated knowledge base files of the project.

Conclusion

A well-designed, constructed, and operated TSF is expected to pose a low risk. The application of the ALARP principle is consistent with the requirements of Rio Tinto's risk management standards, maintains a downward thrust on this already low risk, ensures that the risk situation does not deteriorate, and drives continuous improvement of dam safety management.

Determining whether a risk has been reduced to ALARP requires judgment. Risk characterization is an iterative, analytical-deliberative process. There is no simple formula for computing what is ALARP. Rio Tinto has adopted an ALARP roadmap for dam safety (Zhu and Pascoe, 2023) to help practitioners to meet the need for ALARP demonstration. This paper presents the details of a real case on ALARP demonstration by following the Rio Tinto ALARP roadmap for dam safety. The same process is being applied to the rest of TSFs in its portfolio. While deciding whether a risk posed by a tailings storage facility is reduced to ALARP is a deliberate and separate exercise, seeking improvement of dam safety management and conformance with good practice is continuous throughout the lifecycle of the TSF.

Acknowledgements

The authors appreciate the permission of Rio Tinto and the Oyu Tolgoi mine to publish this paper to advance the risk related engineering designs and approaches for tailings storage facilities.

Importance of Environmental Components in Assessing Risks under GISTM

Karen Bechard, Geosyntec Consultants Inc., Canada

Rachel James, Geosyntec Consultants Inc., Canada

Abstract

Risk management is a key component under the Global Industry Standard for Tailings Management (GISTM), which strives towards zero harm to people and the environment. Under this standard, a large part of assessing potential risk to people and the environment is understanding the geotechnical stability and tolerance of a Tailings Storage Facility (TSF) to withstand certain events (e.g., weather, seismic). However, understanding how environmental factors affect the risk potential of a TSF can be important, and the evaluation of environmental risks under the GISTM is not clearly defined. When evaluating the potential risk of harm to people and the environment, it is imperative to understand the conceptual site model, for example, how various environmental components interact spatially and temporally, to understand the full spectrum of risks and how to most effectively manage them. Environmental considerations cover many topics, two examples of which are geoenvironmental and ecological factors.

Geoenvironmental factors consider impacts from surface water, groundwater and pore water transport, interactions with the local hydrology (water balance), chemistry/geochemistry of mine wastes (i.e., acid generation potential and longevity of acid generation, and metal leaching potential) and impacts to geotechnical stability. Ecological factors consider ecological community structure, whether that may include the presence of endangered species, or valued ecosystem components (e.g., fish spawning area). Under GISTM, the information listed above comprises a large part of the environmental Integrated Knowledge Base (IKB). This paper describes how environmental components are threaded throughout the GISTM, along with geotechnical stability components, how they are included in the decision processes within the GISTM risk evaluation framework, and ultimately how they feed into risk management design considerations and closure planning. Examples of potential impacts and design input based on the authors' experience with closed mine site projects will be provided.

Introduction

A Tailings Storage Facility (TSF) at Vale's Córrego de Feijão mine in Brumadinho, Brazil collapsed in January 2019, causing the deaths of 270 people. In response to this event, the Global Industry Standard for Tailings Management (GISTM) (PRI et al., 2020), a program voluntarily entered by mining companies, was developed with the intent of increasing the level of safety to people and the environment by improving tailings governance and management. The GISTM contains 77 auditable Requirements, distributed among 15 Principles, which in turn are grouped into the following six topic areas:

1. affected communities;
2. integrated knowledge base;
3. design, construction, operation and monitoring of the tailings' facility;
4. management and governance;
5. emergency response and long-term recovery; and
6. public disclosure and access to information (PRI et al., 2020)

Environmental components are woven throughout these six topic areas of GISTM, either directly, or indirectly and hold increased weight with respect to interpretation of material impacts as described below. This paper will discuss:

- the environmental components of GISTM;
- the environmental "what's new" under GISTM;
- interpreting connections between environmental disciplines and other technical areas of GISTM; and
- integration of environmental components into the assessment of risk and risk management.

Environmental components within GISTM

The majority of the direct environmental aspects of GISTM are addressed through Topic Areas II (Integrated Knowledge Base [IKB]) and III (design, construction, operation and monitoring of the tailings facility), as summarized in Figure 1. While requirements underlined in Figure 1 indicate direct environmental deliverables and/or input to TSF management, the subsequent discussion in this paper emphasizes that environmental characterization and evaluations should be completed to inform all components of TSF design and design implementation (e.g., construction, operational, and progressive closure and reclamation).

Under topic areas II and III, environmental components like Comprehensive Site Characterization Report (Requirement 2.2), Water Balance Model (Requirement 5.3), Environmental Surveys, and

Environmental Impact Assessments (Requirement 3.3) are clearly defined (PRI et al., 2020) and are associated with clear deliverables to be incorporated into the sites IKB.

Topic 2: Integrated Knowledge Base		Topic 3: Design, Construction, Operation and Monitoring of the Tailings Facility			
Principle 2	**Principle 3**	**Principle 4**	**Principle 5**	**Principle 6**	**Principle 7**
2.1 Document and update knowledge about social, environmental, and local economic context of TSF **2.2** Prepare, document, and update comprehensive site characterization **2.3** Develop and document dam breach analysis **2.4** Assess and document potential human exposure and vulnerability to TSF failure scenarios	**3.1** Adaptively manage TSF using climate change knowledge **3.2** Analyze multi-criteria alternatives for tailings management (new TSF) OR periodic review of technology and design (existing TSF) **3.3** For new TSFs, assess lifestyle impacts including climate change factors **3.4** Define 'material change' for social, environmental, and local economic impacts; Adaptively manage impacts	**4.1** Determine consequence of failure classification **4.2** Determine external loading criteria (new TSF) AND perform 5yr DSR; ITRB/SITR review **4.3** Adopt classification and flexibility for future upgrades (AE) **4.4** Identify and document the design criteria (DBR) **4.5** Apply design criteria, considering material properties, slope stability, seepage and deformation **4.6** Identify and address brittle failure modes **4.7** Implement ALARP in upgrades, signed by EOR/AE if not feasible **4.8** Prepare DBR (by EoR); ITRB/SITR review	**5.1** Incorporate multi-criteria alternatives (new TSF) **5.2** Develop a robust design demonstrating feasibility of safe closure **5.3** Develop a water balance model **5.4** Address all potential failure modes to ALARP **5.5** Develop design for each stage of construction **5.6** Design closure to demonstrate feasibility, incl. progressive closure and reclamation **5.7** Approval by AE of design to ALARP **5.8** Conform with standards for resettlement	**6.1** Build, operate, close TSF according to design intent **6.2** Implement QA/QC and Construction Design Intent Verification **6.3** Prepare "As-Built" reports, signed by RTFE/EOR **6.4** Develop, implement, review, and update OMS **6.5** Implement change management system and Deviation Accountability Report signed by AE **6.6** Include new and emerging technologies and approaches in TSF design	**7.1** Design, implement, and operate a performance monitoring program **7.2** Design, implement, and operate engineering monitoring for potential failure modes **7.3** Establish specific and measurable performance criteria for monitoring **7.4** Analyze monitoring data; Identify and address deviations through Trigger Action Response Plan **7.5** Report monitoring results with approval of EoR/RTFE

Numbered requirements are listed under each Principle; Requirements with direct environmental deliverables/input are underlined.
TSF = Tailings Storage Facility, AE = Accountable Executive, ITRB = Independent Tailings Review Board, SITR = Senior Independent Technical Reviewer, DSR = Dam Safety Review, ALARP = As Low As Reasonably Practicable, DBR = Design Basis Report, EoR = Engineer of Record, RTFE = Responsible Tailings Facility Engineer, QA/QC = Quality Assurance/Quality Control

Figure 1: Requirements under GISTM with direct environmental deliverables/input

A brief description of key environmental disciplines (excluding those related to stability evaluations, which are well understood under geotechnical engineering, seismicity, and physics) that support GISTM, and how they provide technical inputs integral to interpretations of environmental conditions under GISTM are listed as follows:

- **Geology** – The geologic setting, including both regional and local geology, plays a critical role in understanding the natural environment and forms the foundational understanding for several other GISTM components, including hydrology, geochemistry, hydrogeology, and geotechnical studies. Geological investigations identify potential risks such as active faults and unstable slopes as well as initial characterization of soil and rock formations.
- **Hydrology** – Hydrologic components, defined to include site and regional surface water volume, flow rate, and conveyance, are considered within a tailing's facilities' design, operation, monitoring and closure. GISTM requires a solid understanding of the mine site hydrology through IKB components such as: site characterization, hydrological modelling, and the Water Balance Model (WBM). It is also linked to flood (RA), as well as through monitoring and reporting.

- **Geochemistry** – Geochemistry utilizes knowledge of the regional geology alongside targeted environmental testing to assess the acid generating and metal leaching (ML) potential of stored mine waste to understand the risk of producing acid rock drainage (ARD). Geochemical characterization is a core component to environmental RA for each type of mine waste such as waste rock, overburden, tailings, and process water. Geochemical characterization forms the basis of the geochemical conceptual model (GCM) which integrates with mine waste and mine water management plans to predict site wide water quality and downstream environmental impacts. Hence, geochemical assessment supports environmental assessments and plays an important role in the selection of potential contaminants of concern.
- **Hydrogeology** – Groundwater at mine sites is most frequently impacted by seepage into the subsurface from waste disposal sites. The fate and transport of those contaminants is controlled by the hydraulic parameters of the water-holding subsurface rock and soil layers, which transmit groundwater along the hydraulic gradient. Thus, hydrogeological investigations characterize the subsurface to understand the flow of groundwater and to identify areas where surface contaminants may more easily impact groundwater quality or where groundwater may discharge to the surface and impact downstream ecosystems. Within GISTM, hydrogeological investigations support site characterization, the WBM and Site Water Quality Model (WQM), and closure planning.
- **Ecology** – Ecology supports the IKB and environmental consequence classification by allowing an understanding of the rare or endangered species within the area, and the quality of habitat in the surrounding environment that could be potentially impacted. Ecology is integrated into the GISTM to ensure environmentally responsible practices that minimize impacts on ecosystems. This includes conducting baseline ecological studies/surveys and Environmental Impact Assessments (EIAs), avoiding sensitive habitat, and designing facilities to minimize ecological impacts. Biodiversity conservation plans, long-term ecological monitoring, and adaptive management strategies are implemented to protect local habitats and species. Effective water management practices safeguard aquatic ecosystems, while RAs and emergency response plans address potential ecological threats. Closure and post-closure plans include ecological restoration and sustainable land use to promote ecosystem recovery.
- **Ecotoxicology** – The evaluation of ecotoxicity is dependent on understanding the presence of contaminants or constituents with the potential to become toxic over time or under specific conditions. In other words, it is dependent on an understanding of water quality, geochemistry and the receiving environment ecosystem. It evaluates the potential for toxic effects to ecosystems and is a component of the environmental consequence classification, Ecological RAs and EIAs under

GISTM. Ecotoxicology is one of the main reasons that chronic loss of contaminants may require mitigation plans.

- **Water chemistry** – This includes the chemical characterization of existing surface water and groundwater, and projected chemistry of TSF impacted water. Tracking water quality and field water chemical parameters over time allows for the identification of potential transport of TSF-impacted water that can aid in site water management planning. Site water chemistry projections are conducted by utilizing the outputs and interpretation from geochemical laboratory testing (and hence GCM) and WBM to develop the Conceptual Site Model (CSM) and WQM; which then further inform the overall environmental and social impact assessments.
- **Meteorology/climatology** – Meteorological and climatological data inform accurate water balance calculations, essential for planning water management systems. These data help predict extreme weather events whose probable maximum precipitation (PMP) values support climate evaluations of tailings dam structures and inundation mapping in the event of a catastrophic failure. Meteorological data are used in hydrological models to simulate water movement and to inform design flood levels, while climatological data aids in long-term planning and RA.

The authors interpretation of the connections of the listed environmental disciplines to key components of the Environmental IKB, as well as how the IKB feeds into the RA framework under GISTM are shown in Figure 2.

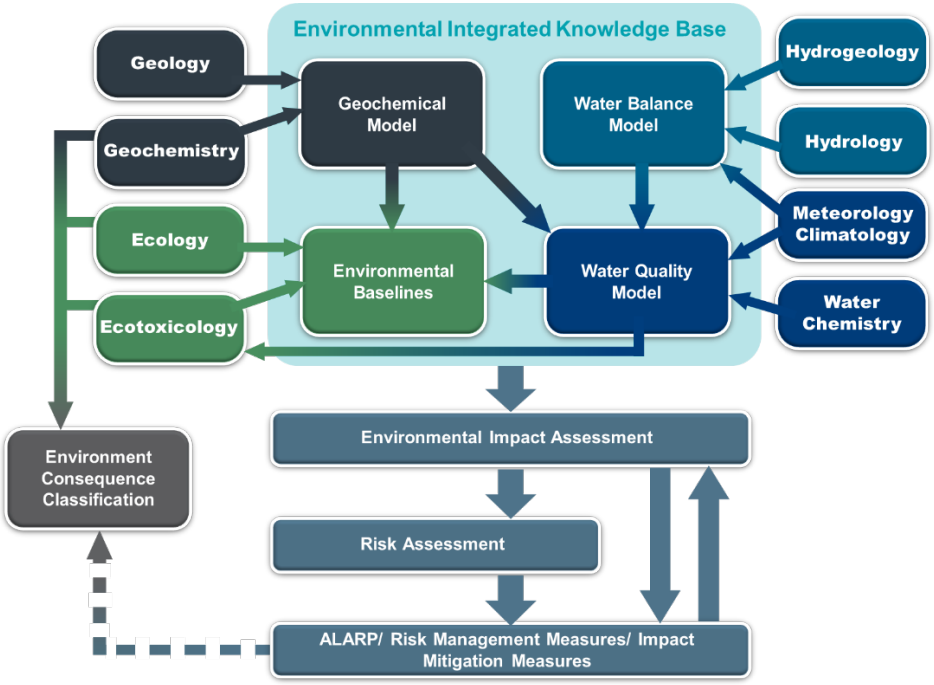

Figure 2: Environmental disciplines supporting GISTM framework

Another clear environmental component within GISTM can be found within Principle 3 "Use all elements of the knowledge base – social, environmental, local, economic and technical – to inform decisions throughout the tailings facility lifecycle, including closure" within the definition of material impacts (PRI et al., 2020), which leads to a new interpretation of 'loss of contaminant', as discussed below.

The environmental "what's new" under GISTM

Prior to the formation of the GISTM standard, loss of containment at a tailings dam at operational sites was mainly considered to be a dam failure. The GISTM, however, acknowledges that there are other avenues through which loss of containment can occur via its inclusion of 'chronic impacts' and 'long-term impacts' in its explanation of potential material impacts to a tailings facility which would require impact mitigation and management plans (for new tailings facilities; Requirement 3.3), or an update to the tailings facility management following adaptive management best practices (for all tailings facilities; Requirement 3.4). In other words, GISTM allows that material impacts can occur through loss of containment over time (e.g., chronic loss), instead of solely by an acute catastrophic event. There are two main environmental contributors that fulfill the chronic impact meaning, and both fall under the environmental umbrella: contaminant loss due to dust transport, and contaminant loss due to seepage. The authors acknowledge that, particularly for closed sites, contaminant loss due to these types of plumes were an identified risk prior to GISTM, however the inclusion of these within GISTM pushes these considerations forward into earlier planning stages within a mine's life.

Given the inclusion of chronic contaminant loss events as material impacts, long-term chronic downstream effects are put into question. The implications of this are discussed further under the topics of RA and Risk Management below.

Interpreting connections between environmental components and others technical areas under GISTM

While the preceding section identified the obvious, or 'direct', environmental components under GISTM, this section discusses the role that environmental components may have as an 'indirect' factor. For example, where environmental input is not specifically identified, but where that component may be influenced by environmental factors or outcomes. Figure 3 shows a high-level framework for GISTM, highlighting those areas where environmental components are linked in some capacity either directly, or indirectly, for example, as a predecessor where input from the environmental team is essential to achieve the intent of GISTM. It highlights the integral nature of environmental components/input throughout the duration of GISTM integration.

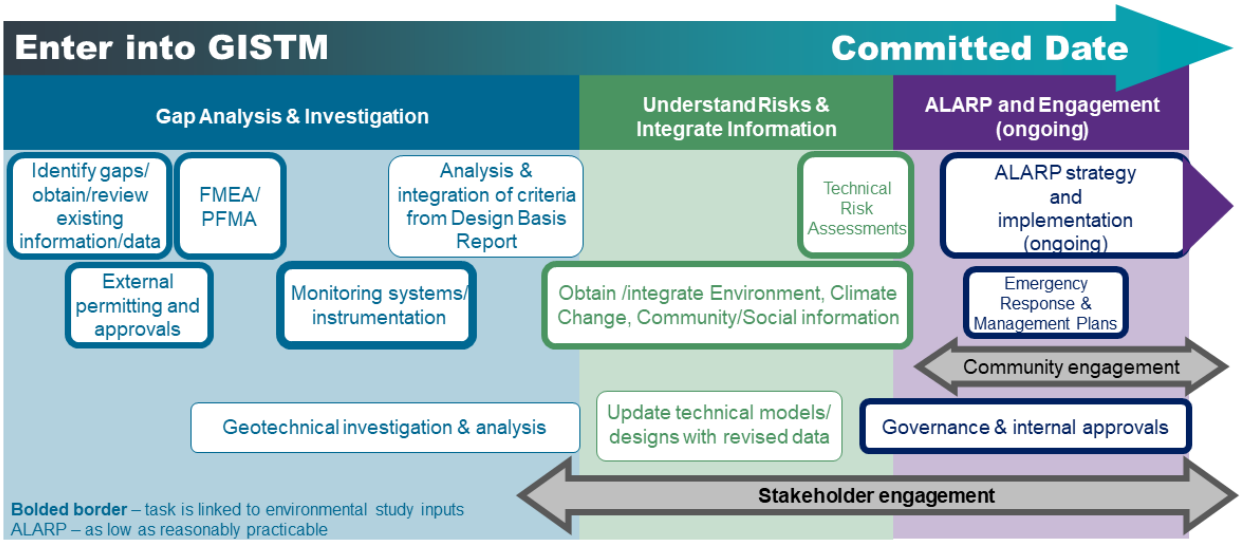

Figure 3: High-level schedule GISTM roadmap showing environmental study touchpoints

An example of an indirect relationship would be the dependency that dam breach analyses (non-environmental component) have on the climate change RA (environmental component), which provides necessary inputs such as PMP values and frequency of extreme storm events required for the assessment to use climate change knowledge according to the practice of adaptive management.

Another example of an indirect relationship would entail utilization of environmental site characterization information (e.g., tailings geochemical characterization and projected water quality under the GCM and WQM components) to inform operational, closure and reclamation, and overall site waste management and water conveyance design. An example of this indirect component and its importance under GISTM is further detailed below.

Weaving environmental components into the assessment of risk and risk management

Environmental component in RA

The evaluation of risk occurs within the 'Risk Assessment' box in Figure 2 and can be evaluated because it encompasses the knowledge of the environmental IKB and relevant EIAs. Formal RAs are required under GISTM in two key places. Foremost is the assessment of risk to potential failure modes of the TSF structure, foundation, etc. (Requirement 5.4). Typically, this is achieved through a Potential Failure Modes Analysis (PFMA) and is sometimes combined with a Failure Mode and Effects Analysis (FMEA). RAs must consider all potential failure modes until they are deemed non-credible (ICMM, 2021). Thus, environmental components must be considered in this process if they are a credible risk. The relevant environmental components evaluated are Site-specific. For instance, a site with existing or potential ARD

will include significant geochemical considerations compared to one with no ARD potential. In general, data (including environmental data) is reviewed in the context of the design and closure plan to identify potential failures that could occur, as well as the potential impact those failure modes could have from an environmental perspective. This requires a solid understanding of the site characterization data, including the water balance model, GCM, surrounding habitat quality, and other relevant environmental information.

Requirement 10.1 of the standard requires that a multi-disciplinary RA (MDRA) be conducted every three years, or in response to a material change to any of the RA components – this includes tailings facility, social, environment, or local economic changes. Environmental data is one of the main components for an MDRA, especially the environmental studies interpretation "…*which emphasizes the human relationship with the environment and the social and political dimensions thereof."* (Britannica online, 2024). The outcomes of the RA feed into the as low as reasonably practicable (ALARP) process under GISTM along with the implementation of impact mitigation measures and risk management measures. Two examples of how environmental data could lead to significant risks are included below. The examples highlight why the Canadian Dam Association (CDA) Environmental Consequence Classification (ECC) framework (Nikl et al., 2022) includes 'intrinsic hazard of contents' in the classification system, along with ecological impact and duration of impact.

Example of environmental component with potential for significant risks (geochemical)

TSF contact water can contain elevated concentrations of metals, sulphate and other parameters of concern; the source of these parameters can be in situ reactions of residual minerals in the tailings solids, or process water discharged with the tailings slurry. The geochemical evolution of a TSF may also influence the physical characteristics of TSF solids, impacting flow and stability through the tailings. An example of this occurred in 2019 at Córrego do Feijão mine near Brumadinho, Brazil where the failure of Dam-I was partly attributed to geochemical evolution. Iron oxidation products, observed by scanning electron microscopy (Robertson et al., 2019), resulted in bonding between coarse tailings particles. Interpretation of pre-failure cone penetration test results in the context of in situ shear wave velocity (Vs) profiles suggest the "development of microstructure due to a small amount of bonding" (Robertson et al., 2019).

Thus, it is possible that the bonding created by iron oxidation products could have contributed to the development of a microstructure in coarse tailings, impacting geotechnical parameters of the solid tailings (Robertson et al., 2019). Robertson et al. (2019) concluded that the bonding between particles created stiff tailings, that were potentially very brittle if triggered to become undrained. It was also noted that the "unusual mineralogy" of the tailings also impacted the interpretation of standard methods used to evaluate

material parameters that are considered in deformation and stability analyses (Section 6.6, Robertson et al., 2019).

Geochemical alteration is evaluated in the GCM, which accounts for the interaction of the solid tailings and process water with the tailing's particle properties, as well as water transportation (i.e., hydrogeological regime) across the site. Processes that are considered in the integrative GCM for TSF stability include:

- Dissolution of acid generating (e.g., sulfides) and neutralization minerals (e.g., calcite, dolomite) may alter tailings mass, which can in turn affect geotechnical stability through reduction in grain size and changes to hydrogeological regime.
- Secondary mineral formation from porewater saturated with products from previously dissolved minerals. Precipitation of secondary minerals may lead to changes in the hydrogeological regime through decreased porosity/permeability, which may also change the hydrogeological regime and affect geotechnical stability.
- Changes in pH from mineral dissolution and precipitation reactions may impact tailings porewater pH, and thus the physical strength of clay minerals which may be present in TSF foundation or embankment materials thereby affecting their structural integrity (Durocher et al., 2022).

Example of environmental component with potential for significant risks (ecological)

Habitat destruction or contamination due to either inundation from a dam failure, or long-term deposition through dust dispersion or seeps can also lead to significant risks. The former, impact to habitat due to a dam failure, can be identified via an assessment of the ecological impact e.g. as recommended under the ECC framework recommended by Nikl et al. (2022). This assessment includes components such as identifying species of special interest (threatened/endangered/species at risk/species of special concern), defining the region of study, as well as identifying similar habitat in the region.

In an ECC conducted by the authors evaluating the potential ecological impacts related to a modeled inundation area in the event of a dam failure, potential impacts to a trout spawning area, supporting a nearby healthy sport-fishing industry, was a main consideration of the ecological impact assessment included in the ECC (Confidential Site, Montana). The Montana Natural Heritage Program have classified the specific trout species as an "S2-species of greatest conservation need," meaning they are "at risk because of very limited and/or potentially declining population numbers, range and/or habitat, making it vulnerable to global extinction or extirpation in the state" (MFWP, 2022). Habitat impacts and restoration implications, including both costs and duration, are considered in the ECC within the GISTM (ICMM, 2020; Annex 2, Table 1).

The conundrum of environmental protection in risk management

Including long-term effects as material impacts that require management is a game changer for the tailings industry and introduces many more questions on how these impacts should be assessed and managed. For sites that are active, chronic environmental impacts can often be managed at an operational level through maintenance actions like dust suppression and pump-and-treat of TSF-impacted water that may seep off-site from the facility. For sites on their way to closure, management of risks posed by chronic environmental impacts can be more of a challenge.

Key considerations along with pertinent questions requiring thought as an industry, especially for sites entering closure, are listed in Figure 4.

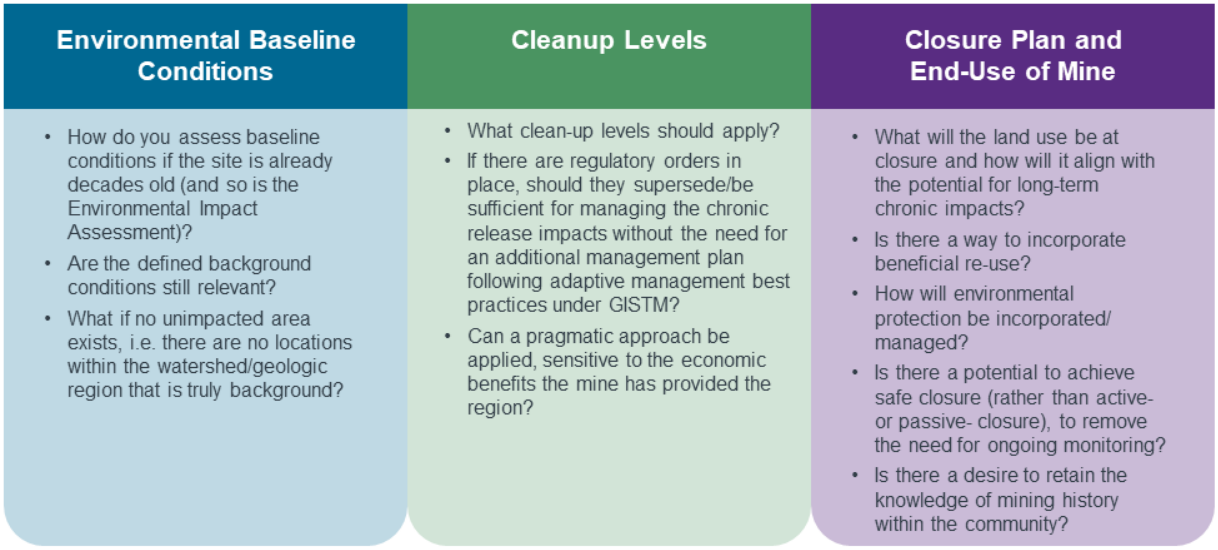

Figure 4: Key considerations for management of chronic environmental impacts

In brief, the questions to be asked as an industry relate to defining environmental baseline conditions, what we are willing to accept as a society with respect to cleanup levels, and how chronic environmental impacts effect the closure plan and end-use of a mine. Ideally, considerations on the benefits that mining has bestowed upon the community and region will be considered in management planning. By permitting a mine, there is an inherent understanding that there will be some associated level of environmental impacts.

Conclusion

This paper discusses how the environmental components under GISTM play an important role in understanding site conditions and how they link with other technical areas within the GISTM framework. Environmental components are integral to assessing the risk for a TSF. Metal leaching and acid rock drainage (ML/ARD) may affect downstream environments directly through degradation of water quality

and habitat and indirectly by increasing the risk of geotechnical instability, while understanding the water balance is integral to closure planning. Further, due to chronic releases being included within GISTM as material impacts, environmental components are an important factor to consider in both the long-term management and on-going assessments of tailings facilities.

Maintaining Continuity Lessons – Learned from a TSF Incident Linked to Engineer Transitions

George Afriyie, Newmont Corporation, USA
Jeremiah Williams, Newmont Corporation, Ghana
Rashida Umar, Newmont Corporation, Ghana
Ankomah Bosomtwi, Newmont Corporation, Ghana

Abstract

Effective management of a tailings storage facility (TSF) requires key roles to be in place for the design, construction, and operations of the facility. These key roles collaborate and need to work closely for the successful management of the facility. One of these key roles is that of the Engineer of Record (EoR).

The EoR role is defined by the Global Industry Standard on Tailings Management (GISTM) as the "qualified engineering firm that supports a mining firm in confirming that a TSF is designed, constructed and decommissioned with the appropriate level of integrity that aligns and meets applicable regulations, statutes, guidelines, codes and standards." To effectively achieve this, the named EoR for a TSF must be a long-term role that is involved in the life cycle of the facility. Prior to the GISTM, the role of the EoR and other key roles were not mandated within many mining companies (and still are not) unless it was an explicit requirement of the jurisdiction in which the facility was located. To this end, many operational TSFs did not have EoRs in place and may have used different consultants for the design of the various construction stages, often driven largely by competitive bidding processes (i.e., supply chain). This approach is discouraged as institutional knowledge of the facility is lost through the changeover and introduces the risk of loss or miscommunication of certain key information from consultant to consultant. In addition to this, the lowest cost consultant may not necessarily be the most qualified to be the EoR. These can lead to undesirable outcomes in the operation and monitoring of these facilities, such as the development of an incomplete knowledge base, leading to untimely response to upset conditions or deviations from normal condition. This paper discusses how changes in EoR led to an incident on a TSF.

Introduction

The safe and proactive management of tailings storage facilities (TSFs) require key roles to be in place for the operations, maintenance and surveillance of these facilities. These key roles collaborate and work

closely to successfully manage these facilities (ICMM, 2021). One of these key roles is the Engineer of Record (EoR).

Prior to the Global Industry Standard on Tailings Management (GISTM, GTR 2020), the role of the EoR and other key roles such as the Responsible Tailings Facility Engineer (RTFE) were not a requirement in some jurisdictions where mining companies operated. The GISTM defines the EoR role as the "qualified engineering firm that supports a mining firm in confirming that a TSF is designed, constructed and decommissioned with the appropriate level of integrity that aligns and meets applicable regulations, statutes, guidelines, codes and standards." To effectively achieve the intent of this role, the named EoR (external or internal) for a TSF must be a long-term position that is involved in the life cycle of the facility (Sova et al., 2023; Morrison et al., 2017). Considering the jurisdictions where this role was not a requirement, some operational TSFs did not have long-term EoRs (external or internal) and may have used different consultants for the design of the various TSF expansions. The EoR may have often been selected via competitive bidding. This approach is discouraged as it can lead to undesirable outcomes such as loss of institutional knowledge of the facility through the changeover; it introduces the risk of miscommunicating certain key information from one consultant to another; it impacts on longer-term planning for the facility considering the TSF lifecycle; it may not necessarily result in the selection of the most qualified candidate; and it may potentially impact the timely response to upset conditions or deviations from normal operations, in the management of these facilities.

This approach was practiced at one of the mines within the portfolio of the organization prior to the appointment of the current EoR. The loss of knowledge from change in consultants led to an internal erosion incident, but without release of tailings, as a result of a construction defect.

Overview of the facility

The TSF embankments are constructed by the downstream method, comprising the use of local borrow on the upstream portion with the downstream shell constructed with run of mine waste rock from an open pit. Geotextile was previously placed in between the two material types to act as a transition from the local borrow to the waste rock. The embankment upstream slopes on the southern portion have a composite liner system, which consists of a compacted low permeability clay and a High-Density Polyethylene (HDPE) geomembrane liner, whereas embankments in the northern portion have a low permeability clay with riprap on the upstream face. The rate of rise for the TSF is about 2 m per year. The south and southeast embankments are buttressed by a waste rock facility (WRF). Further downstream of the south embankment is an open pit where mining activities have ceased. The spillway of the facility is located at the right abutment of the south embankment and, if activated, flows into the open pit downstream of the embankment.

The supernatant pond is maintained at the southeast corner of the impoundment. The TSF has an overliner drainage system to promote dewatering and consolidation of the tailings on the southern half of the TSF where the pond is located. In addition to the overliner drainage system, a leak collection and recovery system (LCRS) is installed beneath the composite liner to mitigate seepage from the TSF into the surrounding environment. The northern half is lined with a compacted clay liner. In the design and construction of the facility over the last decade, the services of three different consultants have been used.

Governance structure for TSFs

The organization uses the Line-of-Defense (LoD) model, as shown in Figure 1, for the responsible management of the facilities in the portfolio. The model has key roles at the site and corporate levels with defined roles to manage the facilities.

1st Line of Defense	**Site-based implementation** The site teams that actively manage the facilities include the site's General Manager (GM); a Responsible Tailings Facility Engineer (RTFE), who is responsible for the integrity of the site's tailings facility (or facilities) and oversees their design, construction and monitoring; and a dedicated Engineer of Record (EoR) and EoR team, who provide technical expertise and assurance that the tailings facility is safely designed, constructed and operated. The Regional Leadership Team (RLT) is responsible for the respective site team.
2nd Line of Defense	**Systematic third-party review** This process includes Independent Tailings Review Boards (ITRBs) for all active operations and legacy sites with an "extreme" or "very high" consequence classification, senior independent technical reviews for other tailings facilities and periodic dam safety reviews (DSRs) by an independent consulting team.
3rd Line of Defense	**Functional accountability** An Accountable Executive (AE), who reports directly to the CEO, communicates regularly with the Board and is accountable for the safety of Newmont's tailings facilities. The Corporate Tailings and Dams Team (CTDT), serves as a delegate to many of the AE's responsibilities, providing centralized leadership, oversight and support for all tailings facilities (including inactive and legacy operations).
4th Line of Defense	**Leadership commitment** Newmont's Executive Leadership Team (ELT) and the Board of Directors commit to the safe management of Newmont's tailings facilities. The Board's Safety and Sustainability Committee provides oversight, and the AE communicates with the Board through the Committee.

Figure 1: Line-of-defense model

In terms of the site, the governance structure (first LoD) was not fully in place for the TSF under consideration prior to 2020; an RTFE was not appointed. An EoR was appointed for the facility. However, there were changes of the EoR firm based on the outcome of competitive bidding that was organized periodically. Although there were corporate stakeholders involved in management of the facility, they were not required to be involved in decisions to change EoRs or the adjudication of the competitive bids. An RTFE was not appointed for the facility until 2020. In terms of the second LoD, an Independent Tailings Review Board (ITRB) has been in place since 2018. The third and fourth LoDs were implemented as part of tailings management activities in 2020.

Following the full implementation of the governance framework in 2020, changes in EoRs or key roles through competitive bidding that was the previous practice is no longer the case. A guideline is in

place within the organization, which lays out the requirements and interactions required for the different levels around the management and decision-making for the facility.

Changes in EoR

The facility has been in operation over the last two decades and during this period, three different consultants have had some involvement in the design, construction supervision, monitoring, and regulatory reporting for the facility. Figure 2 shows the various stages for the design and construction that these companies were involved in the project. Company 1 was involved in the project from the feasibility stages initiating the design for the starter through to stage 10 of the facility. With regards to the construction supervision, quality assurance (QA) and the construction completion report, Company 1 was responsible for the initial stages until stages 9 and 10, early works. The involvement of Company 1 with the project came to an end in 2014 following adjudication of competitive bids undertaken by the organization.

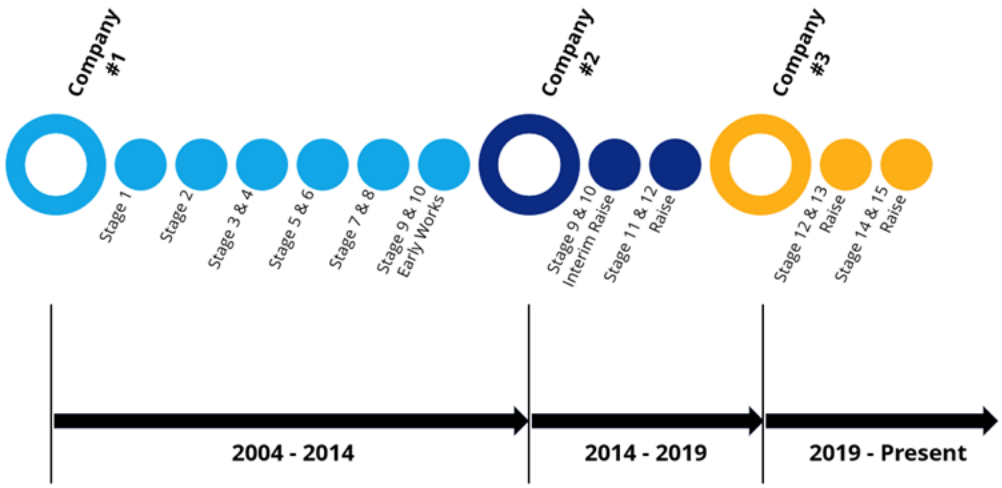

Figure 2: Chronology of EoR involvement with project

Company 2 was contracted in 2014 to replace Company 1 mainly in reviewing the construction supervision documents, quality control (QC) and QA documentation for interim raise of stage 9 and stage 10 undertaken by the organization. This company also compiled the construction completion report. Following the completion of the initial scope, the stages 12 and 13 expansion contract which had design, construction supervision and QA as part of the scope was awarded to Company 2. Following completion of the scope in 2019, Company 2 was replaced by Company 3 through competitive bids.

Company 3 has been involved with the project since 2019. The contract covers the design, construction supervision, QA, and regulatory reporting for the TSF. A terms of reference is in place between

the organization and company 3. The document details the scope of services, authority, roles, and responsibilities of the EoR, as well as the organization's obligations, and forms the basis of the long-term contract that is in place.

For the different changeovers there was no handover period or review, prior to contract execution. During these changes there were no communications around non-conformances or deviations from design with regards to the TSF management or construction. For periods of transition between EoRs, the site undertook the construction supervision and QA activities.

Effects of EoR transitions

This section discusses the observations made through the different changeovers at the site.

Long-term TSF panning

The changes of the EoR as well as the site not having an RTFE has affected the longer-term plans that could have been put in place for the TSF. These changes had the effect that each company that was involved was reviewing previous activities, rather than continuously improving the existing design, monitoring, or management practices. The lack of long-term planning has led to the delay of certain activities such as instrumentation planning and data collection to fill design gaps in a timely manner. Following the appointment of a longer-term EoR, many important activities that could have been completed in previous years are required to be completed within a shorter period of time.

Operational changes and inconsistency

The changes in EoR led to inconsistency with certain construction activities like instrument raises for the facility. In addition to this, certain operational requirements that may have been aligned to a design intent were changed without implementation of appropriate management of change processes. With a longer-term EoR in place, changes are considered over the facility life cycle to understand the impacts prior to completing such changes, and this provides an opportunity for a more systematic approach to improving practices on the facility.

Dam safety concerns

In situations where key information is not adequately passed on to a new EoR, it can lead to undesirable outcomes. For this TSF, such changes led to a change in the manner in which vertical raises of TSF instrumentation through the geomembrane liner, as shown in Figure 3, were completed. This event presented a condition with increased risk of internal erosion of one of the facility embankments. Due to the lack of the appropriate QC and QA activities during the vertical raise through the geomembrane liner, a

pipe developed via the liner boot. In addition to this, operational volume on the pond was not strictly followed in between transitions.

Figure 3: Extrusion weld around the piezometer extension

Internal erosion mechanism

A cross-functional internal forensic team together with the current EoR investigated the conditions that led to the internal erosion incident. The investigation concluded that the incident occurred vertically along the extended standpipe of the instrument, as shown in Figure 4, after the geomembrane liner tore along the extrusion weld of the HDPE geomembrane boot, which can be observed in Figure 3. The instrument was a standpipe that had been converted to a vibrating wire piezometer (VWP); hence, the vertical raise through the liner was to extend the cable for readings to be taken.

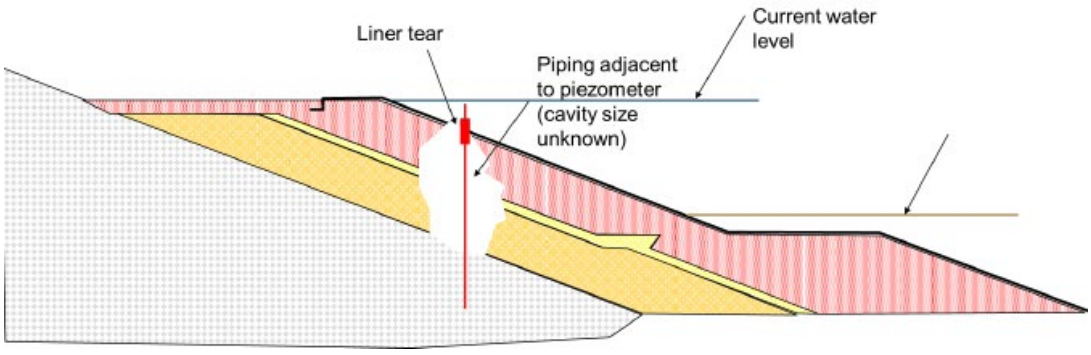

Figure 4: Illustration of piping incident along piezometer penetrating the geomembrane

Considering the robustness of the downstream rock shell, minor damage was observed on the upstream slope of the embankment beneath the liner. The established procedures within the organization were followed by the site in responding to the incident as well as the completion of the repair process.

Lessons learned from the EoR transitions

The lessons learned through the EoR transitions, and the internal erosion event included the following:

- The change of consultants at various stages of facility expansion led to knowledge of the facility not being retained or passed on. This has been evident in the planning for the facility considering the complete lifecycle. Having an appointed EoR in place has ensured that longer-term planning for the design and/or operational practices are aligned to the closure and post-closure goals.
- Appropriate documentation should be developed for key tasks that form part of TSF raises. The instrument raise through the liner that is required with each raise for this TSF was not clearly captured in previous construction completion records and no procedure was developed. To this end, the change in supervisory personnel without a reference led to poor QC and QA of the instrument raise.
- Although competitive bidding can be effective in meeting the commercial objectives of an organization, in the instance of a facility built over multiple years like a TSF such an approach does not necessarily yield the desired value. For this TSF, the amount of money spent to repair the internal erosion incident quickly eroded the difference in cost during the competitive evaluation of the consultants.
- A robust governance structure in place for a TSF is essential in ensuring that management and decision making involves a cross-functional team. The governance structure in place prior to the transitions did not require stakeholder engagement for such changes regarding the EoRs. The robust governance currently in place requires such decisions to be approved by the Accountable Executive or their delegate.
- There was cross-functional collaboration from different departments on site, regional, and corporate level as well as the EoR in the monitoring and repair of the internal erosion incident. This ensured that all components of TSF management were taken into consideration. Collaboration and transparency with the regulators built a stronger relationship and trust with the organization. The forensic report from the investigation was shared with the regulator.
- A well-documented and effective Operation, Maintenance and Surveillance (OMS) manual with well-defined Trigger Action Response Plans (TARPs) are effective in guiding the site to determine deviations from normal operations.

Conclusion

Change of EoRs at various stages of design and construction with inadequate handover had adverse effects on the management and operations of a TSF facility. Over the last two decades of operations, three different

companies were involved in the design and construction supervision of the different stages of the tailings facility. Following lessons learned on an internal erosion incident and effects on long-term planning for the facility, effective changes have been implemented to ensure that a long-term EoR contract is in place. A more robust governance structure is in place within the organization to ensure that such decisions concerning EoR changes, if required, involve other stakeholders at the site, regional, and corporate levels.

The internal erosion incident was due to failure of an extrusion weld around an instrument that penetrated the HDPE geomembrane liner. The continuous use of a single consultant would have most likely prevented the occurrence as the instrument raise deviated from practices used for previous construction raises. The practice of changing consultants as a result of competitive bidding is strongly discouraged (or should be highly scrutinized if required), as the design and construction of these facilities benefit greatly from a long-term consultant (EoR) to ensure learnings are effectively incorporated into the management of these critical infrastructures.

Repairs related to the incident on the TSF have been completed. Lessons from these incidents have been shared across the organization to prevent reoccurrence.

Preventing Potential Consequences of a TSF Failure: Addressing the Other Side of the Risk Equation

Susan Joyce, On Common Ground Consultants, Canada
Keiran Doyle, Satarla, UK

Abstract

Implementing the new GISTM is introducing a series of challenges to operating companies as they seek to upgrade their geotechnical stability, adjust tailings management systems and organizational structures, and to adapt existing technical decision-making modalities to the new demands of GISTM requirements. Companies have frequently focused on Topic III: Design, Construction, Operation and Monitoring of the Tailings Facility, and Topic IV: Management and Governance. Many companies have sought to integrate into existing operational systems the new components of integrated decision-making laid out in Topic II. Some requirements of Topic II are poorly understood and lagging in implementation, even though they contribute to the overall objective of building and managing TSFs for safer outcomes, and inform decision-making processes required by Topics III – VI.

With a strong focus on reducing probability of failure, less has been reported to date on steps to eliminate or reduce potential consequences of a TSF failure. This paper considers requirements within GISTM that support understanding and decision-making directed at reducing potential consequences of credible tailings failures, and argues that this process should take place in parallel with efforts to reduce the probability of failure. It presents two shifts in approach to address this gap; first, we propose a strategic shift in risk assessment approaches to put "safety of people" at the center of the risk analysis rather than "TSF failure." Building on that shift, we propose a pathway – a sequence of short-term actions for assessing and reducing potential consequences to prevent harm to people. We argue that this allows sites to apply all levels of the risk-control hierarchy, employing proactive controls aimed at eliminating or reducing consequences, in contrast to the current practice of proactive engineering controls combined with primarily reactive mitigation measures as a response to actual impacts on people's lives.

Introduction

Increasing production and forecasts of resource extraction, particularly for copper, suggest a continued trend towards larger tailings storage facility (TSF) structures containing more tailings that are potentially

deposited more quickly, all of which increase the probability of TSF failures (Robertson, 2018). They already represent some of the largest engineered structures on earth, and by deduction, the largest hazards created by humans.

The Global Industry Standard for Tailings Management (GISTM or the Standard) came into play in 2020 due to the steep rise in TSF failures, and fatalities arising from them. ICMM companies committed to the implementation of the GISTM standard, and to ensure that very high and extreme Consequence Classification dams are "compliant" by August 2023, with two additional years to bring other TSFs online. Considerable work has been done to align management systems and put in place "levels of defense" – Dam Safety Reviews, Change Management, Independent Tailings Review Boards, Responsible Tailings Facility Engineers, and so on. Considerable effort has been expended by companies to improve the design and construction of geotechnical containment structures to optimize the stability of existing TSFs and their ongoing management.

While not possible to quantify from the available data, it is reasonable to assume that the effort and investment to date in complying with GISTM has been predominantly focused on reducing the probability of failure. This work, given the underlying uncertainty in geotechnical parameters and the pre-existing instability or information gaps identified in recent failures, is critically important. However, geotechnical studies and subsequent strategies to improve stability take time and resources, so providing for safer facilities is not usually a quick solution. Further, industry recognizes that engineering and monitoring improvements are not going to eliminate the risks of failure; they may even increase the risk in the short term, such as in the Cadia embankment failure of 2018 (Jeffries et al., 2019). Meanwhile, the assessment of the very real consequences for at-risk populations situated downstream of these facilities, and actions to eliminate or manage those consequences, are far less mature.

Understanding and quantifying the consequences for people is important – critical in fact – because it is the threat to people that is at the core of the standard – and it is what drives many specialists doing this work. Kemp introduced disaster literature to the discussion of TSF failures in 2020 by contextualizing TSF failure events in terms of their human cost. The example used was of a hurricane offshore that is just a hurricane unless it wreaks havoc with peoples' lives and property, in which case it becomes a disaster. Equally a tailings dam failure is not a disaster unless there are people – and property, infrastructure, etc. killed or damaged – although it may still constitute an environmental disaster. For a TSF failure to be considered a disaster requires people, their livelihoods, infrastructure, or critical ecosystems to be in the path of a TSF failure, and for it to cause serious disruption to the functioning of affected people through losses and impacts (Kemp, 2020).

A similar focus was put forward by Robertson in 2018 when he conceptualized TSF management in terms of a system that includes what is at risk downstream. He put forward a systems approach to tailings

governance that identified three components of the system that must be assessed – 1) the stability of the TSF; 2) the failure path or route; and 3) the receiving environment. In Robertson's terms, each of these components of the system needs to be identified, assessed, and strengthened in order to manage risk and improve resilience at the level of the TSF system (Robertson, 2018). The agreement between the two approaches is that the TSF containment failure is a disaster depending on what happens downstream.

Discussion

Different understandings of risk assessment

The definition of risk from the perspective of threats to objectives is simple enough; the *Oxford English Dictionary (OED)* defines risk as simply a "hazard or danger, or exposure to a mischance or peril" (RAIS, 2024). A TSF presents a hazard to people, property and the environment – there is no probability associated with the existence or reality of the concept. Through the development of risk assessment as a decision tool, which the *OED* dates to 1957 as a term, one of the tools for assessing and prioritizing response to risk is the assessment of risk as a relationship between consequences and probability. Risk assessment is a core practice and tool used by tailings professionals to identify and understand the hazards that pose a threat, and to allow prioritization of the actions to be taken to reduce the risk(s) associated with that threat. Prioritization is helpful and even necessary in a world of limited time and resources in which to respond to a hazard.

Risk conceptually considers both probability and consequences when it is used to evaluate options in a complex situation and to direct proportionate effort and money towards the most important contributors to the risk. But how you ask the initial questions, or how you posit what the risk is, will determine how you assess the root causes, pathways, consequences, and subsequently the controls that are developed. The people usually at the table – frequently all trained in the same ways of thinking and analyzing TSF risk (Ospina and Chovan, 2022) agree on the risk question: how to stop TSF failures. They then agree on control measures that are put in place to prevent or respond to the unwanted event, identified as the TSF failure. In doing so, operators are only addressing the risk probability and are missing a range of potential tools and actions available for consideration that place greater emphasis on eliminating or reducing potential consequences.

This is not consistent with GISTM intent, which includes several requirements aimed at identifying and assessing potential consequences and, when these are high, requires operators to take actions to reduce the consequences in case of a failure. The most explicit, Requirement 5.7, states that for new facilities classified as High, Very High and Extreme, "… the Accountable Executive … shall approve additional reasonable steps …to further reduce potential consequences to people and the environment." And that for existing TSFs, the Accountable Executive "... shall seek to identify and implement additional reasonable

steps that may be taken to further reduce potential consequences to people and the environment." (GISTM, 2020).

Risk assessment is also applied to the field of Business and Human Rights, but the approach differs in several important ways from environmental or safety risk management. When considering risks to human rights there are the requirements that: 1) all risks to human rights caused by companies should be eliminated; 2) there are no "offsets" to compensate for negative impacts to human rights; and 3) mitigation is defined as reducing the probability of an impact occurring and is employed when elimination of the risk is not possible (UNHCHR, 2012). Prioritization of actions is based principally on the assessed severity of the risk based on context and scope (extent), scale (gravity of the harm), and the ability to remediate the harm done.

The most significant difference when assessing risks to human rights is that the probability of the risk occurring is considered, but it is a secondary level consideration to ensure adequate attention is paid to high-severity, low-probability impacts (UNGP Reporting Framework, 2024). Severity is the predominant factor considered; the probability of the harm occurring "may be relevant in helping prioritize the order in which potential impacts are addressed" (UNHCHR, 2012).

In contrast with risk assessments formulated as "probability x consequences," severe risks to humans should not be qualified by the probability of it occurring; actions should be taken to eliminate the risk. Hence, companies need to take action to reduce the severity of human rights risks (i.e., consequences) in parallel with reducing probabilities.

Using risk assessment for proactively reducing consequences

One of the most versatile and widely used tools for risk assessment and communication is the bowtie analysis. Disaster analysis and process safety management provided the impetus for developing the bowtie tool, the use of which is driven by the need to understand high consequence hazards that endanger multiple lives and have far-reaching impacts. Bowtie analysis facilitates the mapping of pathways to and from unwanted events across defined occurrence time-zones to inform and strategize the development of proactive and reactive controls.

As illustrated in Figure 1, proactive controls are typically applied to causes, with reactive controls implemented to directly or indirectly mitigate consequences or impacts after they have occurred. If the risk assessment identifies embankment failure as the critical Unwanted Event, that is the focal point of the bowtie and control measures are built based on that. Controls aimed at prevention – the left side of the bowtie – are subsequently focused on TSF stability from an engineering perspective. Harm to people is a consequence and by design, subject to only reactive controls.

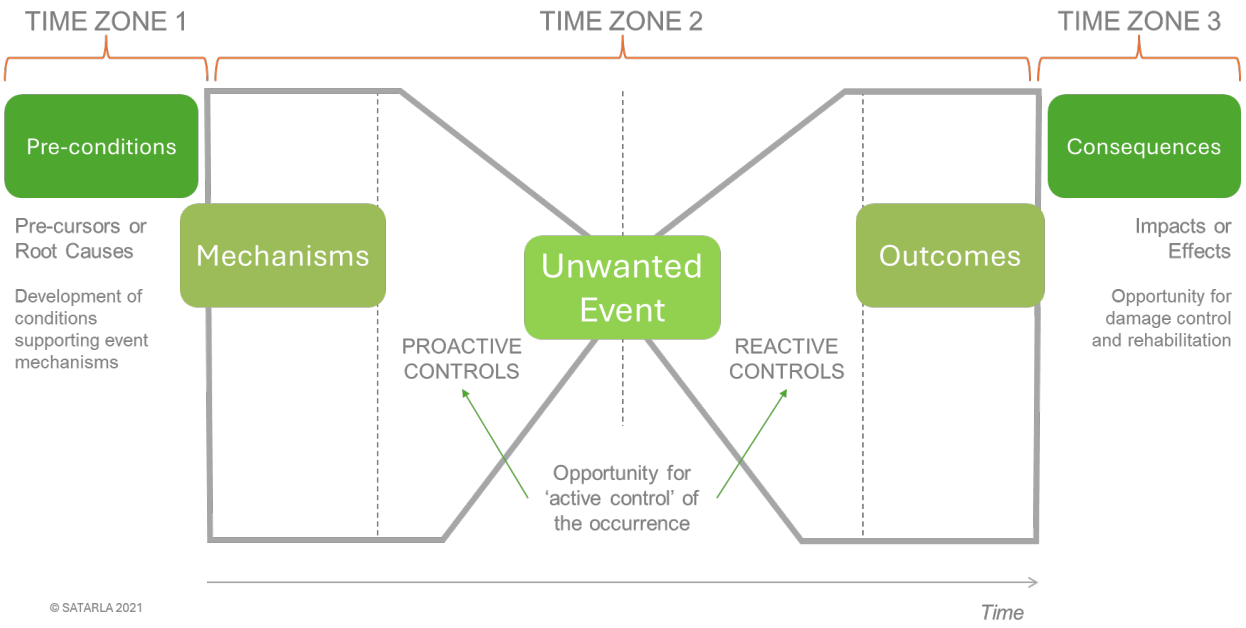

Figure 1: Generalized time sequence of events in bowtie analysis. Doyle (2024) with influence from Viner (1991)

If the chosen material unwanted event is "harm to people," an effective bowtie analysis should enable the identification of a range of pre-conditions, contributing causes/mechanisms requiring the implementation of preventive controls. This likely would include TSF instability, and it also would generate additional causes relative to what puts people in the pathway of a failure; what exposes them to the hazard; and what makes them vulnerable to harm if it occurs. This "risk statement" should lead to identification of both direct and indirect reasons for why people are exposed to harm by the hazard, e.g., location of people and facilities, poor construction of downstream homes, unavailability of surface water in other potential locations, etc. (see Kemp, 2020, for a detailed discussion of exposure and vulnerability).

If the intent is to identify effective controls for preventing "harm to people," then positioning that as the problem or unwanted event results in a bowtie analysis that is more focused on the causal pathways that put people at risk and consequently supports development of preventive and proactive controls to remove or reduce that exposure to harm, not just preventive and proactive controls considered relevant to geotechnical stability.

Review of the GISTM approach to reducing risk as a consequence-based standard

GISTM requirements provide a pathway to deliver on improved safety of tailings management in the short term, through the identification of people who are exposed to the TSF hazard, how they are exposed to the specific outcomes (e.g., liquified tailings inundation or base slump, etc.) and steps to be taken to prevent consequences and to be prepared to respond – engaging controls on both sides of the bowtie analysis. These are actions the operator can implement during the time required for upgrading geotechnical stability of

existing facilities. This proposed sequence is even more critical for operators of those facilities where geotechnical instability has been identified, or with limitations to being upgraded as required by the standard (see Requirement 4.7).

As has been discussed at earlier conferences (Small et al., 2023), the mandate for the Expert Panel that developed GISTM was to use a consequence-based approach to inform requirements for design and other aspects of TSF management such that consequence and probability of failure are evaluated independently. The consequence-based approach aligns with a human rights principle, which is to eliminate the risks associated with an event if the consequences are high or extreme, even if the relative probability is low (UN Guiding Principles Reporting Framework, 2024).

A sequence of key requirements for preventing harm and reducing consequences

Implementing the 77 requirements of the GISTM requirements requires delivering on over 200 deliverables across the 15 Principles (McNab et al., 2023), and determining which deliverables and requirements are highest priority is a challenge and is influenced by decision-makers' areas of expertise. Built into the GISTM are a series of requirements or actions designed to provide operators with the information needed to act on worker and community safety relative to a potential TSF failure, and social performance expertise in the tailings management team can fine-tune this sequence to the specific situation.

Using that expertise, a sequence of actions for existing TSFs can be construed from the requirements that has the potential to provide a basis for decisions on reducing potential consequences in the short term, while additional studies are underway and/or geotechnical engineering upgrades are being put in place. This same sequence serves as the basis for a more comprehensive set of controls when the studies and assessments making up the Integrated Knowledge Base have been completed. This allows development of a deeper and more robust analysis of how people are exposed to various forms of harm from potential TSF failures (Kemp, 2020; Owen et al., 2020), as per the assessment of causal pathways in a bowtie analysis and the disruption of those pathways through proactive controls to prevent harm.

The assessment of potential human exposure and vulnerability (Requirement 2.4) is the linchpin in this process and cannot be carried out without meaningful engagement of those at risk (Requirement 1.3). This assessment starts with the outputs of the Dam Breach Analyses for credible failure modes (Requirement 2.3) and the resultant inundation maps. Based on these inputs, social specialists should be mobilized to carry out a targeted engagement and assessment of potential impacts to people's lives and livelihoods to understand who and how people are exposed in the case of a TSF failure, including the workforce, contractors, and itinerant users of downstream areas.

In urgent situations such as at-risk populations downstream from an unstable TSF, the approach may be drawn from well-established social research methodologies such as Rapid Rural Appraisal (Townsley,

1996), or others appropriate to the context. The information obtained is fundamental to inform short-term decision-making around safety, to support safety-focused risk assessments (as per the bowtie analysis approach discussed above), and to inform decisions on the allocation of key resources to address both stability (probability) and safety (consequences). Finally, this information is necessary to inform reactive controls to mitigate consequences, in particular emergency response preparedness – just in case.

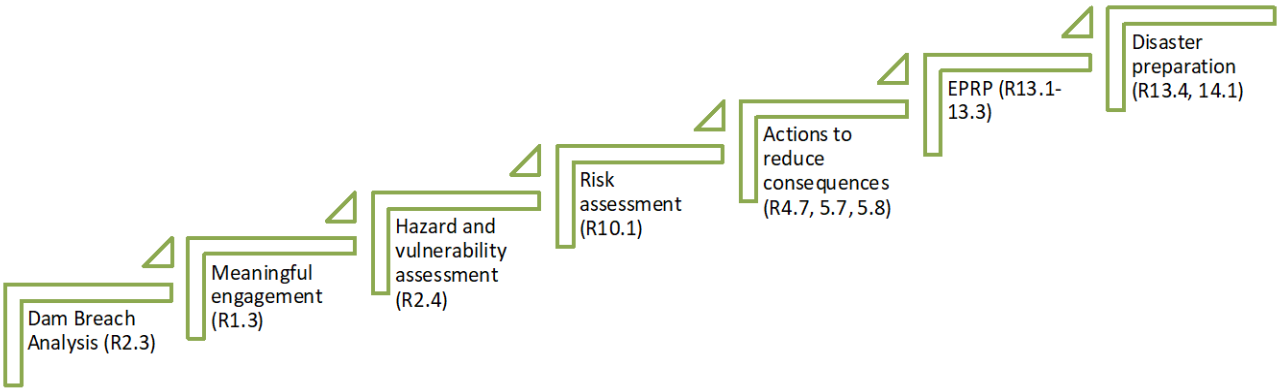

Figure 2: GISTM Harm Prevention Sequence for an existing TSF

This Harm Prevention Sequence also requires meaningful engagement and disclosure of the risks people are under to complete the remaining steps effectively and deliver safer outcomes. Involvement and ongoing engagement with at-risk stakeholders are built into the remaining requirements of the Sequence as they are into the Standard:

- At risk groups should be represented at and participate in risk assessment workshops as part of the multi-disciplinary and multi-stakeholder input to ensure that a diversity of perspectives and perceptions are included and to avoid bias, overly like-minded thinking, and over-confidence in reduction of probability as being sufficient for the reduction of risk (Ospina and Chovan, 2022).
- Identification of proactive controls aimed at reducing consequences for at-risk people will require disclosure and their participation in decision-making.
- Emergency Preparedness and Response Planning (EPRP) cannot be effective, nor it is aligned with GISTM Requirements 13.1–13.3, unless it is carried out collaboratively with first responders and local authorities as well as directly with at-risk workers, contractors, and community members.
- Disaster preparation and planning is fundamentally about engaging with public sector actors, first responder and authorities, as well as at-risk people.

This sequence, and GISTM in general, requires an effective internal and external engagement process; the importance of building internal cross-functional literacy and capacity between social and engineering teams while negotiating these stages, should not be underestimated (Ospina and Chovin, 2022).

In time, an initial rapid assessment focused on short-term actions to reduce consequences and inform emergency planning should be built into in-depth social and environmental impact assessments of the inundation zone(s) and more robust exposure and vulnerability assessments, in line with the requirements of Topics I and II of GISTM but also as the required knowledge base for the integrated decision-making embedded across the standard. The intention behind identifying a key sequence of actions to prevent harm is that these studies take time to carry out effectively and comprehensively, as do geotechnical investigations, and those responsible for high-risk TSFs should be informed on how to reduce potential consequences as soon as possible.

The Requirements presented here provide a proposed set of actions to be implemented in sequence, and to ensure that each step informs the next and that consecutive steps are aligned with the intent of keeping people safe. The information inputs, analyses, and engagement processes allow for informed decision-making on the appropriate and acceptable (to the people at risk) steps for proactively reducing consequences. This also provides a credible process whereby the Accountable Executive can attest to and demonstrate that further actions have been taken to reduce consequences (Requirements 4.7 and 5.7). While geotechnical improvements are fundamental to long-term safety, this approach recognizes that TSF failures remain possible – if less probable – and that people need to be kept safe.

Key for safety – EPRP

The Emergency Preparedness and Response Plan is an output of the risk assessment process, and it is typically identified as a reactive control for consequences articulated on the reactive right-hand side of bowtie analyses. An operation-wide EPRP is a standard part of a mining operation's physical security and OHS safety programs, with scenarios described, planned, and in principle trained on for all identified potential emergencies through pre-arranged drills and simulations. The emergency response kicks in when the event is imminent or has occurred, so it is by definition a set of reactive controls and intended to mitigate or minimize negative impacts, not to prevent them. The intent of the EPRP is to limit the damage done by the TSF failure to the greatest extent possible through response preparedness, training, availability of specific equipment and resources, etc.

The pre-GISTM practice of developing EPRPs only for hazards or emergencies identified within the footprint of the operation presents a problematic gap in both management and governance if not addressed explicitly through the engagement and coordination required by the Standard. On-site safety teams may have no mandate off-site, and TSF teams have no mandate or expertise in emergency planning or response. Probably neither of these functional areas have any knowledge of or expertise to understand types of exposure of downstream populations. Hence, the planning, coordination, training, and testing associated with emergency preparedness for hazards/emergencies that leave the operational footprint may require an

entirely new approach, organizational structure, and team to ensure clear assignment of responsibility and accountability for this critical task.

Drawing on the strategic shift in risk assessment proposed above, emergency planning associated with potential TSF hazards can be implemented in ways that make it more of a proactive control, contributing to reducing community exposure to hazards and improving resilience. This can be accomplished by conducting EPRP development with communities at risk from TSF failures in line with the UN APELL (Awareness and Preparedness for Emergencies at Local Level) approach (UNEP, 2015). In the process of engaging and training for emergency response to a TSF failure, a broader capacity to identify and eliminate direct consequences, or mitigate and prepare for a wider range of hazards present for the community can be constructed.

Conclusion

The arguments for acting in the short term to reduce potential consequences in parallel with the measures adopted to reduce the probability of a failure are two-fold. First, it is aligned with GISTM intent and will support the responsibility that the Accountable Executive has relative to this issue. Secondly, carrying out consequence prevention measures to address the exposure of at-risk people to harm provides additional tools with a higher visibility with the local community and potentially a faster delivery than many engineering fixes. Thirdly, prevention is more cost-effective than remediation, as evidenced by the costs associated with the three largest and most deadly TSF disasters of the last decade; Mt. Polley, San Marco, and Brumadinho. The investments made by BHP and Vale in recovery programs through the Renova Foundation after the San Marco failure are likely to be higher than the cost of averting the failure from the start (Kemp, 2022). Quantifying the probable cost of a disaster can focus decision-making onto taking measures that will reduce consequences in case of a failure; the win-win associated with these actions is the probable positive contribution to quality of housing or security of tenure, etc., for at risk people as actions are taken to address their vulnerability.

The argument is not to stop making TSFs more stable – as is widely recognized, dams that have failed and killed people were found after the fact to have been unstable prior to failure. However, in facing hazards with the potential to lead to major disasters, represented by multiple fatalities and significant damage to livelihoods, ecosystems, and social infrastructure, reducing probability is not sufficient. And neither are the requirements of GISTM solely focused on reducing probability. Tackling the problem from multiple fronts, due to multiple causal pathways, makes greater sense and reflects an urgency that is not always perceived. If we can broaden the scope of activities being undertaken to more than engineering, we have a wider range of tools available, which subsequently broadens the scope of action and focus of efforts.

Accountability for decisions to reduce consequences is clearly defined in GISTM as sitting with the Accountable Executive; there remains work to determine who has responsibility and the capability to ensure that this work is being done on site. As discussed above, reducing consequences requires carrying out assessments of exposure, vulnerability of people to the failure modes, and engaging with them to address the risks they face, the solutions for these may be varied and need to be determined with them. In other words, the work is bringing the core practices of social performance specialists to the table in managing TSF risk.

There needs to be a clear focus in the GISTM implementation on keeping people safe in the face of the real and ongoing hazard presented by TSFs, and there are tools at hand to do so. If people are permanently situated in the pathway of a credible failure, the potential for harm to them is almost never eliminated through geotechnical stability and TSF management alone. The point is to ensure that there is a risk management strategy in place that puts "avoiding harm to people" at the core – as the unwanted event, so that consequences are being reduced when lives are at risk. The two dimensions of reducing risk – probability and consequences – can and should take place in parallel, mobilizing different internal teams so that different resources are channeled to the relevant controls aimed at prevention of the unwanted event, rather than solely reacting to it.

Acknowledgements

We would like to acknowledge the contribution of Dr Deanna Kemp for bringing disaster literature and perspective to the work of the Global Tailings Review Expert Panel that developed the GISTM, and for her ongoing critical thinking relative to root causes of human exposure and vulnerability to TSF failures in conjunction with her colleague Dr John Owen. Dr Keiran Doyle and Chris Neal's previous work on the use of bowtie analysis has shaped our understanding of its potential effectiveness in this context. Any and all errors are ours.

Surveying the Landscape: Understanding Engineer of Record Challenges and Perceptions in the Brazilian Tailings Industry

Luciano Souza, Federal University of Rio de Janeiro, Brazil

Abstract

This study investigates the perceptions and experiences of professionals in the Brazilian tailings engineering sector regarding the Engineer of Record (EoR) role. The research utilized a comprehensive survey inspired by similar studies in North America, adjusted for the Brazilian context, to gather data on participants' involvement, aspirations, risk perceptions, and understanding of the legal implications associated with the EoR role. The surveys also captured important information regarding experience level, demographics, and education of the tailings community in Brazil. The findings reveal a significant hesitation among professionals to assume EoR responsibilities, largely due to the recent high-profile dam failures in Brazil and the associated legal consequences. The survey also highlighted a demographic disparity within the industry, with notable gender and race gaps, and an alarming trend of Junior professionals overestimating their competency. These insights suggest a need for improved education and clearer communication of legal responsibilities to the involved professional, alongside initiatives to address demographic imbalances in the field.

Introduction

The demand for qualified professionals in the tailings engineering job market in Brazil surged significantly, starting in 2015 with the Fundão failure and accentuated by the Brumadinho failure in 2019. The high demand was experienced by consultant companies that were suddenly inundated with an enormous demand for new projects to improve the safety of existing tailings facilities in the country. This demand was not all driven by the proactive motivation of dam owners to improve current operations, but rather was mainly motivated by the myriad of state and national legislation updated since 2016, which became stricter in just

a couple of months following 2019, as explained by Braga (2021), due to new international standards, such as the GISTM (Global Industry Standard on Tailings Management, 2020).

Suddenly, the Brazilian tailings job market, which has a stablished consultancy hub located in the city of Belo Horizonte (Minas Gerais), experienced an influx of professionals from different parts of the country. New consultancy companies were established and experienced a rapid growth, and senior international firms expanded work in Brazil. As expected, the demand was higher than the supply of qualified professionals, especially Senior engineers, who suddenly saw tailings engineering as an opportunity for professional growth after a decade of slow economic growth for engineering firms in Brazil. This new marketplace was now composed of a few experienced tailings engineers and an immense number of professionals who either had previous experience with engineering (outside of the tailings environment) or were completely new to the profession.

In 2024, five years after this sudden shock to the market, the demand for new projects seems to be slowing, but the challenges remain. The most recent one was the inclusion of the Engineer of Record (EoR) as a mandatory role for tailings facilities in Brazilian national legislation in 2022, following the guidelines of the GISTM.

Looking to the future of the profession to explore our capacity for meeting the current and future demand for qualified professionals, this paper presents the results of a survey conducted online with tailings professionals with different backgrounds who are currently working in the tailings engineering job market. Initially, the efforts were motivated by the work of Prince and Boswell (2023) who surveyed 164 young engineers and investigated via multiple means their willingness to become EoRs in the future. The authors decided to broaden this investigation by asking professionals working in the tailings industry with different sets of experiences about their perceptions of the EoR role and the tailings industry.

The following sections will present the methodology, outline the limitations, and detail the findings of the survey. The diverse pool of respondents has yielded a rich dataset that potentially presents a substantial number of combinations to be explored in future research. For this paper, the authors decided to present a broader overview of the data, with the aim of presenting a comprehensive understanding of the current state of the tailings community in Brazil. As this work progresses with the engagement of national and international peers, this research will be expanded to include more participants, fostering a more comprehensive understanding of the Brazilian tailings management landscape.

Survey methodology

The survey was anonymously conducted using the Google Forms platform. Anonymity was guaranteed and no personal information was collected. This step was important because the authors are active members of the tailings community, working for different companies, and the participants might feel intimidated to

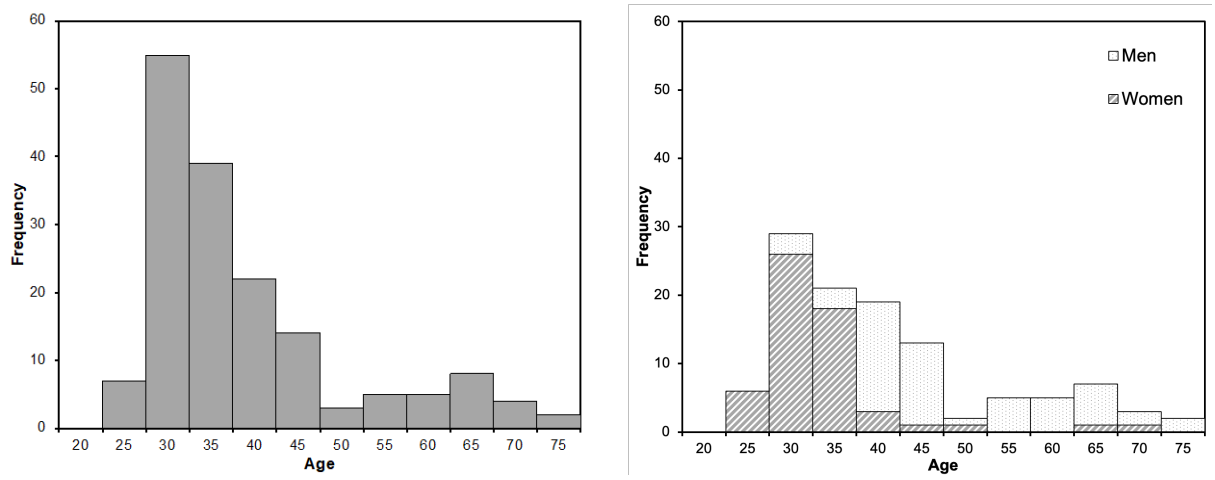
sincerely share their views.

The survey was divided into the following sections: demographics, which included questions regarding gender, age, experience, and area of expertise; academic experiences, which included a brief survey of the educational background of the respondents; professional experience, which surveyed the current level of professional classification and if the participant is currently affiliated with any professional association; professional perception, which included questions aiming at understanding the participants` self-perception on topics such as professional experience, field work, regulatory knowledge, risk profile and soft skills; Engineer of Records, which included questions that are generally based on the work of Prince and Boswell (2023), with some specific adjustments to include Brazilian characteristics.

The survey was mainly advertised using the authors' own social media and message groups, with some contribution from participants in their network. The survey was also shared by the Minas Gerais branch of the Brazilian Association of Soil Mechanics (ABMS) in an email message.

With a total of 165 participants, the authors believe that the number of responses is an adequate number to represent the tailings industry in Brazil. However, considering the pool of respondents, the following limitations were noted:

- More than 80% of the respondents are currently working in areas related to consultancy and only 14% are employed by mining companies. Hence, most of the results presented in this research are representative of the views of professionals working in the consultancy industry.
- Approximately 80% of the respondents work in geotechnical engineering, while the others are divided into water management, geology, and project management roles. Thus, the results drawn in this research are limited to a general overview of the current state of geotechnical consultants working in tailings engineering.



Results

Demographics

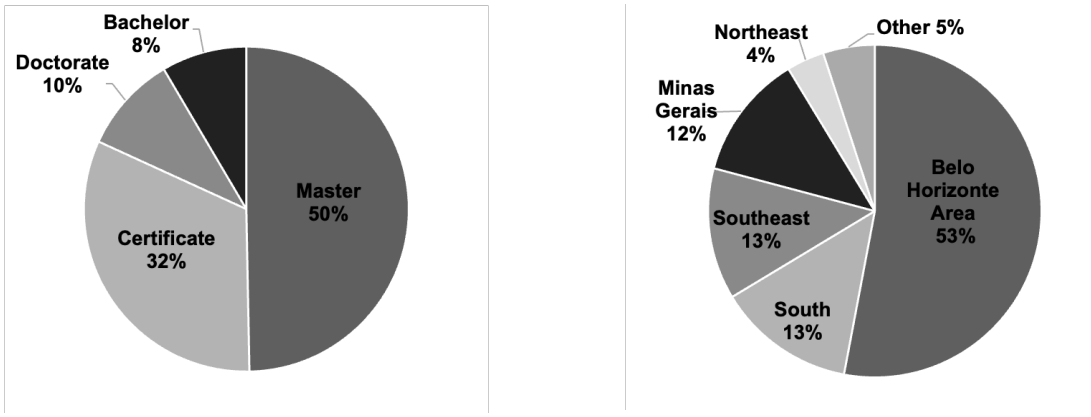
The demographics results showed that 64.8% and 35.2% were men and women, respectively. These results, while they reflect gender inequality in the tailings technical community, are aligned with other surveys conducted around the world. The results also showed racial inequality, as 70.3% of the respondents identified themselves as white, while 22.4% identified as mixed race *("Pardo")* and only 5.5% as black *("preto")* and 1.2% as Asian *("Amarelo")*. Comparing these rates with the last national census results (IBGE, 2022), one can deduce a high level of racial inequality, since the division for the census was 45.3% mixed race, 43.5% white, 10.2 % black and 0,4% Asian.

With respect to age, Figure 1 presents a histogram with the age groups. As one can see, the great majority of the respondents (>70%) were less than 40 years of age (38% less than 30 years; 37% between 30 and 40 years). From the histogram presented in Figure 1, it is possible to observe an age gap around the ages of 40 to 50 years (10% of respondents), with an increasing number of respondents older than 60 years. Although this inference is limited to the representativeness of the number of respondents considering the whole tailings community, this result corroborates the general impression of the market that professionals with around 25 years of experience (around 50 years of age) are the scarcest in the market.

Dividing the histogram to account for gender distribution (see Figure 1 [b]), it is possible to confirm something that is easily observed in the tailings community: the low number of female Senior professionals. For professionals older than 40 years, the number of female engineers is almost zero, highlighting that the gender gap identified in the general pool of respondents is linked to age groups. Based on the results presented in Figure 1 (b), one can infer that gender inequality tends to lower with passing time, as this gap reduces in professionals under 35 years of age.

(a) (b)

Figure 1: Age distribution histogram – (a) general (b) by gender

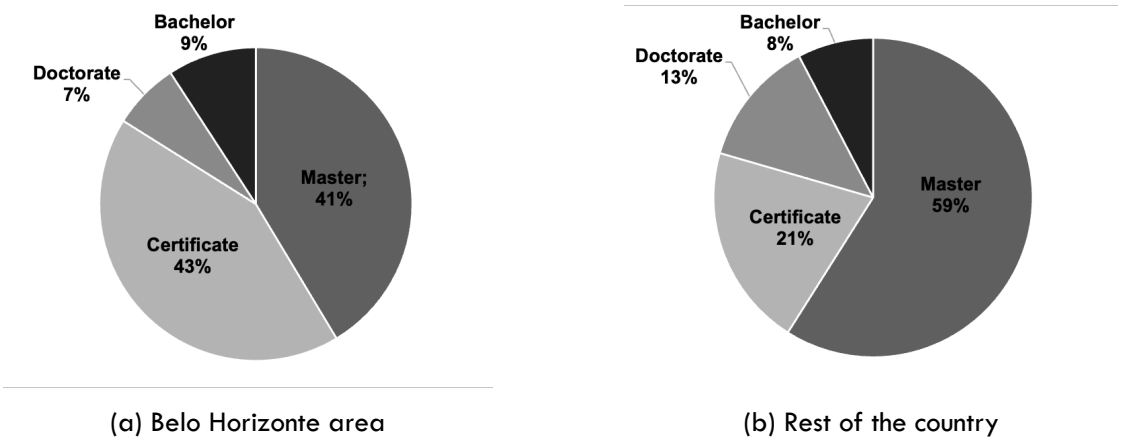


Education

Another important aspect of the initial assessment of the survey was the investigation of the educational level of the respondents. In total, half of the respondents had a master's degree, 32% had an equivalent to a certificate degree (Lato Sensu Graduate), 10% had a doctorate degree, and only 8% had a bachelor level (Figure 2 [a]). These results highlight the high level of specialization required to work in this field, and that only a small percentage do not go further than the bachelor level degree.

An additional aspect investigated in this study was the evaluation of the academic institutions where these professionals graduated. There is a general perception that the tailings job market in Brazil, which is

mainly concentrated in Belo Horizonte (Minas Gerais state), lack diversity in terms of the presence of professionals coming from different universities, and that the majority of the professionals graduated in institutions located in Minas Gerais (the location of the headquarters of most mines and consultancy companies).



The results presented in Figure 2 (b) corroborate this general impression, since 53% of the participants did their undergraduate degree in universities close to Belo Horizonte (< 100 km), while the rest of the country had fairly uniform numbers, ~12% for each region, including the rest of Minas Gerais state, and the southeast and south regions. The states in the north, northeast and central parts of the country produced only 8% of the respondents, while 1% did their undergraduate studies abroad. This reflects a lack of diversity, despite recent efforts to include professionals from different parts of Brazil in the last years due to the need of qualified professionals. In terms of the type of institution, 76% of the respondents studied in public universities, while 23% studied in private universities and 1% in foreign universities.

(a) Educational level (b) Location of undergraduate studies

Figure 2: Educational background – (a) level of education; (b) region of undergraduate studies

Another finding is related to the level of education based on where the respondents did their undergraduate studies. The participants who did their undergraduate studies in universities in the Belo Horizonte area preferred to continue their education with a master's and doctorate degree, while just a small fraction (21%) preferred the professional certificate degree (Figure 3 [b]). Participants who did their undergraduate studies in universities in the Belo Horizonte area almost equally chose master's degrees or a certificates degree to advance in their higher education study (Figure 3[a]).

(a) Belo Horizonte area (b) Rest of the country

Figure 3: Educational level by location of undergraduate studies: (a) Belo Horizonte area (b) rest of the country

These results indicate another general trend observed in the market. Professionals who studied in the Belo Horizonte area had the opportunity to complete internships in tailings consultant companies that facilitated their passage to an appropriate job. After they secured their job living in the Belo Horizonte area, a high number of people preferred to do a certificate degree, since it is easier to combine this with a full-time job (Figure 3 [a]), as reflected by the low supply of master's degrees in this region. On the other hand, the majority of the participants (~75%) who did their university degree in the rest of the country chose either a master's degree or a doctorate degree to increase their educational level (Figure 3[b]). With less opportunity for internships in their hometowns, professionals had to further improve their educational level in order to secure jobs.

Experience

The research investigated how long the respondents had been working in general engineering versus in tailings. The results show that 75% of responses were from professionals who had been working in tailings for less than 10 years. Within this group, 22% were professionals with more than 10 years of general engineering experience who started working in the tailings job market after the tailings dam disasters in 2015 and 2019 in Brazil.

Regarding the job category of the respondents, the survey showed parity in the representativeness of each level (Junior, Intermediate, Senior, and Expert) with around the same number of respondents for each category. Nonetheless, an important aspect of the current job market was observed: the inconsistency in experience across job categories, as shown in Figure 4. For Experts, for example, the answers varied from 11 to 50 years of experience; for Senior level, from 3 to 32 years; for Intermediate level, from 4 to 17 years and, finally, for Junior level from 1 to 11 years of experience as an engineer. It is important to highlight,

however, that since the question was formulated as an open question, multiple types of answers were given. Hence, filtering and categorizing were necessary to ensure that the data could be analyzed effectively.

The average values for each category showed some coherent trends, as seen in Figure 4. Nonetheless, as seen in the number of years of work experience mentioned above, there is no clear separation between the Junior and Intermediate categories, which had very similar years of experience. It was noted that Senior engineers were usually professionals with more than 10 years of engineering experience. However, it was also noted that this position is held by professionals with less experience with tailings than is usually adequate (<10 years of tailings experience). As expected, for Experts, Consultants or Master (a type of classification created in Brazil), the distribution is even more diverse, and it is clear that there is no clear criteria to which to attribute this classification.

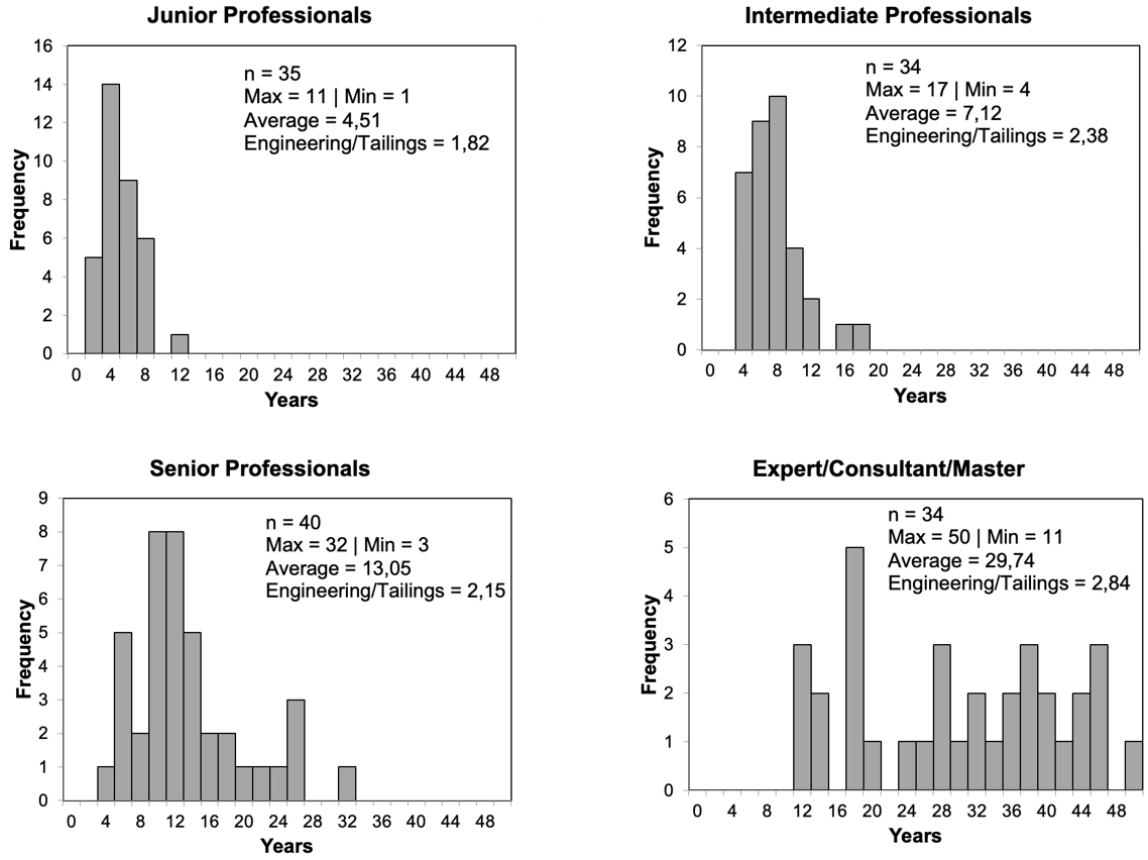


Figure 4: Years of engineering experience: distribution histogram per job category

The authors believe these results accurately depict the current state of tailings engineering in Brazil, where the demand for qualified professionals surpasses the available supply. This imbalance leads to a distortion of the relationship between job category (Junior/Intermediate/Senior/Consultant) and time of experience. Caution should be exercised by the industry so as to allow adequate time for professional

development before people are able to take on large commitments and significant responsibilities within such complex structures.

Professional perception

The Professional Perception section of the questionnaire aimed to research the participants' opinions on Professional Experience, Field Work, and Regulatory Knowledge. The responses reflect a self-evaluation of various career markers considered by the authors to be important in tailings practice. Most of the questions on this section could be responded to with Strongly Agree (SA), Agree (A), Indifferent (I), Disagree (D), Strongly Disagree (SD). The participants also responded to a question on whether academic experience or professional experience is more important for professional development, and self-evaluated their level of understanding of the tailings practice.

The data shows that 37% of the participants find that available working hours are insufficient for their assigned workload. A possible interpretation of this response is that there is still a need for more qualified professionals – an interpretation that is in agreement with the current market understanding (Hatton et al., 2020). Most of the participants (>75%) believe that their assigned responsibilities, job category, and professional progression are coherent with their experience level. More than 80% of the participants responded that academic experience and professional experience are equally important for professional development.

The vast majority (>95%) of the participants understand the importance of field work. The authors consider this to be an interesting finding given that this research population is strongly represented by geotechnical engineers working in consultancy, which has a primarily office workload. Although 80% of the participants claim to have done fieldwork for professional development, 56% would like still more fieldwork experience. This result could also be understood from the perspective of the study population.

Responses show that 83% of the participants claim to have an understanding of national regulations that is coherent with their job category, which is consistent with the current heavily regulated tailings engineering environment in Brazil. Also, 72% claim to understand international regulations such as CDA, GISTM, ICLOLD and MAC. The authors found it noteworthy that 56% of the participants claim to be indifferent or to not understand the civil and criminal liability associated with their work. Additionally, more than 55% are indifferent or do not understand the CREA (Brazilian NSPE corresponded) regulations, which defines technical attributes and liability. This complementary information shows that, even in a job market that boomed after the failure of two major structures, which resulted in civil and criminal lawsuits, most of the engineers are not aware of the potential judicial consequences associated with their work and have not tried to learn more about it.

The participants also responded to a self-evaluation of their level of understanding of the tailings engineering practice by choosing one of three pre-set responses developed by the authors to simulate a Junior, Intermediate and Senior level knowledge, as follows:

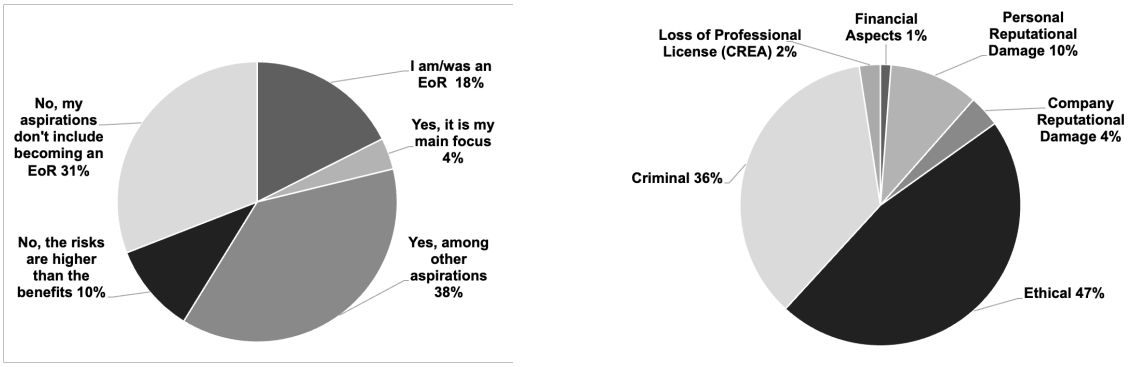
- Junior: "I execute assigned tasks with basic understanding of the information and existing tools, but not necessarily understanding the results and implications."
- Intermediate: "I have advanced understanding of the physics and engineering of a project, as well as the nuances of the structure's operation, and have the ability to contribute to problems based on previous experience."
- Senior: "I possess deep understanding of all the technical areas related to the structure and the current state of practice, am able to fluently communicate them to all stakeholders, and possess the feeling of ownership of the structure."

The self-evaluation responses by the participants resulted in 12.1% with Junior knowledge, 67.3% with Intermediate knowledge and 20.6% with Senior knowledge. These numbers should be compared to the demographics of this study: 21% are Juniors, 45% are Intermediate/Seniors, and 21% are Expert/Consultants/Masters. The authors' interpretation is that Junior participants judge themselves to have a better understanding of the tailings engineering practice than is expected for their category. Unfortunately, this might reflect a typical Dunning–Kruger effect.

EoR

The EoR section of the survey included questions generally based on the Prince and Boswell (2023) work, with adjustments to include Brazilian characteristics. The questions were developed to understand:

1. the participants' involvement with EoR practice;
2. their aspirations to become an EoR in the future;
3. their risk perception regarding assuming this role;
4. their understanding of the lawsuits against engineers involved in the Brazilian failures; and
5. their main concerns as an EoR in the event of a failure.



All responses in this section should be understood in the context of the participants' demographics, education, and experience, as previously presented.

Within the response pool, only 14% claim to be assigned an EoR or Deputy EoR role; nonetheless, 64% claim to be working in an EoR team. This data is coherent with the authors' understanding of the Brazilian consulting industry: as the EoR has become a mandatory role for high DPA (Associated Potential Damage, as per ANM, 2022), teams were created in the consulting industry to provide this service to the mines, but only a minority of existing Seniors can assume this role. Signing off on a structure's stability, either as an EoR or with a DCE (Declaration of Stability, as per ANM, 2022) – which is commonly done

by a small niche of Senior professionals – has become a major industry demand, as confirmed by this data. But will the industry be able to fill these positions with the upcoming generation?

In the responses to the questions "Do you aspire to assume an EoR role at any point in your career?" and "How do you see the personal risks of assuming an EoR role?", nearly half of the participants (41%) responded negatively to the first question – although with varying justifications – and 42% responded "risky" or "unacceptable" to the latter. The authors compared these findings to those of Prince and Boswell (2023), who found that only 16% of respondents (who were in Canada, the USA, South America, Australia, and South Africa) were not interested in this role, and that 33% responded with "risky" or "unacceptable." The authors offer as a possible interpretation that the two Brazilian failures are not only more recent, but also had a higher fatality rate than the Mount Polley failure in Canada. Furthermore, Brazil currently has 64 mine dams at an emergency level (ANM, 2024), which could also impact participants' personal wiliness to assume the associated liability.

A related question was: "How did the civil and criminal repercussions of the professionals involved with the recent failures influence your decision to assume an EoR role?" More than half (55%) of the participants responded "negatively" to this question, compared to the 33% found by Prince and Boswell (2023). Also, only 5.4% of the Brazilian professionals claimed to have no understanding of the repercussions, comparing to 35% found in the primarily North American population (Prince and Boswell, 2023). The latter comparison could indicate that participants found the consequences to the involved engineers in Brazil following the failures unacceptable.

(a) Do you aspire to assume an EoR role at any point of your career?

(b) What would be your biggest concern as an EoR in a failure event?

Figure 5: Survey results for questions (a) and (b) regarding EoR

When asked what their biggest concern as an EoR in a failure event would be, 47% responded "Moral/Ethical," 36% "Criminal," 10% "Personal Reputation," and 7% chose either "Financial Aspects," "Loss of License," or "Firm Reputation" (Figure 5 (b)). This result is comparable to data presented for the primarily North American industry (Prince and Boswell, 2023). The responses to this question could be

motivated by what is socially acceptable. The authors were surprised as they expected a larger percentage to have criminal concern. This might be explained by a lack of awareness of the potential judicial consequences associated with the professional work, as shown in the previous sections.

Discussion

Based on the strong survey turnout, the authors believe that the results presented in the last section represent well the entire technical tailings consulting community in Brazil. The survey gathered responses from professionals with diverse backgrounds and experiences, and the age distribution shown in the histogram reflects market conditions. There is a high number of Junior and Intermediate professionals, with relatively few Senior or Expert professionals.

The demographic results reveal a considerable gender and race gap in the consultancy industry, which any attentive professional might have anticipated. The gender gap is particularly pronounced among seasoned professionals, while it is almost non-existent in rookie roles. Optimistically, one could argue that within 10 to 15 years, the gender gap in the consultancy industry may close, given that equal numbers of men and women are entering the job market at Junior positions. However, understanding the historical and current reality of the job market for women, it is crucial to continue implementing gender equality initiatives to further reduce the gap.

The numbers presented reflect the significant racial inequality in Brazil, making it difficult to draw specific conclusions. It is essential to implement additional measures to reduce this disparity, as university-level affirmative action alone has not sufficiently increased the representation of black and mixed-race individuals in the highly specialized engineering job market.

The experience section of the survey indicates that there is a clearly dysfunctional relationship between experience and professional category. The authors believe that sector-wide research – possibly funded by market stakeholders and developed by an experienced human resource company – could be a strong tool to expedite the rebalancing of the job market after the recent rapid growth.

Regarding the professional perception section, the authors believe that there is space for further segmentation of the results, which should focus on finding relationships between gender, educational level, and experience to the answers provided in this section. Nonetheless, the current analysis showed interesting data on the professional perceptions of topics such as workload and field work. However, concerning results are presented next.

The first is related to the level of understanding regarding civil/criminal liability related to their jobs. Considering the repercussions for the professionals who were involved in the past disasters, the authors believe that schools, professional associations and other institutions should target educational programs to

provide better information regarding the judicial aspect of the job as a method of empowerment of technical professionals.

The second concerning finding is that Junior professionals reported a self-evaluation of tailings understanding that does not coincide with their age or experience. As mentioned above, this could be a clear sign of the Dunning-Kruger effect, but it would be troubling if a Junior professional is responsible for a project of high consequence. Unfortunately, in Brazil, there is no restriction preventing Junior professionals from signing off on a project.

Finally, with respect to the EoR section of the survey, the majority of the participants claimed that they either work or have worked with EoR projects. Nonetheless, when it comes to assuming the role of EoR, there was a negative tendency in the results, which was more pronounced than in the work of Prince and Boswell (2023) for the primarily North American industry. The vast majority seemed to be aware of the negative repercussions for professionals in Brumadinho and Fundão, and this might have had an impact regarding the personal risks of assuming the role of EoR. Also, living in Belo Horizonte, a common negative aspect of working with tailings dams is that they are frequently in the news and, as expected, are often portrayed negatively.

As the mines in Brazil continue to grow, the industry will need to create ways to adapt to the lack of capable professionals for tailings structures. Following the international trend, educational initiatives combining multiple stakeholders should be explored as a possible solution. Nonetheless, there needs to be a change in the public reputation of the companies and professionals in order to attract new talent.

Conclusion

The survey results provide a valuable snapshot of the current state of the Brazilian tailings engineering sector, particularly regarding the EoR role. There is a clear reluctance among professionals to take on this responsibility, driven by the high risks and severe legal consequences highlighted by recent disasters. This reluctance is compounded by a lack of understanding of civil and criminal liabilities among young engineers, suggesting an urgent need for targeted educational programs. The findings also indicate significant gender and racial disparities within the industry, which require ongoing efforts to ensure diversity and equality. Overall, the study underscores the importance of addressing these issues to foster a more knowledgeable, cautious, and inclusive professional community capable of safely managing Brazil's tailings dams. Further research is needed to research a more diverse pool of respondents that includes professionals working for mining companies and professionals specialized in other areas than geotechnics. Also, further data segmentation is required to identify trends in answer related to age, gender, and experience.

Acknowledgements and disclaimer

The authors acknowledge the contribution of the 165 participants who kindly provided information to this paper. We also extend acknowledgement to those who assisted in the distribution of the survey to a larger public than was possible within only the authors' own network – notably the Minas Gerais branch of ABMS (Brazilian Association of Soil Mechanics and Geotechnical Engineering). The opinions expressed herein are solely those of the authors and do not express the views or opinions of their employers.

The Role of Engineer of Record – a Reflection of the Current State of Practice from an Australian Perspective

Theo Gerritsen, Rio Tinto, Australia
Laura Fidel, WSP, Canada
Lis Boczek, South 32, Australia
Chris Hatton, WSP, USA

Abstract

The role of Engineer of Record (EoR) was predominantly implemented in the United States and Canada, with origins in the civil engineering sector dating back to 1927, prior to the inception of the Global Industry Standard for Tailings Management (GISTM) in 2020. Since the adoption of GISTM across the mining sector, the EoR role has been adopted internationally, with countries like Australia becoming more familiar with the role. This has led to ongoing discussions in professional committee forums, comprised of both Owner and engineering consultancy groups, on the appropriate implementation of the role. The Queensland Tailings Group (QTG) held a series of workshops and discussions beginning in November 2023 and attended by over 40 Australian-based EoR practitioners from 12 Mining Engineering Consultants. The workshops were attended by Laura Fidel, who was nominated as the EoR at the time of the 2014 Mount Polley Failure. This paper discusses the role of the EoR (from an Australian perspective) against the backdrop of Laura's experience, and with input from the workshop attendees. Discussion points included:

- Australian EoR guidelines and references;
- personal and legal risk;
- EoR as a career path – risk and reward;
- EoR – quality and career development and succession;
- setting up for success;
- are mining companies employing the EoR correctly; and
- why become an EoR.

The key objective of the workshop was to listen to the people who are EoRs and ask them their views, instead of relying completely on the various standards and guidelines describing what an EoR should be. In other words, "What about me, does my opinion count?"

Introduction

A key component of the mining industry, albeit not the most glamorous, is the management of waste from the mining process. The facilities designed to store and manage this waste can range from simple to extremely complex. The absence of properly designed and managed facilities has led to a considerable number of tailings storage facility (TSF) failures across the industry on a global level, and these continue to occur with some level of regularity. It must also be recognized that these structures are ever-expanding in size – both vertically and laterally – continually raising the tailings engineering and operational bars to a whole new level (Morrison and Hatton, 2016). As such, the industry has pushed to increase the level of accountability and responsibility for those tasked with maintaining the safety and integrity of these facilities. Does it make sense to expect professionals to willingly put this onus in part on themselves by undertaking such roles when the repercussions of any degree of error seem to profoundly outweigh the advantages? An example of this is the emergence of the role of the Engineer of Record (EoR), in which this paper will summarize the opinions of several practitioners from an Australian perspective.

History of the EoR role

The term EoR is believed to have been first used in the civil works industry, related to the design of structures (buildings). It is known to date back to at least 1927 in North America. It was later codified in 1976 by AISC in their code of standard practice. The use of EoR terminology in other areas of engineering, including the design of dams and tailings storage facilities, is less certain. The government of British Columbia (BC) introduced the Dam Safety Regulation in 2000 (Government of British Columbia, 2000), which included a requirement for mining companies to employ professional engineers to certify the design and construction of tailings dams. This requirement was reinforced and further evolved following the Mount Polley tailings dam failure in 2014. This led to the creation of a formal Tailings Review Task Force and a new regulation that established the EoR role as a mandatory requirement for all new tailings facilities.

The Mount Polley tailing dam failure brought to the forefront the challenges and pitfalls of having multiple engineering firms involved with tailing dam design and was a catalyst for the development of EoR guidance that established a single responsible individual backed by an experienced firm.

The catastrophic tailings dam failure in Brumadinho in 2019 pushed further accentuated the need for appropriate action to enhance the safety of TSFs across the globe. The tragic event motivated the United Nations Environment Programme (UNEP), the International Council on Mining and Metals (ICMM), and Principles for Responsible Investment (PRI) to convene the Global Tailings Review to develop an international standard for safer management of TSFs. It was called the Global Industry Standard on Tailings

Management (GISTM) (ICMM, 2021). The GISTM effectively globalized the EoR role in 2020. Figure 1 shows a partial history of the development of the EoR role as we know it today.

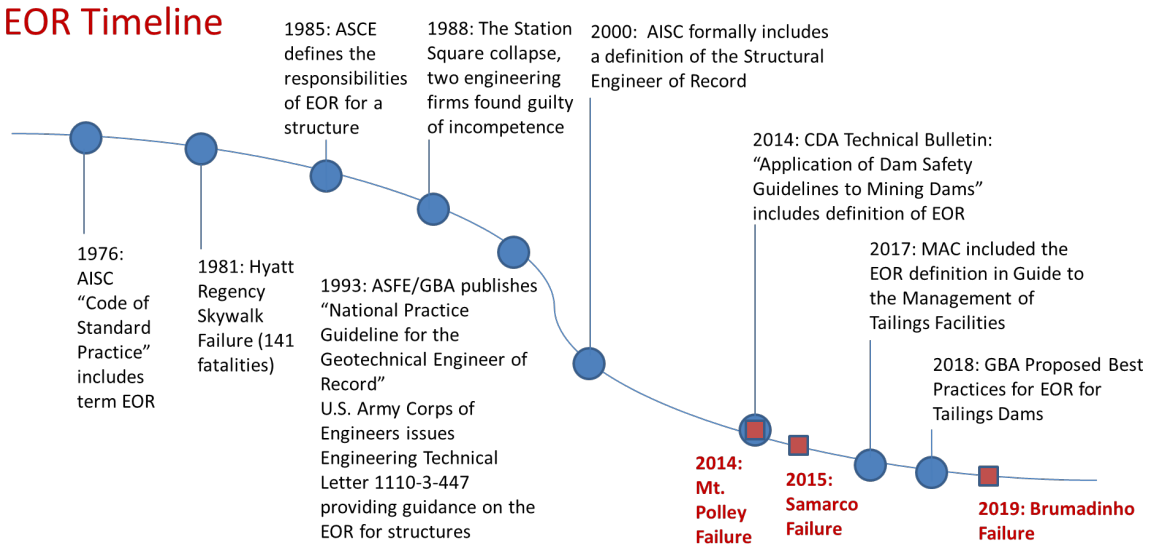

Figure 1: Abbreviated history of the EoR (courtesy of Paul Ridlen and Amanda Adams)

EoR guidelines and references

There are many guidelines and papers outlining the requirements of an EoR for the TSF governance process, with some references providing additional detail on what qualities and experience an EoR must possess. These requirements have progressed and evolved, particularly in the years following the Mount Polley failure. Specific to Australia, the Australian National Committee on Large Dams (ANCOLD) provides some guidance. The following is a list of currently published general requirements expected of an EoR for tailings dams:

- ANCOLD (ANCOLD, 2019)
    - In addition to the responsible Site Person, there should be a Responsible Technical Person assigned to each tailings dam, this person, named the "Engineer of Record" in some jurisdictions, must be appropriately qualified and experienced in the scale and type of dam involved.
- Canadian Dam Association (CDA) (CDA, 2019)
    - Experience and knowledge commensurate with the complexity and potential consequences of a failure. Typically, have at least 10 years of related experience.
    - Current knowledge of applicable regulation and good practice
    - Registration and good standing with the engineering association in the local jurisdiction.

- Engineers and Geoscientists of British Columbia (EGBC)
    - A minimum Bachelor of Science level degree but a Master of Science with specialization in geotechnical is more typical (EGBC, 2021).
    - 15 years of geotechnical engineering practice with at least 10 years in progressively increasing responsibility for tailings dam design, operation, monitoring, risk assessment, and emergency response action planning … for dams that are not complex or not very high-risk dams (EGBC, 2021).
    - 20 years or more for complex and high-risk tailings dams (EGBC, 2021).
    - Supported by a firm that has Dam Safety professionals and specialists who can provide the necessary support and oversight. The EoR cannot be a firm (EGBC, 2023),
- GISTM (GISTM, 2020)
    - Engage an engineering firm with expertise and experience in the design and construction of Tailings Facilities and for close facilities with "High," "Very High" and "Extreme" Consequence Classification that are in the active closure phase,
    - The firm nominates a senior engineer, approved by the Operator, to represent the firm as the EoR.
    - Necessary expertise, skills, and time to fulfill this role.
    - Must be competent and have experience appropriate to the Consequence Classification and complexity of the tailings facility.
- Ministry of Energy, Mines and Low Carbon Innovation (EMLI)
    - Technical expertise and experience commensurate with the complexity of the TSF or dam.

The EoR in Australia

The role of the EoR and its implementation within the respective local governance framework has varying levels of maturity, depending on the geographical location of the practitioners. The EoR, in some jurisdictions such as Canada, is a position with legal ramifications. In Australia, the EoR role is heavily associated with the GISTM governance, with little if any recognition of the role outside of mining organizations committed to GISTM implementation.

From the references summarized above, it is apparent that there is good international guidance on EoR responsibilities, and on why the role of EoR should be adopted. There is also some guidance on EoR requirements. However, when focusing on Australian and Australian-based practitioners, ANCOLD seems to be the only Australian-based/focused reference and it does not refer to EoR but to "Responsible Technical Person." The later adoption of the EoR concept by Australian practitioners and mining companies, together

with still limited guidance, may be the catalyst for the ongoing discussion in Australia on the various aspects of the role of EoR. The numerous discussions the authors have had and observed prompted the organizing of the QTG EoR Workshop in November 2023.

The Queensland Tailings Group EoR workshop

The Queensland Tailings Group (QTG) EoR workshop brought together some 40 Australian-based tailings practitioners who currently had one or more EoR commissions, or had previously worked as an EoR. Representatives from the Consulting and Owner side attended the workshop, with Laura Fidel drawing on her experience as the assumed EoR for Mount Polly to prompt the group discussions.

Laura Fidel's presentation captivated the audience and received positive praise. More importantly, her work and discussions brought to the forefront key issues that are relevant to the EoR position. The current guidance focuses on the technical aspects and qualification of the individual EoR. However, there are so many more questions that need to be answered and addressed as we move forward. Laura Fidel's presentation addressed some of these non-technical subjects including:

- Personal and legal risks.
- The EoR as a career path and the associated risks and rewards.
- The quality of the EoR, continuing development and succession.
- Setting our new EoRs up for success.
- Are Owners presently applying the EoR correctly?
- Why become an EoR?

Personal and legal risk

What is the personal risk for an engineer who takes on the role of EoR? Based on discussions at the QTG events, individual discussions among many of the Australians practicing EoR, and views shared during the November 23 workshop, the risk is too high. The experience shared by Laura Fidel during the workshop confirmed this sentiment for a majority of the participants.

Having been in the industry's spotlight for years, due to the exhaustive punitive process initiated by Engineers and Geoscientists of British Columbia (EGBC) following the Mount Polley failure, Ms. Fidel's experience sheds valuable light on the level of personal risk EoRs face. She had naïvely assumed the EoR for the Mount Polley TSF at the time of the 2014 failure. The decision was innocently made out of a sense of duty to the company in an attempt to do the right thing for the company and the Owner. She was intended to be a stopgap until more senior resources could be identified. This altruistic decision was subsequently viciously targeted by EGBC and underwent a lengthy inquiry. She shared that the investigation stage involved frequently providing supporting evidence of her professional experience as well as all

documentation related to the project, legal representation at the company's level, a day-long fact-finding interview, and being the subject of a subcommittee's findings report.

The progression to the disciplinary stage involved different legal representation, now at a personal level, retaining an industry expert to opine on her behalf, submitting multiple documents and retorts to evolving allegations, and among other things, being the subject of an intense hearing that lasted two full weeks. The formal disciplinary decisions involved the temporary suspension of her license to practice engineering in BC and mandated completion of three technical courses. However, there was a high level of risk that the disciplinary outcome could have been much more severe, involving permanent loss of her license to practice engineering and destroying her career, and costing hundreds of thousands of dollars in fines and legal costs. This process highlights the extreme measures that can be taken by governing bodies regarding the EoR role, however unnecessary or heinous they may be.

It is easy to focus on the risk to the monetary outcomes; however, it does not end there. The risk extends to having personal and/or professional reputation tainted, negative effects on mental health, and even strained personal relationships. Ms. Fidel's ability to weather the storm created by EGBC overstepping its authority is a testament to her fortitude and legacy.

Only one or two workshop attendees indicated they had some sort of personal indemnity as part of the contract they had with their employer. This brings to attention that the following issues should be called out for further discussion between the Consulting Industry, the Owner's side, and regulatory bodies and working groups:

- If and where feasible, implement a process where the Consultant protects the EoR employee from personal risk.
- Should the Owner invest in the EoR by way of secondment while in training as part of their development?
- Can limitations be set within regulatory bodies regarding the degree of prosecution applied to individual EoRs, as opposed to their consultant?

EoR as a career path – risk and reward

A topic of considerable discussion was focused on the EoR as a career path, within the Consultant organizations. The following development areas resulted from the discussion:

- The reward for undertaking an EoR role needs to start better aligning with the risk involved should there be a failure of the facility. This is especially true for the case where the EoR is taking responsibility for a facility that they have not designed. There was a widely shared sentiment at the workshop that the risk and responsibility/accountability carried by the EoR are not in proportion to the general compensation currently received by those undertaking the role. Should an EoR be paid

more than an engineer with the same experience who does not take on an EoR role? Other professions such as surgeons, aircraft pilots, rocket scientists, or lawyers are generally compensated based on the level of risk that is involved, so why is the same logic not being applied to EoRs?

- Should the Consultant provide a career path for people who want to dedicate themselves to the role of EoR, including appropriate compensation? Currently, EoR roles are fulfilled by Principal Engineers with significant experience in the design, construction, and operation of tailings storage facilities and are in short supply. This would mean that there may be a discrepancy between general Principal Tailings Engineering design work and the role of EoR.
- As an EoR, are you an Owner-facing representative of a larger team or are you the responsible person regardless of the team? The benefits for individuals are not clear.
- Is becoming an EoR career limiting? Once a person is responsible for two to three sites, there is limited opportunity for involvement in emerging projects within the business. The EoR role becomes the only focus.

EoR – quality and career development and succession

The shortage of appropriately experienced engineers to fulfill EoR roles is forcing the recruitment of engineers from other discipline areas. Will having EoRs from other disciplines be considered acceptable, considering the precedence set by EGBC regarding geotechnical experience (EGBC, 2021) and the high number of years of "related experience" that various existing guidelines include as minimum qualifications (CDA, 2019)?

These guidelines certainly suggest that internationally this would not be acceptable. In other jurisdictions, how are these engineers developed to ensure they have the appropriate understanding to perform in the EoR role? Should there be a tailings discipline associated with the National Professional Engineers Register? There need to be minimum requirements outlined and accepted internationally for the EoR as an individual and representing a company in a guidance document.

Setting up for success

For the EoR role to be successful, a trusting relationship between the Owner and Consultant needs to be established. The following comments were made during discussions around the development of trust and improving the role of EoR:

- How are (technical) disagreements approached and resolved: is there a formal process, does the Owner's side have a review and performance process in place which is factual and non-emotive, is there sufficient opportunity for recourse and feedback, and does the EoR have a method for escalation to the Accountable Executive (AE) or leadership beyond the day-to-day

reporting (i.e. Tailings Superintendent or equal)? These issues are a critical part of working on and keeping the trusted relationship growing and developing.

- How is the scope of work defined: is the scope and remittance of the EoR fully described and understood by both parties? The procurement team often has too much input into the scope, or the scope is written generically or by Owner personnel with limited understanding of the specific requirements of the operations.
- Is the EoR working with the Owner's operational and corporate technical teams as one team: there should be little or no barriers in terms of the decision-making process and where possible, the EoR should be integrated and attend the various asset technical meetings. The EoR should also have regular contact with the Owner's representatives in the Community and Social Performance and Environmental, Social, and Governance departments to ensure the impact of the TSF on said disciplines is understood, so that risk can be anticipated and mitigated. This is key to the effective implementation of the GISTM.
- Does the EoR have access to an external support network? Contact and regular communication with the Responsible Tailings Facility Engineer/Responsible Dam Engineer, Independent Tailings Review Board, AE, and Owner's subject matter expert (SME) are essential.

Are mining companies employing the EoR correctly?

The implementation of the EoR in the governance structure and adoption of the EoR role, in the Australian context, suggests experience with the following issues:

- The procurement processes must be improved on the Owner side to provide clear requirements and expectations for the role commensurate with the consequence classification of the facility. The intent of the EoR is to form a long-term partnership between the consulting firm and the mining company, not for a set period where, at the end, the role is to be re-tendered. The procurement process is often too long, complicated, and too onerous; sometimes the procurement department has undue influence on both the selection of tenderer's and terms and conditions – even though the GISTM suggests this must not be the case.
- The EoR is too often used as a design house without consideration of the role outside of facility design. The EoR has a design function, but the main purpose is to act as a safeguard on risk. To do this, the EoR needs to be involved in all areas of the operation, not just design. In some cases, the EoR company struggles to perform in the EoR role and deliver on design packages due to a lack of resources or projects not specifically related to the TSF being included in their remit. The Owner could help with the EoR workload by allowing pro-active

prioritization of design and analysis works, particularly when a facility has significant safety performance requirements to meet.

- The term EoR tends to be broadly used, but is applied universally and often interpreted in varying ways by owners, regulatory bodies, and professionals working in the industry. For this reason, both Owners and consultants can very easily misunderstand the role.
- On the Owner side – a high degree of commitment and sacrifice is expected of the EoR, and the limits of obligations are blurred.
- On the consultant's side – there is a misunderstanding of the role in terms of the required support team, and an improperly documented scope framework.
- It is important to detail the requirements, responsibilities, and obligations of an EoR and also of the owner that they are to be contracted to. EoRs should never be hired by procurement personnel or based on commercial reasoning. EoR appointments should not be subject to competitive bidding-type processes but rather selected based on the best-fit candidate to satisfy the unique requirements of the facility.
- The EoR should form a partner relationship with the Owner and be empowered to affect change in designs around the tailings storage facilities they are responsible for.
- Competitively tendering design work and introducing a Designer of Record (DoR) and EoR complicates the role of the EoR and their ability to take responsibility for a design from a different company. The EoR should be given the first right of refusal and if a DoR is required, the EoR must be involved from inception, including the choice of DoR. However, if possible, combining a DoR and EoR from different companies on the same project should be avoided.
- Terms of Reference are key to providing clear expectations of both the EoR and the Owner. The United States Society on Dams (USSD) EoR working group is currently working on developing a guidance document that looks at frameworks for terms of reference. They note: *"A term of reference (TOR) for Engineer of Record (EoR) engagement is an important document that details the requirements, responsibilities, and obligations of the engineer of record and the mine owner that engages the EoR. It is an essential component of the EoR/Owner relationship to set up the team for success."*

Why become an EoR?

It is a demanding, risky, stressful, moderately rewarded, all-encompassing, time-consuming, ever-evolving role that requires an incredibly high level of knowledge and experience. Hands up in the air for all those interested.

For some, it may be an extraordinary opportunity to grow as a professional. A successful EoR should be communicative, have a solid foundation of technical knowledge, demonstrate emotional intelligence and leadership, have operational understanding and management, regulatory comprehension, and awareness, among other attributes. However, personal and professional growth tends to prompt a limited level of drive to be in an EoR role for many. It currently seems to be a role that is performed out of necessity more than anything else. Is this the anticipated future for the role, or will transformation occur?

Conclusions from the workshop

At the conclusion of the workshop, the attendees felt that a Charter should be developed for the EoR role in Australia.

Is it possible to make an EoR a desirable role? It must be. The EoR role is increasingly becoming a mandatory requirement for mine owners to employ and adopt. The standard for the responsibilities of the EoR is also significantly increasing. An example of this is the recently updated publication of the HSRC in British Columbia, which, among other changes, puts the onus on the EoR over any other professional engineer for many sections of the code (EMLI, 2024).

So, what are the key selling points, and how will the role be positively promoted? Questions like these must be posed to every individual and company who is involved in the business of managing mine waste, from the mine owner to the governing regulatory body to the engineering consultant.

The responses make it clear that major changes are essential to cultivate a culture where developing professionals are eager and interested in becoming an EoR, and where those already established in the role have a sense of satisfaction and security. Local and global governance initiatives are gaining traction towards providing consistency in clarity regarding the expected responsibilities of an EoR; however, improvements are needed in many areas.

Areas needing further development include:

- granting individual professional legal indemnity;
- increasing compensation;
- strengthening employer and Owner support;
- providing easy access to continued training and development; and
- promoting EoR role awareness and exposure within tertiary or post-secondary education.

The EoR role for mine waste facilities should not be the role that no one knows about outside of the mining industry. They should be well-known experts that the public admires for the intense amount of effort, expertise, and responsibility they hold for keeping the public and environment safe from disaster.

Perhaps most importantly, the role of EoR and its requirements should be developed with and by EoR's and prospective EoR's and their (often) personal sacrifice should be understood and supported by the Owner.

Suggestions for further discussions, in Australia and perhaps elsewhere

Perhaps a round table or working group modeled on or led by the USSD/CDA EoR working group could help to further dissect the issues raised. This paper does not claim to represent all EoRs, nor does it claim to represent the voice or opinion of EoRs based outside Australia. The views collected in this paper are based only on the voices of the participants in the November 23 QTG workshop. The following topics are suggested for further discussion, with the Owner as well as the consultants.

- clear career path;
- legal protection/indemnity/positive;
- risk vs. reward (appropriate compensation); and
- promotion/professional registration including: increased CPD, working with universities for (advanced) courses to supplement EoR experience, supplement experience with placements in different fields/regions.

Beyond HR: Embedding GISTM Principle 11 in Leadership for Transformative Tailings Management

Johan du Toit, Data Riders Consulting & Education, Portugal
Fernando Damasio, Data Riders Consulting & Education, Brazil

Abstract

Leadership in mining must embrace Principle 11 of the GISTM (Global Industry Standard for Tailings Management) as a solemn duty, thereby avoiding the tempting and all-too-easy option of delegation to Human Resources. Principle 11 seeks to replace cultures of fear with ones of learning and open communication, in which surprises and deviations are not treated as issues to be hidden but as catalysts for early learning and knowledge sharing. This allows productive problem-solving, where issues are openly discussed and become shared experiences to help prevent unwanted events.

This shift is not just procedural, but strategic. Mining leaders are encouraged to do what only they can do. Use their positions-of-power deliberately and diligently to permit previously "undiscussable" discussions to be aired (versus "don't bring me problems … bring me solutions"). By treating unexpected events as invitations for learning, leaders can build the basis of effective tailings management. The responsibility for this transformation lies not just with support departments, but with the operational leadership at every level, showing their pivotal role in the creation of safe tailings facilities *and* a robust safety culture.

Introduction

The Global Industry Standard on Tailings Management (GISTM, 2020) was launched in August 2020 by the ICMM, the United Nations Environment Programme, and Principles for Responsible Investment. The GISTM was created in response to the catastrophic dam collapse at Vale's Córrego do Feijão mine in Brumadinho, Brazil, in 2019, which drove home the need for enhanced safety and effective governance of tailings facilities globally.

Origin of the Global Industry Standard for Tailings Management

The GISTM aims to achieve the goal of zero harm to people and the environment and applies to current and future tailings facilities. The Standard comprises six topic areas, 15 principles, and 77 auditable

requirements, and is supported by implementation protocols that provide more detailed guidance for certification or assurance and equivalence with other standards.

ICMM members have committed to implementing the GISTM by August 2023 (for extreme and very high-consequence facilities) and August 2025 (for all other facilities).

Importance of the GISTM Principle 11

Principle 11. Develop an Organizational Culture that Promotes Learning, Communication and Early Problem Recognition (GISTM, 2020).

Consider a hypothetical organization that has a culture characterized by a *lack* of learning, communication, and early problem recognition *in a complex, high-intensity industry*. That alarming state of affairs would surely be a huge red flag for all the stakeholders. Hence the pressing need to foster the positive culture required by Principle 11 (du Toit, 2022).

The problem with the GISTM, in this one case, is that while the original Standards document does a very fine job of laying out the five Requirements for Principle 11, the subsequent Conformance Protocols document (GISTM, 2021) adduces examples and clarification notes that reduce Principle 11 to an impoverished version of its original form.

Methodology used in this paper to demonstrate the "complication" with Principle 11

Content analysis is a research method used to systematically analyze texts, images, videos, and other communication materials (Wikipedia). Researchers code or label the content into categories, which allows them to quantitatively analyze patterns using statistics or qualitatively examine meanings. Content analysis practices vary across disciplines, but typically involve defining the data being analyzed, its context, boundaries, and what is being measured. The approach used for this paper is qualitative: exploring intentionality and implications behind the content.

This paper uses seminal documents (GISTM, 2020 and GISTM, 2021) to investigate whether their underlying intentions are consistent. To do this consistency check, use is made of prominent frameworks in the Human Resources domain: Ulrich's (2008) book titled *HR Competencies: Mastery at the Intersection of People and Business* and the *People-Capability Maturity Model* (Curtis et al., 2009). The relatedness, if not equivalence, of the maturity levels between the Ulrich and P-CMM frameworks has been demonstrated (du Toit, 2010), as shown in Figure 1. The evidence that the principle 11 Requirements are misaligned with the Conformance protocols is based primarily on analyzing the content between the two key GISTM documents and the precise levels-based language in the encyclopedic P-CMM (2009).

The People-Capability Maturity Model (P-CMM) Version 2.0 is a framework designed to help organizations improve their workforce practices and enhance overall organizational performance. It provides a structured approach for characterizing the maturity of workforce practices, establishing

continuous workforce development programs, and setting priorities for improvement actions. The P-CMM consists of progressive maturity levels, each focusing on different aspects of workforce management and development. By implementing the P-CMM, organizations can systematically address critical people issues and align workforce activities with business objectives, creating a culture of excellence and continuous improvement.

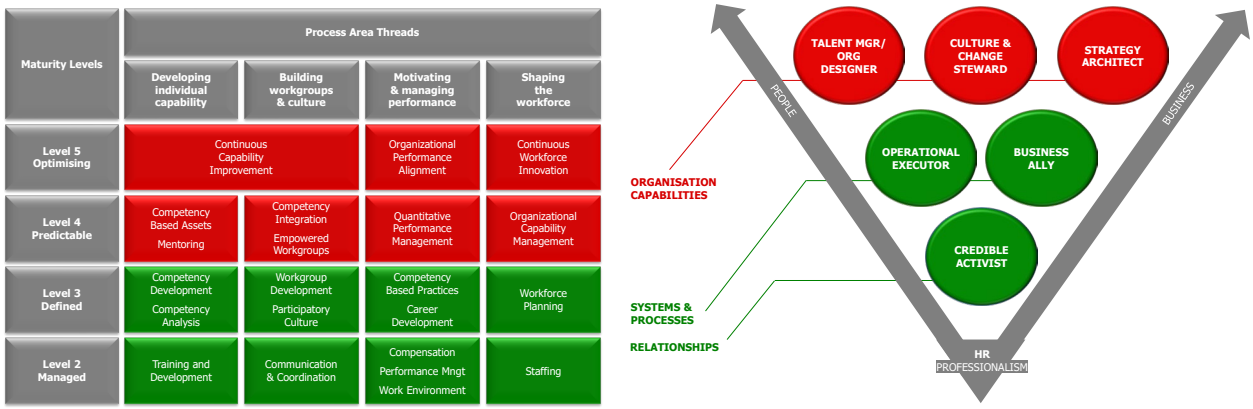

Figure 1: P-CMM 2.0 process areas (left) compared to Ulrich's HR competencies (right)

Evidence of impoverishing Principle 11 at the Conformance protocols stage

Table 1: Textual comparison between GISTM Standards and protocols statements

Req. #	Requirements of Principles 11	Examples of Conformance protocols
11.1	"Educate personnel … how their job … relate[s] to the prevention of failure"	"Training needs analysis" "Training logs"/"attendance sheets"
11.2	"Establish mechanisms that incorporate workers' experience-based knowledge into … all phases of the tailings facility lifecycle"	"Involved in development of … [systems]" "Providing training to new workers" "Incorporating the … experience they have … into action plans"
11.3	"Establish mechanisms that promote cross-functional collaboration to ensure effective data and knowledge sharing, communication … "	"Information sharing … "
11.4	" … implement lessons from … investigations and incident reports [with] attention to human and organizational factors"	"Limitations of humans" "Resilient to human error"
11.5	"Establish mechanisms that recognize, reward and protect from retaliation, [those] who report problems or identify opportunities"	"Grievance mechanisms" = partially equivalent to conformance

The impoverishment of Principle 11 at the Conformance protocols stage is likely to go unnoticed, because it has the effect of silently shifting critical work from operational executives and managers to support

functions (like HR). Consider the simple phrase "Establish mechanisms …". The danger lies in underestimating the significance contained in requirements 11.2, 11.3 and 11.5. To avoid that, it is useful to examine definitions of "establish" and "mechanism" (taken from the top entries for both words in the online *Merriam-Webster Dictionary*):

es·tab·lish

1: to institute (as a law) permanently by enactment or agreement

2: to make firm or stable

3: to bring into existence: FOUND

mech·a·nism

1a: a piece of machinery

b: a process, technique, or system for achieving a result

By applying these definitions one can fairly construct this meaning for "establish mechanisms that [x]" = "bring into existence, to make firm or stable, a process, technique or system for achieving result [x]."

Using content analysis, we show more fully in Appendix 1 that the Principle 11 requirements and the corresponding Conformance protocols are "at different levels." We use the P-CMM (People-Capability Maturity Model) 2.0 to demonstrate that the requirements from the principle employ language that is more progressed than from the examples-of-conformance (e.g., "educate" versus "training").

The People-Capability Maturity Model supports our findings that the Requirements' language is more generally located at the higher two maturity levels (Level 4: Predictable and Level 5: Optimizing), whereas the Conformance language is generally located at the lower two maturity levels (Level 2: Managed and Level 3: Defined).

What then does managerial leadership involvement in Principle 11 look like?

Since Principle 11 is about how to "develop an organizational culture … " it is instructive to consider what "levers" are available for leaders to affect cultural change (a more sophisticated perspective of organizations as *complex adaptive systems* is in Appendix 2 to expand the insights provided below).

Psychological Safety: The positive result of all-in leadership involvement

The modern work of Amy Edmondson and Timothy Clark, standing on the shoulders of giants like Rogers, Schein, Bennis and Deming (Psychological Safety – Wikipedia), has mainstreamed the urgently needed and useful concept of Psychological Safety.

Edmondson (2018), the latter-day pioneer in this field, cuts to the chase with her latest book titled, *The Fearless Organization: Creating Psychological Safety in the Workplace for Learning, Innovation, and Growth*. Clark (2020) has also made a pivotal contribution with *The Four Stages of Psychological Safety.*

This highly accessible work lays out a conceptual model of the four "stages" of psychological safety that teams and team members need to progressively move through:

1. *Inclusion Safety,* where members feel safe to belong to the team.
2. *Learner Safety,* where members learn through asking questions.
3. *Contributor Safety* ,where members feel safe to offer their own ideas, without fear of embarrassment or ridicule.
4. *Challenger Safety,* where members can question others' ideas (particularly those in authority) or suggest significant changes to ideas, plans, or ways of working.

Inclusion Safety is viable where normative practices are progressive, which is typical of many Western businesses (see the ubiquity of DEI [diversity, equity and inclusion] policies). *Learner Safety* is feasible where semantic practices are customized to link organizational performance to individual and team contributions, which is standard in most Western businesses (see the omnipresence of "cascaded" performance measurement constructs like Balanced Scorecards and OKRs).

Contributor and *Challenger Safety* are much more fragile. It is useful here to recall the definition of "political dynamics" (in Organization Learning Practices listed in Appendix 2): affect *which knowledge is valued* and how information flows. They also influence who has the *authority to make decisions and how conflicts are resolved* (italics are the authors).

Admit that power is the enabler or blocker

"Power is America's last dirty word. Rosabeth Moss Kanter (1997) from Harvard Business School was the first to brazenly state that "It is easier to talk about money – and much easier to talk about sex – than it is to talk about power ". This sentiment was reiterated over a decade later by Jeffrey Pfeffer, a professor of organizational behavior at Stanford Graduate School of Business. It seems that after a generation has passed these truisms have to be restated to not be forgotten.

In his book *Power: Why Some People Have It and Others Don't* (2010), Pfeffer argues that power is a crucial aspect of organizational life, and that understanding and navigating power dynamics is essential for personal and organizational success. He also notes that power is often overlooked or downplayed in American culture, leading to a lack of awareness and understanding of its role in shaping individual and organizational outcomes.

Seek Operating System "balance"

Marquet's book *Leadership is Language* (2020) presents compelling concepts like the Red and Blue Operating Systems, to help achieve positive outcomes in high-stakes environments.

Red Operating System:

- Referred to as "red work," this system focuses on execution and reducing variability.
- It involves strict goals, steep hierarchies, and a "prove and perform" mindset.
- It is effective in the short term for achieving results, but less adaptive in the long run.

Blue Operating System:

- Referred to as "blue work," this system focuses on thinking, decision-making, and embracing variability.
- It involves collaboration, learning, and a "learn and grow" mindset.
- It is more adaptive in the long run but may not yield immediate results.

Enable Share of Voice

Marquet (2020) also introduces the powerful concept of Share of Voice, which emphasizes distributing decision-making authority and influence within an organization. It pushes leaders to give everyone a voice in decision-making processes, rather than relying solely on their perspective.

Key aspects of Marquet's Share of Voice include:

- Distributing decision-making authority to team members, allowing them to take ownership and contribute to the organization's success.
- Amplifying diverse perspectives to inform more innovative decision-making.
- Fostering a culture of inclusivity where everyone feels empowered to contribute regardless of their position or background.
- Developing leadership skills at all levels of the organization.
- Fostering engagement by truly involving team members in decision-making.

Effective leadership should balance, and shift as needed, between both *systems* (mentioned in the previous section), by using and acknowledging that language plays a pivotal role in keeping this balance.

Conclusion

The GISTM was launched in response to the need for enhanced safety and governance of tailings facilities globally and aims to achieve zero harm to people and the environment. The GISTM has received an industry-wide commitment, with ICMM members pledging to implement the Standard for all their tailings facilities by August 2025.

There is potentially a serious misalignment between what the original GISTM (2020) standard espouses and what the later GISTM Conformance (2021) protocols seek to measure. Once this "measurement impoverishment" is recognized, it requires operational executives acting on evidence-based practices that will keep operational leaders in-the-loop, striving to:

- Create deep Psychological Safety that enables learning, innovation, and growth (Edmondson, 2018) that requires leaders to diligently address covert "power" dynamics that can make sensitive subjects "undiscussable" (Smith, 2024).
- Recognize respected academic research that shows that Organizational Learning is a consequence of collective behaviors, that depend on asymmetric power relationships.
- Embrace Marquet's practical emphasis on balancing the Red and Blue Operating Systems, where language plays a key role.
- Allow Share-of-Voice to be more equal as it is a powerful enabler in creating a more collaborative, inclusive, and effective work environment.

Appendix 1: Detailed content analysis

The analysis below is extracted from the "Evidence of impoverishing Principle 11 at the Conformance protocols stage" section of the paper and placed in an Appendix. This helps smooth the flow in the paper.

Table A1: Textual implications between GISTM Requirements and Conformance statements

Req. #	Requirements for Principles	Examples of Conformance
11.1	"Educate" => *critical thinking, problem solving and communications skills*	"training" => *specific job skills or competencies*
11.2	The relevant advanced practices for Principle 11 from P-CMM are mostly from the two upper levels of maturity ("upper half"; the red blocks in Fig. 2)	One example from "lower half" – Workgroup Development at Level 3
11.3	Relevant "knowledge sharing" for Principle 11 from P-CMM are found at Level 4 (Commitment 1 of Competency Based Assets process area)	"Information sharing" appears once in PCMM ("strategic HR management")
11.4	Relevant "lessons learned" for Principle 11 from P-CMM are more from upper levels of maturity ("upper half"; the red blocks in Fig. 2)	Wrong model of accident causation used (people-safety versus process-safety paradigms)
11.5	Highest two levels of P-CMM give the correct view of recognition and rewards (not the "outstanding (individual) contribution" mentioned in lower levels)	The lower levels (the green blocks in Fig. 2) of P-CMM are where the recognition and rewards effort is driven by "formulas" owned by HR

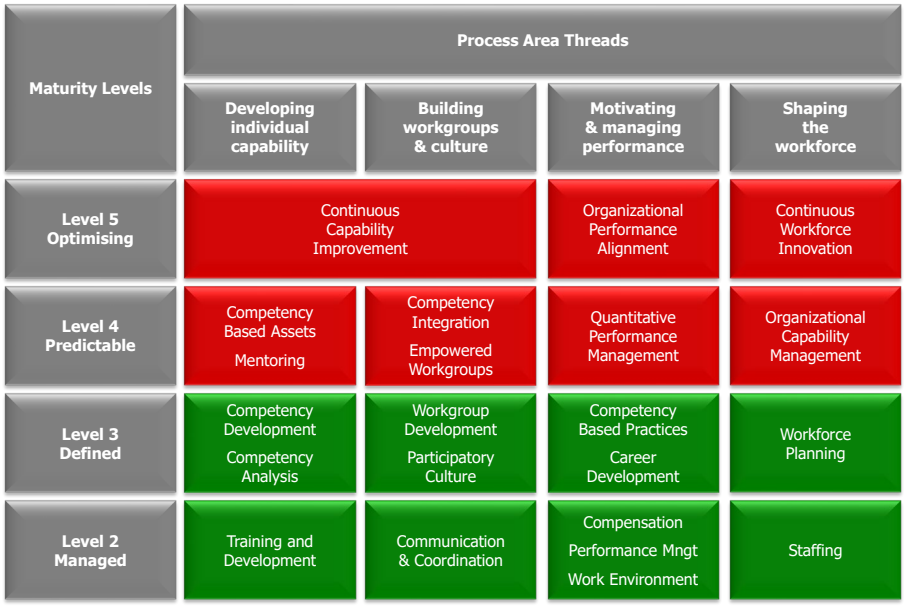

Figure A1: P-CMM 2.0 framework distinguishing lower and upper levels

Example of misalignment for requirement 11.5

"Awareness of, and orientation to, the organization's recognition and reward system" (Curtis et al., 2009). If the recognition and reward system is an example of an OLP (organizational learning practice), then its political, normative, and semantic dynamics need to be made explicit.

Table A2: Comparison of lower- and higher-maturity practices

Dynamic	Lower maturity competencies	Higher maturity capabilities
Political	"Rules of the game" = formal HR policy	"Rules of the game" = Organizational culture
Normative	"Outstanding performance" desired	"Improving workgroup performance" desired
Semantic	"High potentials," "rank-and-yank"	"Continuous improvement," "transparency"

"Recognition and rewards are made to reinforce the skills and behaviors that the organization values." The intent of the Managed and Defined maturity levels is Compliance and Conformance (Control). At the higher levels of Predictable and Optimizing it is Performance (Control plus Continuous Improvement). What a less mature "Control" organization values is different from what a more mature "Performance" organization values. With requirement 11.5 this is painfully clear. The "establish mechanisms" language seeks positive impact, by firstly, "recogniz[ing] and reward[ing] [those] who report problems or identify opportunities *for improving tailings facility management*" (italics are the authors). Secondly, the qualifier is added that these workers should also be protected from retaliation if their contributions are not welcomed, for instance by insecure management. The lofty ambition of 11.5 is to unlock the vast potential of "early problem recognition."

An indication that the Conformance protocols misunderstand this vital point, is evident from listing "grievance mechanisms" as partially meeting 11.5 and is also repeated under requirements 12.1 and 12.2. Perhaps this is due to the unfortunate sequencing of having Principle 12, that deals with whistleblowing related to potentially unlawful activities, being straight after Principle 11 that speaks of a positive, healthy organizational culture of learning, communication, and early problem recognition.

The P-CMM uses language at its lowest level of maturity (Level 2: Managed) that resonates with the language of "grievance:"

- Handling problem employees,
- Documenting and managing unsatisfactory performance.

At the highest-level of P-CMM (Level 5: Optimizing) is the process area of Continuous Capability Improvement. It has an instructive entry under Practice 15: *"The organization's workforce practices are adjusted, as needed, to accommodate continuous improvement activities by individuals and workgroups."* An example of where such adjustment may be needed is "Recognition and Rewards."

The lesson from P-CMM for 11.5 is that there is an urgent need to adjust the workforce practice of "Recognition and Rewards." The Conformance protocol examples do not have a single reference to recognition and rewards; just this lower-maturity reference to "*acknowledgement and feedback when problems and opportunities are raised."* The latter example could quite readily be provided by a system-generated email when the person raising the problem uses one of the "channels" to report the matters (since

confidentiality and anonymity are a design-feature and an option on these channels, it is hard to see how that will help with recognizing and rewarding the people doing the reporting).

Example of requirement 11.3 misalignment

"Establish mechanisms that promote cross-functional collaboration to ensure effective data and knowledge sharing, communication and implementation of management measures *to support public safety and the integrity of the tailings facility*" (GISTM, 2020) (italics are the authors). The language used in the Conformance protocols is mainly pre-occupied with "information sharing." This is the same language found in the lower-maturity P-CMM related to the process area of Communication and Coordination (Level 2, Managed). Collaboration is a more mature practice than coordination (just as knowledge management is a more advanced endeavor than information management).

The ambitions of 11.3 are not modest. This goal of cross-functional collaboration is intended to promote the safety of the public and the integrity of the critical assets.

"The organization's stated values encourage knowledge sharing between individuals and workgroups." Competency-Based assets (CBA) process area, Level 4, Predictable)

The purpose of CBA is *" to capture the knowledge, experience, and artifacts developed in performing competency-based processes for use in enhancing capability and performance."* (Curtis et al., 2009)

Example of requirement 11.2 misalignment

"To achieve … Maturity Level 4, the organization quantifies and manages the capability of its workforce and competency-based processes […]. The organization creates a culture of measurement and *exploits shared experience*." (P-CMM 2009, p.37) (italics are the authors). The intention of requirement 11.2 is relatable to the maturation to Level 4. Refer to the 11.3 example above where CBA is already covered.

The intention here is about *deliberate* processes (c.f. SECI model of knowledge management [Nonaka, 1994]) of turning workers' *tacit* knowledge (privately held) into *explicit* knowledge (a corporate asset). It is hard to see how the examples adduced in the Conformance protocols meet this standard (see Table 1). The emphasis in requirement 11.2 is "externalization" (tacit to explicit); the conformance protocol for 11.2 is closer to Nonaka's "socialization" (tacit to tacit). The latter is easier to try and verify, but like all the other examples covered before it is verifying a much-impoverished version of what the Standard intends.

Appendix 2: Culture as an emergent property of complex adaptive systems

Organizational culture change: steering mechanisms and organizational learning practices

Roger Martin's latest book, *A New Way to Think* (2022), declares that cultural change cannot be affected directly, or mandated by leaders. Instead, they should influence the way organizational members interact

and work together, through the formal mechanisms under their control ("steering," not "driving").

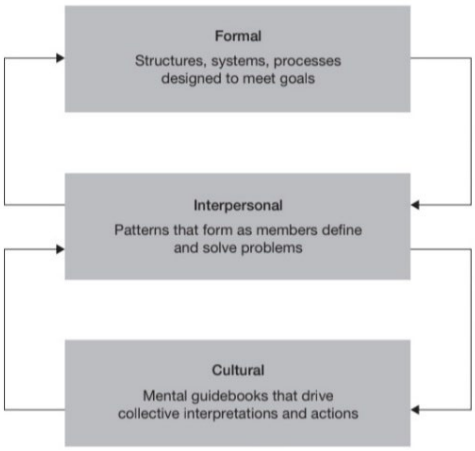

Figure A2: Martin's steering mechanisms for cultural change

Martin's pragmatic advice (from a business consultant and business school dean with over 40 years of experience) is well aligned with rigorous academic research from the Organizational Learning school. Organizational Learning Practices (OLP) – as a critical precursor for the desired organizational culture – are defined (Beauregard et al., 2015) as a set of *collectively shared practices* held by members of a given organization embedded in normative, political, and semantic dynamics.

- Normative Dynamics: the shared norms, values, and expectations that guide members' behavior within an organization. They shape the organizational culture and provide a framework for acceptable practices and routines (compare with the Helps and Hindrances of Patterson et al., 2005).
- Political Dynamics: the power structures and political interactions that occur within an organization. Political dynamics can affect which knowledge is valued and how information flows. They also influence who has the authority to make decisions and how conflicts are resolved (compare with the Bridges and Barriers of Patterson et al., 2005).
- Semantic Dynamics: the meaning and understanding of language and symbols within an organization. Semantic dynamics are about how knowledge is interpreted and communicated among members.

These dynamics interact with each other to shape the *learning environment* of an organization, influencing how knowledge is created, shared, and utilized to achieve organizational goals. This research also reveals some of the more vexing dimensions needed for change, like the issue of power and politics.

Global Industry Standard on Tailings Management (GISTM) – Some Aspects of Implementation

Marcelo Roberto Barbosa, MB CONSULTORIA MINERAL, Brazil
Lucas Samuel Santos Brasil, GWS Engenharia, Brazil
Flavia Cruz Pereira, Lm4tech, Brazil
Denise Capanema, Vale S.A., Brazil
Marina Borges, Vale S.A., Brazil

Abstract

The release of the Global Industry Standard on Tailings Management (GISTM) in August 2020 marked a turning point in the management of tailings storage facilities (TSFs). This comprehensive guide brought together a robust range of technical and non-technical themes, which was unprecedented considering the parties involved in its development. Highlighting its significance, all global mining companies that are members of the International Council on Mining and Metals (ICMM) have committed to its adoption.

At first glance, the Standard may seem complex and difficult to implement, but it is not, as long as it is viewed as a cultural transformation in the company's tailings management. This work presents some aspects of GISTM implementation in companies, highlighting the case of Vale S.A., which achieved compliance in 48 TSFs between 2020 and 2023. Through a governance framework diagram, the macro-processes of the pre-implementation phase will be discussed, suggesting ways to prepare for, achieve, and maintain compliance with the Standard. This aims to encourage other mining companies to voluntarily engage with GISTM, continuously improving processes and enhancing the safety of TSFs.

Introduction

The document "Global Industry Standard on Tailings Management" (GISTM), (ICMM, 2020), referred to in this article as the "Tailings Standard" or simply "Standard," marked a watershed moment for the mining industry in managing tailings storage facilities (TSFs) more responsibly and sustainably. It consolidated a comprehensive range of technical and non-technical themes, unprecedented in scope, given the diverse and robust documentation of guidelines and best practices on tailings already available globally.

The development of the GISTM, published in August 2020, was triggered by previous tailings dam failures, culminating in the Brumadinho incident in Brazil in 2019. Williams (2021) reinforces this initiative

by noting that the progressive raising of tailings dams has led to an unacceptable rate of catastrophic failures, resulting in deaths and environmental and infrastructural damage. The author also points out that the failure rate of tailings dams is about two orders of magnitude higher than that of water dams.

The GISTM was the result of collaboration between the International Council on Mining and Metals (ICMM), the United Nations Environment Programme (UNEP), and the Principles for Responsible Investment (PRI). This unprecedented consortium brought together a productive mix of objectives and values, creating a comprehensive set of guidelines and requirements aimed at safer management, not only in engineering and geotechnics but also in social, environmental, and governance aspects for tailings dams throughout their lifecycle, from design and construction to operation, closure, and post-closure. The Standard also stipulates that it applies to both current and future dams.

Regarding implementation timelines, the GISTM recommended that ICMM member companies implement and disclose their compliance by August 2023 for dams classified as having extreme and very high consequences. For other tailings dams, the final compliance deadline is August 2025.

For clarification, "compliance" means that the company can demonstrate the existence of systems and processes to implement all applicable requirements of the Standard without conflicting with relevant existing legislation.

Several authors have highlighted the importance of the GISTM for the industry. Romero (2023) notes that the Standard strongly emphasizes preventing catastrophic failures by promoting risk-based approaches to ensure the safety of workers, communities, and the environment. He adds that it also encourages the adoption of best practices to minimize environmental impact, and includes measures to reduce water consumption, prevent pollution, and promote rehabilitation and recovery to restore affected ecosystems. The author concludes by saying that the Standard emphasizes the importance of transparency, accountability, and stakeholder engagement, encouraging mining companies to disclose relevant information about their dams and interact with affected communities.

Sova et al. (2023) state that mine owners, regulators, and engineering consultants had already been reporting on dams, but with the new Standard, they now report at a previously unrequired or undefined level. The typical lifecycle of a dam can last from 10 to 100 years, and facilities often undergo progressive construction, keeping them active. The author also notes that complying with the Standard has been a significant challenge for the industry, requiring greater accountability from engineers and dam owners.

This work aims to present some aspects of GISTM implementation in companies, sharing the case of Vale S.A., which implemented the Standard between 2020 and 2023 for 48 tailings dams in Brazil and Canada.

About the GISTM and the conformance protocols

The GISTM (ICMM, 2020) is a document comprising six Topics, subdivided into fifteen Principles, which in turn are divided into seventy-seven auditable Requirements. Table 1 provides a summarized overview of the interrelated themes throughout the Tailings Standard, emphasizing that a significant number of them are, in some way, covered by the National Dam Safety Policy (NDSP).

Table 1: Interrelated themes of the GISTM's Topics, Principles, and Requirements

6 Topics	15 Principles	77 Requirements
1. 1. Affected Communities	1. Human Rights	4
2. Integrated Knowledge Base	2. Knowledge	4
	3. Information for Decision-Making	4
3. Design, Construction, Operation, and Monitoring of Tailings Disposal Structures	4. Planning	8
	5. Design	8
	6. Risks	6
	7. Monitoring	5
4. Management and Governance	8. Policies	7
	9. EoR (Engineer of Record)	5
	10. Review	7
	11. Culture	5
	12. Whistleblower	2
5. Emergency Response and Long-Term Recovery	13. Emergency	4
	14. Recovery	5
6. Public Disclosure and Access to Information	15. Disclosure	3

The current Standard is designed to establish a normative framework that encompasses the critical elements of cultural transformation within geotechnical teams operating tailings storage facilities (TSFs), thus proposing an integrative perspective. This approach supports the premise that organizational structures must be responsible for all interacting areas that create and sustain the teams responsible for TSFs. Uniquely, this Standard can be applied throughout the entire lifecycle of the dam, maintaining relevance and effectiveness over time through continuous maintenance processes. Additionally, one of the Standard's innovations is the customization of internal compliance and specific evaluations for each TSF, alongside external audits aimed at certification. This creates a more personalized approach and a clearer understanding of risks and compliance. Finally, the Standard requires organizations to establish new roles and responsibilities, ensuring an ongoing process that spans the entire chain of command, thereby guaranteeing

the effectiveness of corporate governance and an unwavering commitment to the safety and sustainability of TSFs as assets within the mining sector's production process.

The Conformance Protocols

The document "The Conformance Protocols" (ICMM, 2021) was developed by the ICMM and published in May 2021. This document was created in collaboration with two international consulting firms and the ICMM Tailings Working Group, which comprises professionals from 21 ICMM member companies, including the author of this article (Figure 1).

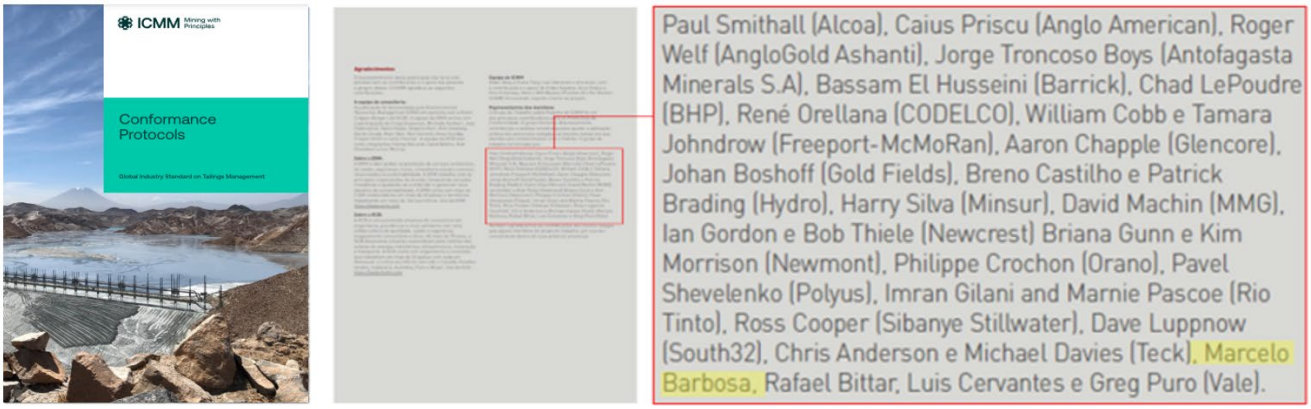

Figure 1: Acknowledgments page of the document "The GISTM Compliance Protocols." The highlighted name is that of the lead author of this paper

The primary objective of these protocols is to serve as a guide for companies and independent third parties to evaluate the implementation of requirements and confirm compliance with the GISTM. The document is in the form of checklists, with criteria on how the requirements should be assessed, and includes examples of documentation, activities, and initiatives that can be presented as evidence for the 77 auditable requirements of the Standard. It is important to emphasize that despite these guidelines, the content of the requirements should be thoroughly studied, interpreted, and understood by the teams involved in the implementation, as they encompass a wide range of disciplines and should be fully utilized to significantly aid in the engagement and integration of the teams.

Therefore, through the ICMM's compliance protocols, the Standard will help demonstrate to all stakeholders that responsible practices are being applied throughout the entire lifecycle of the company's TSFs. Finally, it is important to highlight a recommendation from this document: that ICMM member companies commit to demonstrating their compliance based on, at a minimum, self-assessments within the agreed timelines. However, these companies should engage independent third parties to conduct validation or verification as soon as reasonably possible to confirm the claims made in their self-assessments.

GISTM governance macroprocesses and aspects of implementation

The GISTM governance framework required for a successful implementation within companies, due to the unique characteristics of each organization and the diverse range of factors governing their tailings structures, suggests that there is no "silver bullet" of ready-made or ideal methodologies and frameworks. Gore and Moghaddam (2023) indicate that each portfolio of structures within a company will need its own methodology and transformation journey when adopting the GISTM. This process unfolds over time, benefiting from implementation experiences shared across the global industry, which is precisely the intention of this article.

The macroprocess diagram displayed synthesizes the strategy developed during the implementation period. This timeframe allowed for a detailed analysis and an in-depth understanding of the GISTM requirements. Figure 2 illustrates the sequence of macroprocesses and their interrelationships with the three suggested implementation phases.

It is important to note that the Maintenance Phase should operate as a circular process, where the activities for assessing compliance with the requirements are defined with some periodicity/recurrence, focusing primarily on adherence to the GISTM principles.

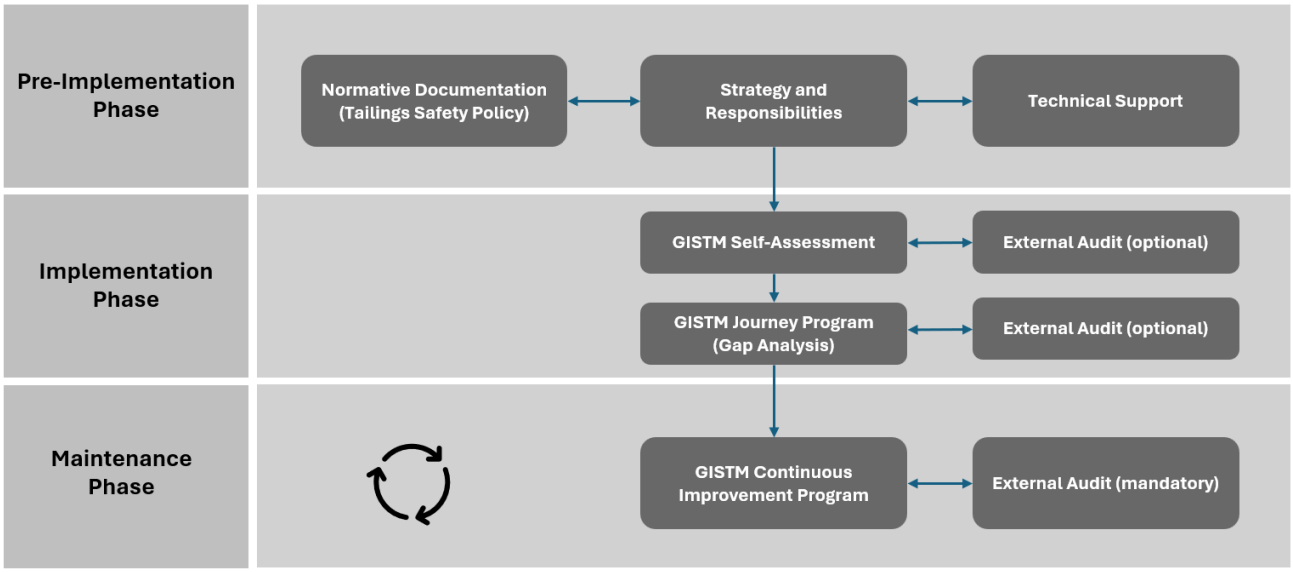

Figure 2: The three phases of GISTM governance macroprocesses: pre-implementation, implementation, and maintenance

All macroprocesses are divided into numerous processes and products. However, this article will focus solely on the macroprocesses of the Pre-implementation Phase, discussing their critical points and key aspects.

Pre-implementation phase macroprocesses of the GISTM

Experience has shown that by focusing on the three macroprocesses of this phase, if well-discussed and planned internally, companies can achieve good visibility on how the Standard will be integrated into the company's processes in the future. The macroprocesses discussed below are interdependent and do not necessarily have a defined timeframe for completion.

Pre-implementation Phase – macroprocess – normative documentation (tailings safety policy)

This macroprocess can be considered the "starting point" for implementing the Standard within the company. It is an extremely important document that may already exist internally alongside other company regulations and/or have other names, but in general, it should be developed and titled as the "Tailings Safety Policy." This document affirms the top management's commitment to responsible tailings management and the implementation of the GISTM, or it can reference another compliance standard, whether external, internal, national, or international.

This document must be signed by the highest level of the company's hierarchy and widely disseminated both internally and publicly, ensuring the necessary seriousness and credibility for employees and the market.

Pre-implementation Phase – macroprocess – strategy and responsibilities

This macroprocess highlights three points of attention to be considered:

Implementation timeline: for non-ICMM member companies, engagement with the Standard is voluntary, and therefore, this timeline is flexible and should be adjusted based on the company's needs and feasibility.

- **Case of Vale S.A.:** It took three years to achieve GISTM compliance for 48 dams.
- **Lesson:** The premise should be a realistic and feasible schedule with progressive goals. The important thing is to plan to achieve the goals gradually, creating a continuous loop of motivation for the involved teams and top management.

Human resources: the "GISTM team" should ideally be dedicated and independent of the operational teams of the dams. The benefit of dedication lies in the fact that, due to the multidisciplinary nature of the Standard's requirements, a central technical liaison is more productive and integrative. This team becomes a reference and focal point in the implementation developments and does not overburden the operational teams with new demands. This dedicated team should include at least one senior professional with expertise in mining geotechnics.

- **Case of Vale S.A.:** the GISTM team consisted of ten professionals (two full-time Vale S.A. employees, one senior and one trainee, and eight contracted from third-party geotechnics and

technology firms, including three full-time mid-level professionals, three part-time junior and mid-level professionals, and two on-demand senior professionals).

- **Lesson:** a small and dedicated GISTM team is sufficient to drive and engage the company in the implementation processes.

Financial resources: The budget to be allocated is another subject of open discussion within the company, directly related to the number of tailings structures and, obviously, the availability of funds. This will have a visible impact on three important points: the implementation timeline, the dedicated team, and the technical support, whether from consulting or technology.

- **Case of Vale S.A.:** The company opted for a long-term implementation (following the ICMM's recommended three-year period), a lean GISTM team, and a preference for developing its own technology platform for management and control.
- **Lesson:** As the timeline, team, and infrastructure can be adapted, so can the implementation budget. The key message is that it is better to start the implementation at a "low profile" pace than to postpone or not start at all.

Pre-implementation Phase – macroprocess – technical support

This macroprocess highlights two points of attention to be considered:

External technical expertise: this point addresses the need to seek external technical knowledge to support the implementation of the Standard, which can be done in three main ways:

1. **Technical consulting:** this form of support is not required by the Standard and is therefore optional and at the company's discretion, based on its need to acquire knowledge for implementation. This could involve hiring companies or independent consultants to guide the initial steps in the GISTM and/or to follow up on the implementation developments.
    - **Case of Vale S.A.:** two companies were contracted to oversee the entire implementation until compliance was achieved. One was an engineering and geotechnics company (providing support in technical and non-technical areas of the Standard), and the other was a technology and project/process management company (providing support in the digital environment for storage, management, performance indicator [KPI] control, and visibility of results).
    - **Lesson:** due to the multidisciplinary nature of the Standard and its broad themes, it is not essential to hire or assemble a large team, as discussed

above. However, acquiring prior knowledge of the Standard, at least for planning a good roadmap, is highly advisable.

2. **Independent professional:** this form of support is recommended by the Standard for result validation, which can also be referred to as verification or audit. This activity is important when the company has already begun the implementation work and decides it needs to calibrate its methodology and ongoing results, or confirm the level of compliance achieved at that point. The Compliance Protocols refer to this activity as "third-party validation" or "third-party audit," which should be conducted by a senior professional or auditor with the necessary experience, skills, and knowledge to expertly confirm the reasonableness and authenticity of the company's self-assessment claims, or to perform an autonomous audit.

It is important to note the timelines, as the Standard recommends that companies hire auditors to conduct third-party validation as soon as possible to confirm the claims of self-assessments. Subsequently, the intervals between independent audits should not exceed three years for dams classified as "Extreme" or "Very High" consequence, and five years for all others.

- **Case of Vale S.A.:** two companies were contracted for auditing at two different periods. The first round was a "calibration audit" after the first self-assessment of the dams (to analyze the methodology and the level of compliance achieved up to that point), and the second round was a "verification and validation audit" before disclosing compliance to the market (to ensure the reliability of the results).
- **Lesson:** although these calibrations, validations, verifications, or audits are not mandatory but are recommendations of the Standard, the important thing is to ensure the quality and trust in the implementation results. The best way to achieve this assurance is through an external and independent perspective.

1. **Independent Tailings Review Board (ITRB) and Independent Senior Technical Reviewer:** this form of support is mandatory according to the Standard. Several requirements, particularly those focused on risks and emergencies, stipulate that some activities, documents, and/or products presented as evidence of meeting these requirements must be reviewed by an ITRB (a group of two or more Independent Reviewers with over 25 years of experience) or an Independent Reviewer (a single professional with over 25 years of experience). The choice between an ITRB or an Independent Reviewer is at the discretion of the hiring company, which may depend on the number of dams (the larger the number, the better it is to have the opinion of a group of experts), or on the level of criticality or risk of the asset at that time, which might also require the opinion of more than one expert.

- **Case of Vale S.A.:** both forms of support were contracted.
- **Lesson:** it is important to meet this requirement of the Standard, as it is a fundamental procedure, especially for the physical safety of the dams.

2. **Digital transformation:** this point of attention addresses the promotion of a digital environment within the company, which is also at the company's discretion and can be adjusted based on the availability of human, technological, and financial resources. It is important to emphasize that these digital environments are generally scalable, starting with basic, low-cost tools and progressively building improvements and robustness. This point is sensitive and should be seen as the optimal way to organize, record, and maintain the entire governance process. Additionally, it has the potential to serve as the "calling card" for the GISTM implementation, both internally and externally, especially in anticipation of future audits.

This suggested digital transformation has at least three objectives:

- **Data registration on a corporate network:** avoid registering and handling data and information on isolated machines. Consider front-end interfaces that are more user-friendly, standardized, and include metadata. This promotes auditability, ensuring data reliability and preventing the production and dissemination of conflicting information within the company.
- **Centralized storage of data and evidence (uploads and downloads):** avoid directories on isolated and uncontrolled machines. Consider more robust repositories for digital evidence files, with cybersecurity, access control, and a backlog of changes and modifications. This aims to demonstrate the integrity of the environment end-to-end, which is important during audits.
- **Data processing, management, and disclosure:** avoid tools without error alert rules for typos and redundancies. Consider developing performance indicators (KPIs) with outputs on customizable dashboard panels, and parameterizable reports and maps.
    - **Case of Vale S.A.:** An appropriate and scalable digital environment was developed.
    - **Lesson:** A digital environment is extremely important and serves as a foundation and stimulus for cultural transformation, providing visibility of the implementation and progressive results.

Conclusion

A proposed GISTM governance framework was suggested, and the Macroprocesses of the Pre-Implementation Phase were discussed, based on the learnings from Vale S.A., which implemented the Standard and achieved compliance for 48 TSFs over a three-year period.

The main message of the discussed Phase highlights the flexibility of the GISTM implementation process for non-ICMM member companies in terms of timeline, team, and financial resources. These can be adjusted to fit any company profile, which helps to alleviate some of the apparent restrictions or complexities due to the Standard's magnitude. This serves as an invitation for other mining companies to voluntarily engage and begin their transformation journeys brought by the Standard.

Acknowledgements

The authors thank Vale S.A. for authorizing the use of the facts described from its implementation.

Risk-Based Planning of Monitoring Programs for TARPs

Richard Sisson, Geosyntec Consultants International Inc., USA
Dirk van Zyl, Independent Geotechnical Consultant, USA

Abstract

This paper describes a rational, risk-based method for developing monitoring programs and trigger action response plans (TARPs) for tailings facilities. It emphasizes the importance of the link between planning instrumentation programs and the risk assessment for the facility. The objective of the instrumentation program should be to either provide specific information regarding potential failure modes, confirm assumptions used to establish that a failure mode is not credible, or provide information that will provide significant value in the future design of similar structures. This paper describes a process that begins with identification of hazards and an assessment of the expected performance and risks for a facility. It continues with a description of the design of the monitoring program so that it is effective and avoids the pitfalls the authors have observed.

Introduction

In 2000, Martin and Davies wrote:

> *"Many tailings dam failure modes are preceded by warning signs that can be readily detected well in advance with a proper dam surveillance program. If the warning signs are promptly detected, and appropriately appreciated, time is available for the implementation of remedial measures. For many of these detectable failure modes, a good dam surveillance program, in concert with emergency preparedness and response plans, represents a highly cost effective, proactive risk management tool relative to the options of a failure or an unnecessarily excessive and expensive degree of design conservatism. It does not however provide a means of safely stewarding a facility whose design and or construction is flawed. A number of failure modes that do not provide readily apparent advanced warning signs and it is important to recognize that these failure modes cannot be properly addressed using the observational method and cannot be appropriately addressed by a dam surveillance program. The only way to deal with*

these latter failure modes is to devise appropriate design and construction measurements."

Almost 25 years later, this philosophy remains prevalent. Trigger action response plans (TARPs) are considered good practice for detecting warning signs of failure modes for tailings storage facilities (TSFs) and are required by some regulators. The purpose of a TARP is to define a range of trigger levels and the associated responses to be initiated if a trigger level is reached. The concept is a useful one, and TARPs have been applied with considerable success for managing hazards in related endeavors, such as pit slope engineering.

Good TARPs have prerequisites. They must:

1. be based on a thorough identification of failure modes;
2. not be so conservative that numerous false alarms occur;
3. not be unconservative resulting in undetected adverse behavior; and
4. identify an appropriate path for escalation of response.

Despite widespread acceptance of the value of TARPS, published case histories describing successful detection of adverse behavior are rare, largely because of the potential impacts of negative publicity. The authors have reviewed multiple projects where TARPS were flawed because triggers were exceeded without implementation of the documented action plan, or where response plans were unnecessarily triggered because the link to an identified failure mode was illogical.

Even well-respected references such as the *Tailings Management Handbook* (Finke Morrison, 2022) provide dubious advice. In the chapter on monitoring, an example of a red slope stability trigger is vibrating wire piezometer data indicating a factor of safety less than 1.3. The chapter indicates "a red trigger indicates conditions close to failure and evacuation should occur." Yet using relationships between factor of safety and annual probability of failure based on actual engineering projects and developed through quantified engineering judgement, Silva et al. (2008) estimate an annual probability of failure of 10^{-4} for a structure with a factor of safety of 1.3 if it is designed and built using best practices for engineering and construction. In the absence of other indicators, the calculated safety factor of 1.3 is not a clear indication that the structure is "close to failure."

This paper describes principles for designing instrumentation programs and establishing effective TARPs while avoiding the pitfalls previously described. While none of these principles are new, it is hoped that this review reinforces principles for improved process for developing TARPs for TSFs. In this paper, the process is organized as follows:

1. Identify hazards and potential failure modes.
2. Identify warning signs that can monitored to provide warning of adverse behavior.

3. Establish actions that could be undertaken to mitigate a potential failure if it began to develop.
4. Determine values of the behavior that would trigger escalating risk management.
5. Select instrumentation to obtain the necessary measurements. Establish how the instrumentation data should be analyzed and reported.
6. Identify responsibilities when a trigger value is exceeded.
7. Document the entire process in the OMS.

The following sections of the paper describe this process.

Failure mode identification

The design of instrumentation should be based on an evaluation of hazards, identification of failure modes, and an assessment of the likelihood that the failure mode will develop. Each failure mode is examined to determine warning signs, and surveillance measures are identified considering the probability that the mode will develop. Much attention has been given to methods assessing risks for tailings dam. Discussion and evaluation of methodology are beyond the scope of this paper, but Figure 1 illustrates the concept described by Martin and Davies (2000). In practice, detailed event trees are needed to link warning signs to failure modes.

Once failure modes and their warning signs are identified, it is essential to separate brittle and ductile failure mechanisms. Brittle failures should be treated using the precautionary method, not the observational method, and are outside the scope of this paper. Although instrumentation may provide advance warning of adverse behavior preceding brittle failures and would typically be considered prudent, monitoring should not be relied upon to significantly reduce the risk of such failures. However, ductile failures may be addressed using the observational method, providing that monitoring is planned and implemented with sufficient diligence that adverse behavior is detected and remediated before it has unacceptable consequences.

In addition to identifiable failure modes, the monitoring program must consider "unknown-unknowns:" the inherent risk (generally very low), that is associated with every dam no matter how apparently well-designed and safe it may be (Dunnicliff, 2017; Stateler et al., 1995; Martin and Davies, 2000.) Two common sources of this inherent risk are construction defects and unidentified weak foundation units. Unless foundation conditions are very competent and consistent and the structure is very robust, and depending on the consequences of failure, instrumentation should be considered as one prudent defense. The size of a likely failure provides an initial guide to instrument density. However, a monitoring program does not eliminate the need for an adequate characterization of the geological environments of deposition in the dam foundation and carefully controlled construction.

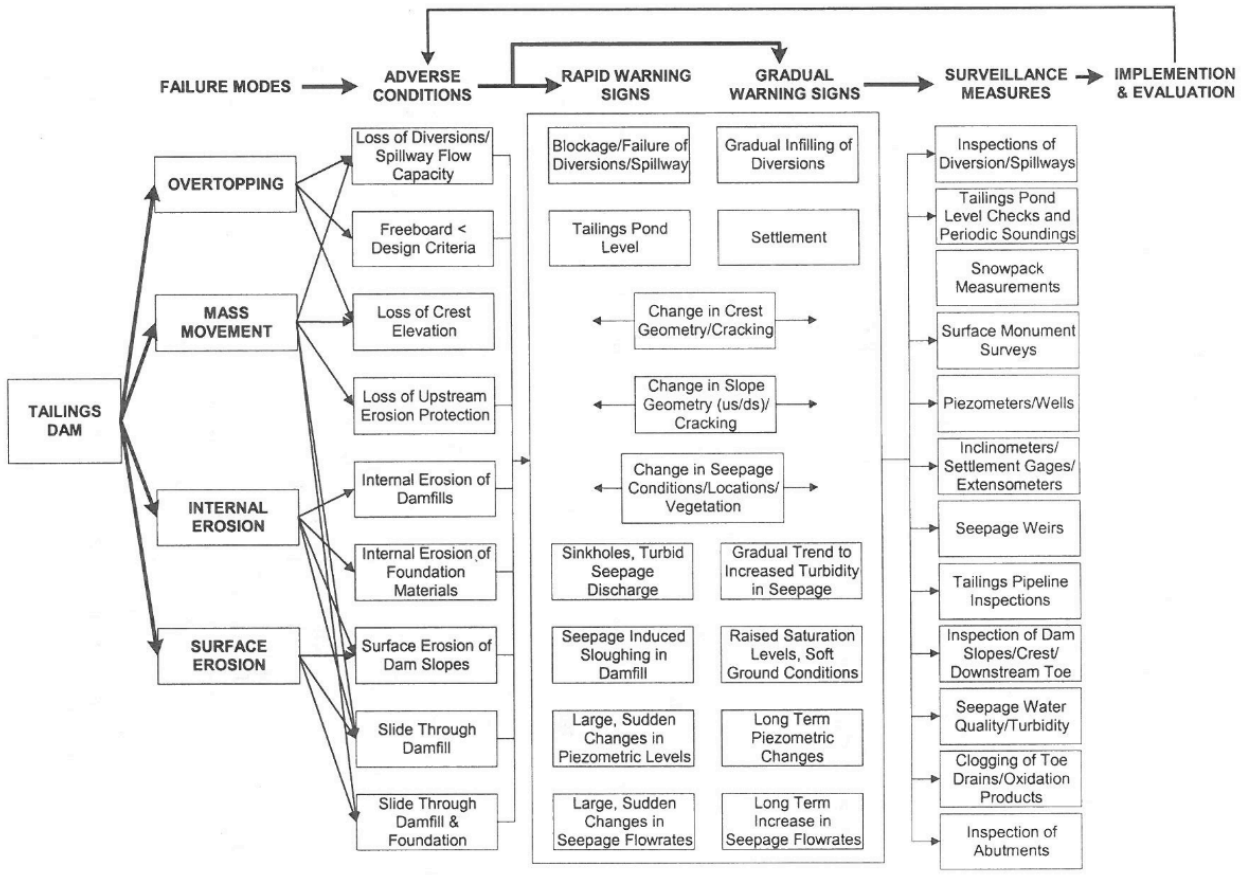

Figure 1: Tailings facility failure modes and observations (Martin and Davies, 2000)

Warning signs

Warning signs should be developed based both on analyses performed during design to predict behavior and on experience gained from thorough understanding of applicable case histories. Expected performance should be defined during the design, as well as key engineering parameters impacting that performance. The uncertainty surrounding those parameters and implications for behavior at the upper and lower limits of those parameters should be evaluated and described. Concepts for contingencies and opportunities that could be implemented if performance deviates from expected should be cataloged. The value of visual observation as warning signs should not be overlooked, as USBR practices have resulted in relating visual observations to the majority of key monitoring parameters (Stateler et al., 1995).

Response plans

Establishing TARPS requires identifying escalating actions if performance deviates from expectations. Actions that might be undertaken in response to instrumentation include:

- Rereading or checking instruments promptly, depending on whether they are read manually or remotely.
- Notifying the Responsible Tailings Facility Engineer (RTFE) and the Engineer of Record (EOR) and increasing monitoring frequency or density, and adding additional types of instrumentation.
- Notifying the Operating Manager and the Accountable Executive.
- Developing construction plans for conceptual mitigative actions.
- Implementing a mitigation action.
- Preparing to evacuate.
- Evacuating.

However, it is generally undesirable to have separate triggers for each response, because in many cases it is difficult to predict performance with sufficient resolution to assign meaningful trigger levels to each action. The authors have seen response plans with up to six trigger levels. While appreciating the value in establishing a structured, systematic response plan to mitigate human error in stressful situations, the authors believe that this objective must be balanced against the flexibility needed to address unique conditions that exist at each site. To provide this flexible crisis response, it is important to have an emergency call-out procedure with sufficient levels of notification to rapidly mobilize leadership. In addition, the range of foreseeable responses should be clearly and succinctly documented so that they are available in a crisis.

Recognizing that regulatory requirements may mandate including specific actions (e.g., evacuation), a three-tier system (green, yellow, and red) would cover the following three conditions:

Green

The structure is performing as planned.

Yellow

The structure is or may not be performing as planned, but an immediate release of fluids is unlikely. The EOR should be involved, monitoring intensity should be increased, and TARPS should be reviewed and, if appropriate, revised. If the condition persists, detailed mitigation plans should be developed. The condition should be reported to the Operating Manager and Accountable Executive (AE) as part of regular reporting.

Red

Intervention is necessary because, without it, a release of fluids is not unlikely. Mitigation must be implemented, and the Operating Manager and AE should be notified immediately. It may be necessary to activate emergency response procedures.

Trigger values

Trigger values typically must be established for the common failure modes of overtopping, piping, and instability due to deformation, but it is often difficult to do so for deformation and piping. Both theory and experience, if available, should be considered. Other failure modes such as surface erosion and subsurface subsidence may also need to be addressed on a site-specific basis.

Triggers for notifying external stakeholders should be carefully developed so that communication protects the public but is not unnecessarily alarmist. The system needs to be carefully designed so that it has a very high probability of detecting imminent failures but a very low probability of false triggering; however, it is not clear that such a system yet exists. Transparency with stakeholders is a key principle of the Global Industry Standard for Tailings Management (GISTM), and appropriate measures should be developed for communicating the performance of tailings facilities. However, false alarms for evacuation will unnecessarily erode public trust and may result in some stakeholders ignoring true emergency situations if they occur in the future. Ideally, response plans for triggers prior to implementing the emergency action plan should consider installing additional instrumentation to better inform the decision as to whether to implement the ERP, especially when the trigger requires a response of evacuation.

Overtopping

Overtopping is a failure mode where trigger values usually can be logically established using analyses. The risk of overtopping can be evaluated using hydrologic and hydrotechnical analyses, with due consideration of the uncertainty in estimates of low frequency high intensity events.

Piping

Piping failures are relatively uncommon for tailings dams, in part because a beach above water often exists at the upstream face of the embankment. The results of the risk assessment should include identification of defense mechanisms against piping and evaluation of how they might not function effectively. If these systems do not function as intended, the TARP should be triggered. Examples would be a beach that does not meet design assumptions or a drain that does not function as intended. While seepage patterns and volumes can be predicted analytically, stratigraphic details may result in significant but localized differences between model predictions and field observations that may not be detected with a reasonable number of instruments. Thus, visual monitoring is a key defense against piping.

Peck (2010) describes practical aspects of piping, and several piping incidents for water dams, and recommends practices for monitoring seepage that provide extremely useful guidance in identifying warning signs and developing monitoring plans for risks related to piping. Gradients or measured flows that change suddenly or are higher than assumed in design would trigger an increased intensity in

monitoring and perhaps mitigation. Seepage that is turbid or exits the structure where it is unfiltered would typically trigger mitigative actions or even implementing the emergency response plan.

Instability

It is often not possible to establish meaningful trigger levels for instability using empirical data for tailings dams, because it is unusual to have sufficient data of adverse performance applicable to a specific site. Initial triggers may be based on a change relative to historical levels, but interpreting monitoring data to predict the likelihood of failure due to instability remains challenging. Methods such as inverse velocity (Fukuzono, 1990) have been developed but experience indicates they need to be calibrated for specific materials being considered. Only a few failures have been publicly documented in detail and most have been brittle undrained failures. As a result, few if any sites exist where case histories provide an appropriate analogy for drained deformation, except for clay shales at residual strength. This situation is different from pit slopes, where the design philosophy is to accept failures that do not threaten human life or create unacceptable impacts on mine costs and production. As a result, instability is not uncommon, and often sufficient site-specific performance data exists to establish appropriate trigger action levels. Documented performance from other sites may also be useful.

Like the use of empirical data, theoretically based analyses have limited value for establishing trigger levels. For most well-designed dams, the design avoids plastic behavior. Thus, stress-deformation models typically predict only elastic deformation (either linear or non-linear), which does not directly create a credible failure mechanism. State-of-the-practice static stress-deformation models do not provide information on time-dependent movements, which are more likely to indicate a failure risk than initial response to loading. Apparent time-dependent deformation is frequently observed in deformation monitoring records for tailings facilities, but it cannot usually be determined what percentages of the deformation can be attributed to elastic response during ongoing construction, changes in details of loading (e.g. upstream tailings properties and geometry), pore pressure dissipation in fine grain soils, time-dependent plastic or viscoelastic deformation, and instrument noise. Triggers also should not be overly reliant on safety factors calculated using limit equilibrium analyses, as there is not a unique correlation between safety factor and probability of failure (Silva et al., 2008).

While neither empirical nor analytical approaches are sufficient to establish meaningful action levels for instruments used to monitor piping and instability, they are useful to develop triggers for major action (mitigation, public notifications) to address ductile instability when combined with expert judgement. In the absence of other indications of adverse behavior such as visual observations, triggers involving major actions such as constructing mitigations or public notification should not be activated solely based on:

- a single instrument;
- instruments that do not directly measure deformation such as piezometers; or
- calculated safety factors.

Instead, sufficient measurement and visual observation of deformation should be initiated when the response plan is first triggered to provide multiple warnings of progressing instability, possibly in conjunction with refinement of the next level TARP. Even with the addition of expert judgement, the level of uncertainty associated with this methodology should be recognized. The industry would benefit from research and pilot testing of instrumentation designed specifically to quickly warn that a loss of fluids is occurring in tailings facilities.

Selection of monitoring instruments

In his classic book on geotechnical instrumentation, Dunnicliff (1988) wrote: "Every instrument on a project should be selected and placed to assist with answering a specific question: if there is no question, there should be no instrumentation." Instruments should be established either to provide specific information regarding potential failure modes, or to confirm assumptions used to establish that a failure mode is not credible.

In planning the scope of a monitoring program, the probability should be evaluated that adverse behavior will develop, instrumentation will detect it, and failure will be avoided. The evaluation should recognize that deformation monitoring of tailings dams often does not achieve the accuracy of which the instruments are capable. (This could probably be improved by using careful design and installation, plus experienced staff who are well trained to follow thoughtful procedures.) Modifying the TSF design should be considered if the probability of adverse behavior is significant, and it is costly or impractical to implement and staff monitoring programs that have a high probability of detecting the behavior and providing warning with sufficient time for successful mitigation.

If the structure will perform adequately for the full range of input parameters and opportunities for design optimization are not significant, instrumentation is only justified by the potential for "unknown-unknowns or by the value of monitoring data for improving future designs." Not enough attention has been paid to monitoring "unknown-unknowns." If construction defects and foundation defects do not create a credible failure mode (likely a rare situation), it could be argued that the probability of unknown unknowns is so low that only visual monitoring is needed for instability.

USACE (2020) provides reasonably up to date summary of available instruments and procedures for use. Specific issues that should be considered in selecting instrumentation are:

- Selection should consider the sensitivity needed to detect performance deviations.
- Routine manual surveying will result in variability (noise) that prevents interpreting anything except long-term trends, unless very high-quality survey methods are used.
- Manually read inclinometers are capable of accuracy within several millimeters and of providing a displacement profile with depth. However, they require diligent, well-trained staff using consistent and appropriate procedures for installation, raising the casing, and regular monitoring. If the instrumentation designer is not confident that these conditions exist, alternate instrumentation may be preferable.
- GPS receivers can provide measurements with sub-millimeter accuracy when appropriate interpretation methods are applied to deal with issues such as changes in atmospheric conditions. However, experience shows that the level of diligence and expertise necessary to do so is often not achieved for tailings facilities. Details of GPS methods and capabilities for monitoring tailings dams must be thoroughly researched during the design process.
- The challenges associated with monitoring downstream construction also appear to be under appreciated. Either the instruments must be incrementally raised as fill is placed around them, or they must be removed and replaced during fill placement. In either case, the instruments often do not capture deformation during fill placement, when it is most likely to be important.
- For high tailings dams, buckling due to casing downdrag must also be considered for inclinometers and piezometers.

These issues can be minimized but not eliminated by planning, procuring, installing, and monitoring instruments with meticulous attention to guidance provided by Dunnicliff (1993, 2017), but mine operators are often reluctant to expend the money and effort, and Engineers of Record are not always insistent.

Implementation of monitoring program

Not infrequently, data from tailings management facility is less precise than the fundamental capability of the instrument, likely due to sub-optimal installation and monitoring procedures. Challenges for the mining industry in conducting surveillance programs are summarized in Table 1, adapted from Martin and Davies (2000). More recent assessments of challenges in monitoring tailings facilities indicate they have not been entirely overcome (Clarkson et al., 2020).

Table 1: Monitoring challenges in the mining environment
(adopted from Martin and Davies, 2000)

Challenge	Requirement
Constructed and operated by organizations whose focus and expertise are in mining, not building dams.	Operations personnel require training, support, and commitment from corporate to mine management and operations levels
Mining must be economic to continue operation. Tailings seen as cost center.	Tailings dam owners must resist the inevitable temptation to cut back on surveillance programs in favor of devoting more resources to profit centers. Resources for surveillance must be independent of cyclical business environments.
Tailings management in general and dam surveillance in particular are not career paths for miners.	Need continuity and clarity in communication between site and Engineer of Record. Procedures need to be documented to facilitate staff turnover

Instrument installation

A "golden rule" described by Dunnicliff (2017) for monitoring tailings facilities is that *"Tasks should be assigned to the people who have the greatest motivation to achieve high quality data."* In many cases, this is the EOR or Responsible Tailings Facility Engineer (RTFE). Current practice, however, is that instrument installation is either performed by the construction contractor or by a specialty subcontractor. The priority in the procurement process should be selecting a well-qualified contractor, not price. If a bidding process is selected, specifications and drawings must be prepared that may include details on the required type of instrument, the installation locations, the qualifications of the installation personnel and their supervision, the method and frequency of reading, environmental concerns, and the payment method (USSD, 2013).

Written procedures should be developed for the installation of monitoring instruments. Documentation of installation procedures is important and should include the procedures for installation as well as the steps necessary for operation (i.e., troubleshooting concerns, connection to data loggers, etc.). Documentation should include the technical requirements of the instruments, calibration requirements, installation details, and servicing requirements and methods (USSD, 2013).

For downstream construction, careful thought should be given to procedures for raising the instruments as construction progresses. One issue is that compaction around the instrument is difficult, and the consequences of a local loose zone around the instrument should be considered. Just as importantly, if the instrument cannot be read during loading, important data may be missed.

Data acquisition

Consistently acquiring accurate data is essential to successfully implementing a TARP. Data can be gathered manually, through automated data acquisition systems, and by documented visual observations. While automated data acquisition systems reduce the potential for human error, errors due to factors such as damaged or mis-identified leads and incorrect calibration factors can and do occur. It is essential to have

trained staff regularly and diligently observing site conditions. Not all instruments are readily automated.

Considerations for manually read instruments are:

- readings should ideally be performed by the same individual using the same equipment;
- the details of procedures are important and need to be clearly documented;
- staff turnover is almost inevitable, so succession planning and training programs are important; and
- sufficient resources must be available to deal with non-routine issues, such as anomalous readings and damaged instruments, so that instruments are re-read promptly when unusual readings are recorded and essential instruments are repaired or replaced promptly if damaged.

Data reduction and interpretation

Once data is collected, deviations from previous readings should be identified within 24 hours so that the instrument can be re-read promptly if anomalies exist. Machine learning may provide opportunities to enhance and streamline this anomaly detection. Once the data is considered reliable, data analyses and presentation can be delegated to junior staff, but it is important for data to be interpreted by experienced staff who understand potential failure modes and design of monitoring program.

Responsibilities

A RACI chart and a notification matrix should be developed for each trigger point to define roles and notification processes. The roles and responsibilities for "red" triggers should be developed working with the teams for mine emergency response and external stakeholder communication and should be endorsed by the accountable executive.

Documentation

Requirements for documentation during the design and implementation of the monitoring program have been described. This documentation should be incorporated into the Operations, Maintenance, and Surveillance Manual. An auditing program should be considered to confirm that implementation of the monitoring program is consistent with the Manual and follows best practices, and to identify whether areas for improvement exist.

Conclusion

While the principles for developing monitoring plans for tailings facilities have been well described going back at least as far as Dunnicliff (1993), implementation must be improved. Literature and the authors' experience indicate that the keys to establishing effective TARPS are:

- The starting point should be a thorough risk assessment that identifies failure modes in detail and associated warning signs for the potential failure mode.
- Establishing TARPS for brittle failure modes may not significantly reduce risk and should be carefully evaluated.
- Logical TARPS are often difficult to establish for many TSFs because documented instances of adverse behavior are rare for analogous situations and analytical models frequently do not capture the complexity of soil behavior.
- The response plan should be appropriate for the severity of the triggering behavior. Once a plan is developed, it should be followed meticulously. Excessive caution should be avoided, but false positives can damage credibility.
- The "achievable" accuracy of instruments is sometimes not achieved. Careful attention should be paid to the procedures for installation and monitoring of instruments. These procedures should be well documented. Staff need to be trained to understand the potential failure modes, the use of the instruments for detecting failures, the use of the procedures, interpretation of the data, and response to the results. Succession planning and training programs are essential to managing staff turnover.

References cited in this paper provide details. Although not referenced here, the U.S. Federal Energy Regulatory Commission also provides detailed information on risk assessment and dam instrumentation. The concepts described by Stateler et al. (1995) are described in further detail in publications available from the U.S. Bureau of Reclamation. Designers of surveillance modes would benefit from studying literature describing failures unrelated to tailings management facilities and the psychology of decision making and risk management (e.g., Kahneman, 2012; Taleb, 2021).

TAILINGS AND MINE WASTE 2024

Application of USACE LifeSim to the Feijão Dam B-1 Tailings Storage Facility Failure of January 25, 2019

William Johnstone, Spatial Vision Consulting Ltd, Canada
Jesse Morrill-Winter, US Army Corps of Engineers, USA

Abstract

Interest in methods and models that estimate potential life loss consequences for tailings storage facility (TSF) incidents and failures has become more prevalent in the last few years. Consequences estimation models such as the US Army Corps of Engineers' (USACE) LifeSim simulator are regularly used to analyze risks posed by water dam and levee systems; however, only a few studies have explored how LifeSim can be applied to the TSF life loss consequences estimation problem. On January 25, 2019, the Feijão Dam B-1 Tailings Storage Facility (TSF) at Minas Córrego do Feijão mine in the State of Minas Gerais, Brazil, failed catastrophically, releasing a devastating downstream mudflow that inflicted extensive damage to buildings and infrastructure, and caused a historic 270 fatalities. In the summer of 2022, the Risk Management Center (RMC) of USACE initiated the Córrego do Feijão Dam B-1 Tailings Dam Failure Case Study to explore how consequences simulators could be used to analyze historic TSF failures and to provide insights into how life loss might be estimated for these types of events. The study goals were to: 1) investigate how LifeSim V2 can applied to TSF failure events and incidents; 2) identify important similarities and differences between water dam and tailings dam failure events; 3) identify strengths and weaknesses in current loss estimation methods; 4) show how LifeSim outputs can be used to classify proposed, active, inactive, and decommissioned TSFs; and 5) identify potential near-term modifications to the LifeSim methodology and simulator, and also longer-term research needs. The results of this study confirm that LifeSim can indeed inform TSF life loss consequences studies. Possible modifications to current methods are proposed, including adjusting building strength characteristics to account for the physical properties of the tailings and introducing evacuation behaviors calibrated to industrial populations.

Introduction

Interest in the capability to estimate potential life loss consequences for Tailings Storage Facilities (TSF) has become more prevalent within the international dam safety community. LifeSim is an agent-based model developed by the US Army Corps of Engineers' (USACE) to estimate potential life loss and direct

economic damages due to water dam and levee failure events (USACE RMC, 2024). However, there is currently only a very small number of application studies that have applied LifeSim to the TSF life loss consequences estimation problem.

On January 25, 2019, the Feijão Dam B-1 Tailings Storage Facility (TSF) at Minas Córrego do Feijão mine in the State of Minas Gerais, Brazil, failed catastrophically, releasing a devastating downstream mudflow that caused a historic 270 fatalities. The Feijão Dam B-1 event provided an important opportunity to demonstrate how LifeSim can be used to analyze a historic TSF failure event, to show how agent-based simulation methods can be used to estimate life loss for these types of events, and to demonstrate how this approach could be used to inform consequences estimation and risk assessments for proposed, active, inactive, and decommissioned TSFs.

In the summer of 2022, the Risk Management Center (RMC) of USACE initiated the Córrego do Feijão Dam B-1 Tailings Dam Failure Case Study. The primary goals for this study were to: investigate how LifeSim V2 can be applied to TSF failure events; identify important similarities and differences between water dam and tailings dam failure extreme flooding and failure events; identify strengths and weaknesses in the current LifeSim methodology and simulator; show how LifeSim outputs can be used to classify TSFs using the Global Industry Standard on Tailings Management (GISTM) (ICMM and UNEP, 2020) and Anglo American's Consequences Classification of Structures (CCS) standard (Anglo American, 2019); and identify potential near-term and longer-term research needs to enhance the applicability of these types of models.

USACE Feijão Dam B-1 LifeSim validation case study

Methodology and timeline

The Feijão Dam B-1 LifeSim Case Study followed an iterative development process in which successively more detailed, representative, and calibrated models of the event were designed, developed, and assessed. Project work began in August 2022 and was substantially complete by January 2024. Two types of model were developed: an event validation model, which attempts to re-create the historic event using LifeSim, and a process validation model, which uses the USACE Modeling, Mapping and Consequence (MMC) Production Center's Standard Operating Procedure (SOP) to estimate potential consequences, assuming that a failure has yet to occur (USACE MMC, 2022).

The first type of analysis asks, "Will our consequences tools give us results similar to what actually took place?" and the second type asks, "If we did not know what happened, would our current approach get us there?" Four tasks were typically performed within each iteration of the validation work: 1. Planning and experimental design; 2. Data discovery and compilation; 3. LifeSim model development; and 4. Reporting and feedback.

History and failure of Córrego do Feijão Dam B-1

The Córrego do Feijão Iron Mine started its operations in 1956 through Companhia de Mineração Ferro e Carvão, and the first production at the facility began in 1963. In 1973 the mine came under the control of Ferteco Mineração, followed by Vale since April 27, 2001. The mine operated 24 hours a day, 7 days a week. It employed 613 direct employees and a number of third-party contractors who worked in three shifts, one of which was six hours and two of which were nine hours (Assembleia Ligislativa do Minas Gerais, 2019; Government of Brazil, 2019b; Robertson et al., 2019; Secretaria de Estado de Meio Ambiente e Desenvolvimento Sustentável and Governo do Estado de Minas Gerais, 2018).

Figure 1 presents a simplified layout of the southern portion of the Vale mine and the primary downstream impact zones where the Population at Risk (PAR) were located. The Feijão Dam B-1 TSF is shown at the upper right.

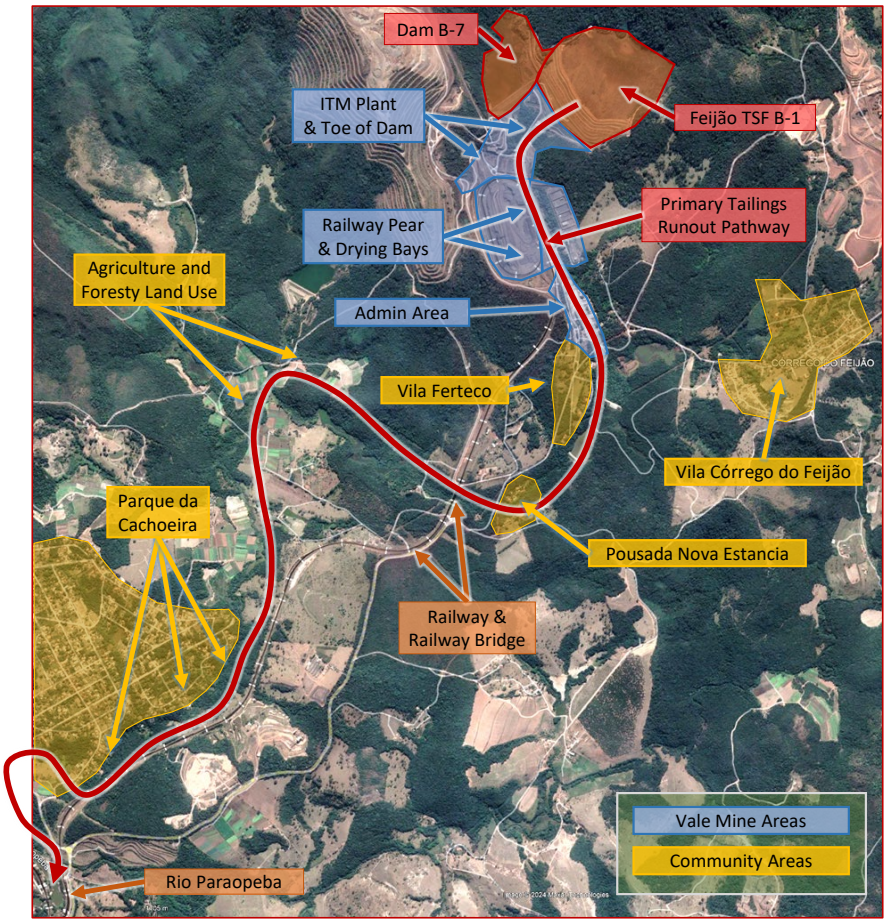

Figure 1: Extent of the primary downstream impact zone from Feijão TSF B-1 to the Rio Paraopeba, and the primary locations of the PAR

The primary purpose of the structure was to dewater and store the tailings from a processing plant called the ITM, where crushing and ore concentration was performed. The starter dam for TSF B-1 was

constructed in 1976, the final raise was constructed in 2013, and tailings disposal ceased in July 2016 (Robertson et al., 2019). At the time of its failure, Dam B-1 did not have a supernatant pond.

Key occupied locations immediately downstream of the TSF included the area below the toe of the dam, the ITM processing plant, the drying bays, the materials storage/transfer/railway area, and the administration area (all shown as blue fill). Downstream communities and locations of interest include Vila Ferteco, Vila Córrego do Feijão, the Pousada Nova Estancia resort, agriculture and forestry land use, and the community of Parque da Cachoeira (shown as yellow fill). Other key locations are the railway right-of-way and bridge crossing, and the confluence of the tailings flow pathway with the Rio Paraopeba.

On January 25, 2019, at approximately 12:28 p.m. local time, Dam B-1 failed, releasing a catastrophic mudflow that travelled rapidly downstream. The initial failure surface extended across much of the breadth of the dam, and the collapse of the slope was complete within ten seconds. While the dam was extensively monitored using survey monuments along the crest of the dam, inclinometers, ground-based radar, piezometers, and other instruments, Robertson et al. (2019) observe that none of these methods detected any significant deformations or changes prior to failure. An estimated 9.7 million cubic meters (Mm^3) of material, representing approximately 75 percent of the stored tailings, flowed out of the dam in less than five minutes (Robertson et al., 2019). The primary impact zone extended 10 km from the dam down to a confluence with the main channel of the Rio Paraopeba.

The primary outflow pathway of the tailings is indicated on Figure 1 with a simplified red line. While the full extent of the impact zone continues beyond the river confluence much further down the Rio Paraopeba river channel, the extent shown here is the primary zone of interest for understanding the exposed PAR and the life losses for the historic event. Rana et al. (2021) observe that the initial tailings outflows moved as a debris avalanche that achieved a peak velocity of 28 m/s (~101 km/hr) with a flow depth of 30 m. Approximately 700 m downstream, the tailings runout transitioned to a high-energy debris flow moving at approximately 18 m/s (~65 km/hr). Simulated maximum flow depths for structures located below the toe of the dam and then downstream to the railway bridge ranged from 25 m down to 10 m.

Most sources report the observed life loss (*N_LL)* as 270 individuals; however, since two of those victims were pregnant, some sources list the total life loss as N_LL = 272 (Assembleia Ligislativa do Minas Gerais, 2019; Passos and Quierati, 2023). While detailed estimates of the PAR were not reported, or statements about the size of the PAR were either incomplete or considered to be not credible, key sources such as Passos and de Freitas (2021) indicate that detailed lists of the full set of PAR (survivors and victims) were developed, possibly down to the occupancy of individual industrial and community structures, outdoor areas, and vehicles. This study recommends that future researchers should locate and use these datasets so that even more detailed consequences validation work can be performed.

Data discovery, assessment, compilation and indexing

The research approach used in this study was based on an earlier Life Safety Model validation study performed by Johnstone et al. (2003) for the Malpasset Dam failure. These methods were updated for the Feijão Dam B-1 case study. The types of data these studies require include a Digital Elevation Model (DEM) surface, TSF runout model, road network, buildings, Emergency Action Plan (EAP), and outcome data such as the observed losses of structures and people. Fortunately, extensive forensic investigations had been conducted by government agencies and research organizations, which means that there were many credible sources. A paper by Lumbroso et al. (2021) and an available non-Newtonian HEC-RAS hazard model of the event developed by Gibson et al. (2022) also helped the study team to develop a more complete understanding of the severity of the hazard within the different downstream zones. Key data discovery and management activities included:

- Google was the primary research tool. Documents and websites were translated from Brazilian Portuguese into English using Google Translate, and news videos were translated using YouTube.
- Key GIS sources were also consulted including: OpenStreetMap, Esri's Living Atlas, Google Maps, NASA, European Space Agency, Government of Brazil GIS websites, and satellite imagery.
- Important sources included the Brazilian Federal and State government agencies, news outlets, university researchers, and international agencies. The materials were compiled at three geographic scales: macro (the whole extent, simple maps, high-level), meso (regional and local land use and ground cover down to collections of buildings and outdoor areas, GIS "polygons"), and micro (detailed GIS points/lines/areas, individual roads, buildings, vehicles, people, destinations).
- The full body of PDFs, MS Office files, GIS files, photos, videos, etc. encompassed 90+ primary folders, 1,300+ files and 15.3 gigabytes of disk storage.

Experimental design of the LifeSim model simulations and alternatives

After completing the data discovery phase, the study team iteratively developed an experimental design for the event and process validation models. Guidance was provided by the US National Institute of Standards and Technology (NIST, 2024). As shown in Table 1, three validation groupings were developed: Event Validation, Process Validation, and Model Verification. A total of fifty-nine alternatives were created, grouped into twelve simulations that focused on key goals of the study. Key aspects of the design included:

- LifeSim's default stabilities for building objects were modified to explore differences between the physical properties of water dam and tailings runouts. Four building strength calibrations were used: 100% (the default settings for water dams); reduced building strength to 75% and 50% of default values to reflect the potential for more severe impacts of higher density tailings outflows

(i.e., extreme damage to a structure and the potential for high hazard life loss is more likely at lower depth-velocity products for tailings flows); and 150% strength (i.e., much stronger than for "water" to assess model sensitivity to stronger structures. The set of four strength calibrations (150%, 100%, 75%, 50%) were used in most of the Event and Process analyses.

- For Event Validation:
    - Model sensitivity variations included: 1) assess whether losses increase if the PAR takes more time to mobilize after initial awareness; 2) model structures as two-story buildings to assess whether sheltering-in-place with additional vertical height can reduce losses; 3) shift LifeSim's high hazard life loss fatality rates higher by 5% and 10% to reflect the observation that tailings appeared to pose more extreme hazards to buildings, vehicles, and people than water; 4) assess sensitivity to the most extreme possible (100%) loss rate; and 5) vary the starting locations and quantity of the employees and contractors within the Vale operations and administration areas.
    - A set of loss mitigation sensitivity variations were also developed: 1) calibrate the protective action initiation times for employees and contractors to reflect their emergency preparedness training so that they respond much faster than community PAR to the approaching tailings flows (i.e., within five minutes, now called a "Fire Drill" calibration); 2) calibrate all PAR (industrial and community) so that everyone in the impact zone responds immediately using the Fire Drill calibration; 3) adjust building locations to assess sensitivity to starting positions; and 4) explore the potential reduction in losses if an early warning could have been issued two to six hours before the moment of breach initiation and TSF failure.
- For Process Validation:
    - USACE's MMC SOP was applied using two types of warning: **Minimal Warning**, in which the community warning and mobilization process starts zero to two hours before failure, and **Ample Warning**, in which warning and mobilization is started two to six hours before failure.
    - A set of "tailings volume" alternatives were also created to model a set of three TSF outflow scenarios that show how consequences can be estimated as a function of a structure's height and storage volume at various stages of an asset's lifecycle. Two additional breach outflow and runout scenarios of 66% and 33% of the historic outflow volume were developed using HEC-RAS. This provided three breach simulations: 100% (the historic event), 66% and 33%.
- Model Verification is a special case with one alternative that was used to confirm that the team had created an Evacuation Route System (ERS) model in LifeSim that correctly reflected Vale's Emergency Action Plan (EAP) for TSF B-1 (Vale and Walm Engenharia, 2018a, 2018b).

Table 1: LifeSim/Feijão Dam B-1 experimental design: simulations, alternatives, key properties

Validation Group		Simulations		Alternatives	Key Properties
Group	Name	Group	LifeSim Name	#	
1. Event	Event Validation	1 Event Validation	*B1_Evac*	4	Friday, January 25, 2019, 12:28:24 PM Local Time. The majority of simulations consider four stability criteria settings: 150%, 100%, 75% and 50%
	Validation Sensitivity	2 Slower PAR Response	*B1_Evac_Slow*	4	Investigate if losses could be higher if the PAR took much longer to mobilize before trying to evacuate
		3 Two Story Structures	*B1_NumStories*	4	Investigate potential value of shelter-in-place / vertical evacuation
		4 Vary Fatality Rates	*B1_5% shift*	4	Shift High Hazard fatality rate curve higher by 5%
			B1_10% shift	4	Shift High Hazard fatality rate curve higher by 10%
			B1_100% Loss Rate	4	Set High Hazard fatallty rate curve to always 100% loss
		5 Vary PAR Size and Location	*B1_PAR_Sensitivity*	3	Uniform PAR: Rather than concentrating the PAR, allocate them uniformly at other structures within the mine area to explore whether losses are sensitive to starting locations. Large PAR: Model a much larger number of industrial PAR as reported by one news agency.
	Assess Mitigations	6. Fire Drill Vale	*B1_Evac_FireDrill*	4	Calibrate protective action response by Industrial PAR (employees and contractors only) using "Fire Drill". These industrial PAR mobilize to 100% within 5 minutes.
		7. Fire Drill All	*B1_Evac_FireDrill_All*	4	Calibrate protective action response by Industrial (employees and contractors) and Community PAR using "Fire Drill". All PAR mobilize to 100% within 5 minutes.
		8. Move	*B1_AdjBldgLoc'ns*	1	Adjust building locations to explore sensitivity
		9. Early Warning	*B1_EarlyWarn*	4	Warn PAR 2 to 6 hours before failure.
2. Process	Process Validation	10. MMC SOP	*B1_MMC_SOP*	6	PAR are allocated for 2:00 am (02:00) and 2:00 pm (14:00). The Vale mine is staffed 24x7, and residential areas have more PAR at nighttime than for daytime.
		11. Vary Tailings Volumes	*B1_100%_Volume*	4	Calibrations are similar to "Event Validation". The only difference is the released volume of tailings.
			B1_66%_Volume	4	
			B1_33%_Volume	4	
3. Verify	Model Verification	12. Verify Road and Trail Network	*Verify_RoadNetwork*	1	Verify correct evacuations along the Road and Trail network pathways to the destinations defined in Vale's PAEBM (EAP)

Preparation of key LifeSim model inputs

This section provides a brief description of the development of the primary data inputs used to create the LifeSim alternatives:

- **Key Sources:** Examples of key sources include the Robertson et al. (2019) expert panel report, a book by the journalist Arbex (2022), post-disaster investigations and support by Brazil's Federal and State of Minas Gerais legislatures, ministries and agencies (Assembleia Ligislativa do Minas Gerais, 2019; Government of Brazil, 2019a, 2019b), reports from media outlets (e.g., Globo, 2019), journal papers by Lumbroso et al. (2021) who developed a post-failure model of the event using the HRW Life Safety Model and by Passos and de Freitas (2021) who describe the immediate post-failure response and longer-term work by the firemen of Minas Gerais to locate and recover the remains of the victims, and work by the Instituto Medico Legal in Belo Horizonte to organize, identify, and return these remains (da Rocha et al., 2022; Quierati, 2019) and to determine causes of death (Araujo et al., 2022).

- **Basemaps and Satellite Imagery/Ground Cover and Land Use:** Web-based sources such as Google, Esri, and OpenStreetMap (OSM Foundation, 2024) were used to provide before and after base mapping and imagery of the full extent of the impact zone and surrounding region.
- **Tailings Dam Breach Analysis (TDBA) Hazard Runout Models:** Four breach outflow and runout models of the event were identified by this study: a pre-failure model developed by Walm Engineering to inform EAP development (Vale and Walm Engenharia, 2018a, 2018b), post-failure models developed by Lumbroso et al. (2021) and by Gibson et al. (2022), and more recent work by Adria et al. (2023) to investigate the properties and arrival times of the runout downstream to the Rio Paraopeba. This study used the HEC-RAS model developed by Gibson et al. (2022) as the 100% (i.e., "historic") event. As noted above, two additional 66% and 33% volume hazards were also developed.
- **Structures and Outdoor Areas:** Structures and outdoor areas located in and around the tailings runout zone were compiled starting with a baseline dataset from Lumbroso et al. (2021). More structures, outdoor areas, and details were then added using pre-failure Google and Esri satellite imagery, and OSM basemap sources. Multiple structure datasets were created to model variations in population sizes and distribution, number of stories, stability criteria and structure location. Four population allocations were used to account for variations in the PAR: population model 1 estimates the final Event PAR size and distribution; model 2 estimates a much larger PAR based on information provided on the day of the failure; model 3 distributes the event PAR more uniformly across the mine administration area; and model 4 uses the USACE's production-level method which varies PAR by time of day.
- **Population:** Two types of population were developed for the area in and surrounding the Vale mine: an "industrial PAR" comprising Vale employees and contractors who were working onsite, and a "community PAR" to represent people located in the impact zone outside of the assumed mine property boundary. Estimates of the number and location of industrial PAR were developed iteratively using many sources. Estimates of the community PAR assumed a nominal number of individuals who occupied their homes at the time of failure. Estimation of the PAR at Pousada Nova Estancia was determined using the list of victims combined with news items and narratives in Arbex (2022).
- **Evacuation Route System (ERS):** Development of the road and trail network started with a downloaded copy of the OpenStreetMap dataset. This dataset was extensive, detailed, and provided a very useful basemap. Additional GIS editing effort was required to ensure that the network model had correct nodal connections at street intersections. This created the need to add a model verification alternative (#59) so that a zero-hazard model could be run to confirm that evacuating

PAR moves correctly along the roadways towards their target destinations. This single ERS dataset was used in all the event and process simulations.

- **Emergency Planning Zones (EPZs) and Destinations:** A GIS polygon layer was created to define the EPZs that are used to vary the community warning and evacuation times. This allowed the LifeSim modelers to set up different ranges of warning times. A new calibration called "Fire Drill" was created to simulate the rapid protective actions of well-trained industrial PAR at the Vale mine site. A related GIS points layer was created to define the set of target evacuation destinations outside of the impact zone. This was based on Vale's emergency action plan design (PAEBM) (Vale and Walm Engenharia, 2018a, 2018b).

Results: historic event simulations

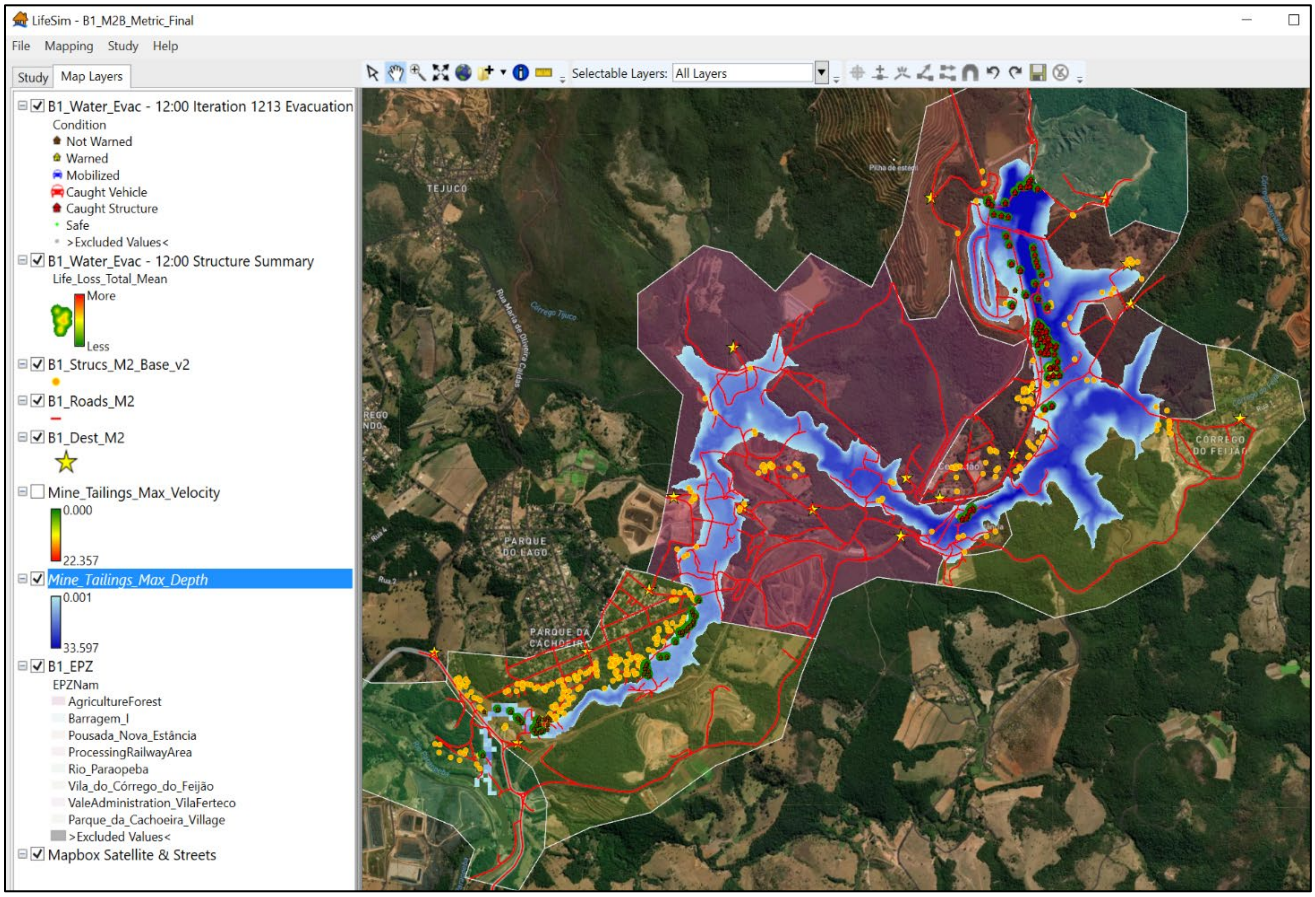

Figure 2: Event validation map for Alternative #2: B1_Water_Evac

Figure 2 presents an example consequences map for one alternative that includes a basemap satellite image, the road network, the tailings outflow maximum depth, building loss or survival, and life loss outcomes. Figure 3 presents a LifeSim whisker diagram, which provides summary statistics for the total estimated life loss for the 100%, 75% and 50% stability calibrations. The observed historic life loss of

N_LL = 270 is indicated in all the whisker diagrams using a vertical red line. Each of the alternatives have uncertainty bands that encompass the historic life loss, and each whisker plot presents the minimum, quartiles, mean, median and maximum. The blue bars indicate the 25% to 75% quartile boundaries. In general, the central tendency of most of these estimates fall below the observed historic value of 270 lives lost.

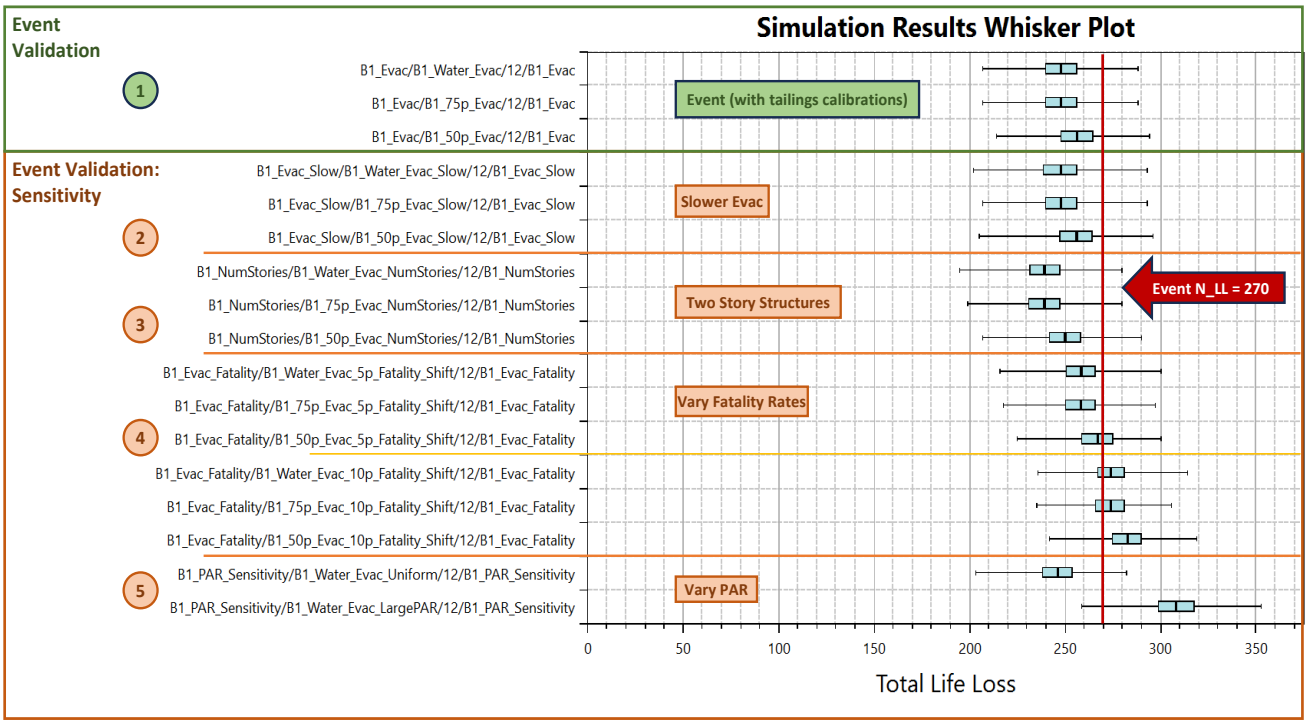

Figure 3: Historic event validation simulations: LifeSim consequences whisker diagram

The assessment of slower evacuations by the PAR did not greatly increase the losses, which suggests that even with self-mobilization, the PAR would be unable to react quickly enough to reduce losses. Modeling the availability of a second story to allow for vertical evacuation also did not reduce losses significantly, which suggests that a shelter-in-place protective action strategy would not have been effective for this event. The shifting of fatality rates by 5% and 10% did indeed increase the life loss distributions marginally so that the central tendency more closely matches this historic event. This might provide some support for the question as to whether outflows from tailings dams are more dangerous to the PAR than outflows from water dams.

The sensitivity of losses to a more uniform allocation of the PAR across the Vale mine site and administration were also not very high, which suggests that the starting locations of the PAR would have had minimal influence on loss and survival outcomes. This is another possible indicator of the extreme severity of the tailings outflows. The Large PAR sensitivity runs were used to explore a news report which

suggested a much larger population at risk within the impact zone. The simulation results suggest that if this higher estimate of the exposed industrial population at risk was correct, then LifeSim would also estimate much higher life losses than the observed value.

Finally, the assessment of variations of building stability parameters indicates that life losses are relatively insensitive to these calibrations. This suggests that the extremity of the flow depths and velocities within the mining operations and administration areas were so high that the LifeSim life loss algorithm was already "maxing out" to yield very high life loss estimates. Reducing the calibrated strength capacities of buildings, vehicles, and people did little to further increase the estimated losses.

Results: MMC SOP process simulations

USACE relies on a consistent production level approach to support its Dam Safety Program by building dam breach consequence models. The MMC is responsible for establishing the standard production level approach that all dam breach modeling efforts follow. The MMC SOP uses two warning scenarios: a minimal warning scenario which samples a uniform uncertainty distribution about the hazard identification time from -2 hours prior to breach through +0 hours at the time of breach, and an ample warning scenario, which samples from -6 hours prior to breach to -2 hours prior to breach.

Both warning scenarios allow for an increased opportunity time for PAR to take protective actions and evacuate to safety (USACE MMC, 2022). Figure 4 presents the LifeSim life loss whisker diagram for these cases. The scenarios model 2:00 a.m. and 2:00 p.m. scenarios. The industrial PAR is located in the mining operation 24-7, and a larger community PAR was assumed to be located at home at nighttime. The plotted results all have central tendencies and uncertainty bands that are well below the historic observed loss, the minimal warning losses are higher than for ample warning, and the upper limit of the 2:00 a.m. event approaches the historic observed loss.

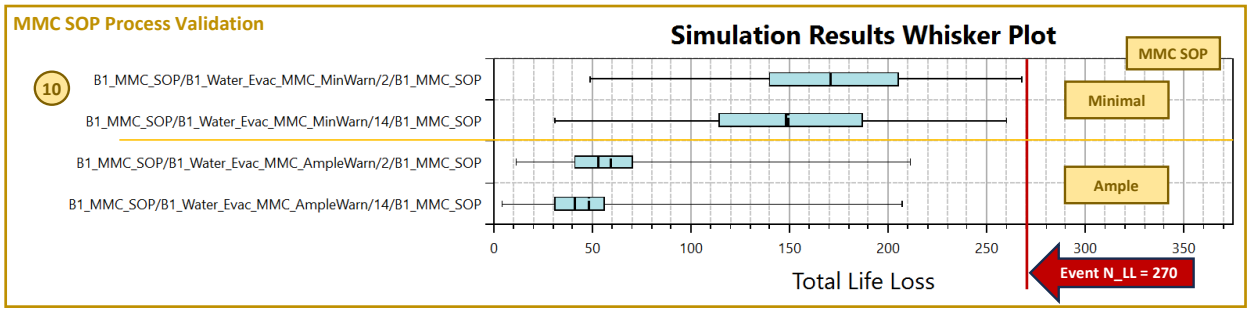

Figure 4: MMC SOP simulations: whisker diagram for minimal and ample warning

An important aspect of the historic event is that a very large number of the industrial PAR were in the cafeteria and the arrival time under minimal warning was so fast that more than 90% of the PAR in that zone could be exposed to the tailings runout. The additional warning time provided under the MMC SOP

ample warning scenario can substantially reduce the number of PAR exposed to the tailings and exhibits a wider variation in outcomes with the central tendency greatly reduced towards N_LL = 50.

The sensitivity of life loss to the volume of breach outflows was also investigated. The results demonstrated the expected reductions in the sizes of the exposed PAR and of life loss as the outflow volumes declined. Building stability calibrations also had a clear influence on the life loss outcomes at the lowest flow scenario (33%). This supports a recommendation that the physical effects of tailings flows on structures, vehicles, and people should be studied further.

Summary

The Feijão Dam B-1 Tailings Dam Failure can be viewed as an industrial disaster with very high mortality rates for the employees and contractors. It was also a societal disaster with many community members and tourists killed. At the macro scale, the observed life loss was N_LL = 270, the total exposed population is estimated to be N_PAR = 418, and the estimated gross mortality rate is F_LL = 65%. This is a very high loss rate. The loss of the industrial PAR below the TSF and in the administration area dominated the life loss consequences. The losses at the Pousada Nova Estancia resort were also severe. Further downstream, the town of Parque da Cachoeira had the highest community exposures but the lowest life losses and mortality rates.

Only self-awareness, immediate evacuation, and a few post-failure rescues saved lives. Important gaps remain with the data used to characterize the location and quantities of PAR and life loss at the micro-scale level (e.g., at individual structures and key outdoor areas such as the "railway pear," drying bays and administration area below TSF B-1, and further downstream in Parque da Cachoeira). It should be possible to eventually gain access to more detailed records so that these uncertainties can be further reduced.

Conclusions and recommendations

The Feijão Dam B-1 Tailings Dam Failure case study successfully demonstrated how LifeSim can be used to develop a useful model of this historic event. Most of the event validity life loss estimates encompass the observed consequences. The study also showed how USACE's MMC SOP can be applied. It was possible to characterize the PAR for a range of location types (e.g. residential, industrial, agricultural), for variations by time of day, to estimate life loss for a range of TSF breach outflow scenarios, and to explore how variations in EAPs and community preparedness can influence outcomes. The MMC SOP simulations appear to correctly characterize the range of possible consequences, with the central tendency of the Ample Warning scenarios falling well below the actual losses, as would be expected, and with the Minimal Warning scenarios presenting more extreme consequences that in some cases approach the observed extreme event. While the study confirmed the strengths of the LifeSim simulator and methodology, and no fundamental

gaps were found, modifications and adjustments to existing methods could increase the value of the simulator for modeling TSF failure and runout events. This includes:

- Develop a better understanding of how tailings flows affect buildings, vehicles, and people via mechanisms such as adhesion, fouling, and deposition. Examples include more building damage, loss of transport (vehicles cannot move, vehicles stall), impacts on pedestrians, and compromised first-responder rescues (deposited tailings become barriers to emergency vehicles).
- Investigate how object stability calibrations can be adjusted to account for the physical properties tailings flows, and whether there is also a need to adjust the mortality rate curves.
- Add the "Fire Drill" Protective Action Initiation (PAI) response pattern to represent well-trained industrial PAR.
- Since the Feijão Dam B-1 failure is only one of four types of Tailings Dam Breach Analysis event identified by the CDA's 2021 Bulletin, the LifeSim methodology (and possibly the simulator) may need to be extended to also support modeling TSF failure events that have both a supernatant pond and liquefiable tailings.
- Finally, given the extremity of the Feijão Dam B-1 Tailings Dam Failure event, it will be important to study other TSF incidents and failures with different characteristics such as: larger communities, larger PAR, the potential for earlier detection and warning, medium- to lower-intensity tailings flows, longer downstream runout distances, lower life loss rates, and successful evacuations.

Acknowledgements

The study team extends sincere thanks to Jason Needham, Woody Fields, and Paul Risher of USACE RMC for their leadership and support, to Stanford Gibson of USACE HEC for developing the HEC-RAS Feijão Dam B-1 TSF failure runout model, and to the USACE LifeSim consequences estimation working group.

Abstract

After mine tailings dam failures, the flowing material often consists of a mix of water and multiple solid phases with different sediment size classes, organic components, chemical solutes, metals, and numerous sediment types in the dam itself. In turn, the high-speed flow can entrain soil from the existing terrain and, under low energy conditions, can deposit or stop altogether.

To determine the areas that could be impacted by tailings, it is critical to utilize models that consider rheology formulations that correctly represent the dam materials and tailings, whether dilute or dry. Also, if conditions require, the model should be able to incorporate the interaction of the tailings flow with existing water bodies such as water reservoirs or rivers.

In this paper, we present a practical application of the RiverFlow2D MT two-phase model for tailings dam risk assessments to the Córrego do Feijão tailings dam near Brumadinho, Brazil, that include rheological formulations applicable to non-Newtonian fluids representing initially dilute tailings but also those originating from dry stacks. The model considers the variability of the soil characteristics in the initial terrain and tailings as well as how fluid properties such as density, viscosity, and yield stress change in time and space as the materials flow and interact with the terrain soils and other water bodies.

The application shows that using a rheological formulation that does not adequately represent the tailings flow would lead to erroneous runout distances. The results highlight the importance of considering an appropriate rheological formulation for tailings deposits and the dynamic interaction of tailings with their surrounding environment. This paper may be of interest to professionals involved in assessing risk and mitigation measures related to tailings dam breaks.

Introduction

Flows of high-density mine tailings are one of the most challenging and difficult to assess gravity-driven flows in environmental processes. In this kind of flow, the fluid in motion consists of a mixture of water and multiple solid phases of different natures, such as different sediment size classes, organic materials, and heavy metals, moving rapidly downstream over steep terrain. Typically, the slurries and debris are considered highly solid-laden fluids, in which the density of the mixture can be more than two or three times the water density, and the bulk solid phase represents 40 to 80% of the flow volume (Iverson, 1997). Tailings flows lie can include hyperconcentrated flows and dry materials avalanches (Hungr et al., 2001). Most of the numerical models reported for highly solid-laden flows use a single-phase approach, neglecting the mixture density in the shallow-flow mass and momentum conservation equations (Murillo and García-Navarro, 2012). Two-phase approaches consider the depth-averaged mass and momentum conservation for the liquid and solid phases separately (George and Iverson, 2011). Note that some tailings flow models depict two layers of different flow behavior, such as upper alluvial sediment flow and an underlaying layer of uniform material mud flow. These models, inaccurately called two-phase models, establish a non-physically based interaction between the layers and therefore cannot be considered realistic two-phase models, and are not tested against experimental results and do not show real event data.

Erosion and sedimentation

The mass exchange between flow layer and the erodible bed involves complicated physical processes, and the understanding of the theoretical basis remains unclear. Experiments in large-scale channels (Iverson et al., 2011) and field observations of real events (McCoy et al., 2012) indicate that the entrainment volume in steep beds can be of the same order of magnitude as the initial volume mobilized. Tailings flows can gain significant mass and momentum as they move over steep slopes as a consequence of the material entrainment from the erodible bed, before deposition begins on flatter terrain downstream. One of the biggest challenges for the application of depth-averaged models to realistic large-scale, long-term mud/debris flows is the computational effort required. These kinds of unsteady flows usually occur over very steep and irregular terrain, which requires the use of a refined non-structured spatial discretization in order to capture the terrain complexity, increasing the computational times exponentially.

Furthermore, the complexity of the numerical resolution and the computational cost of the solvers also increase considerably with the number of equations involved, and the coupling between flow variables adds special features to the mathematical model. Most of the numerical models specially designed for mud/debris flow are one-dimensional, or their resolution procedures are based on square-structured meshes in the case of 2D models. There is a lack of efficient and robust two-dimensional numerical models specifically designed for mud/debris flows and able to work with non-structured triangular meshes. In the

last five years, the use of Graphic Processing Units (GPU) hardware accelerators for sequential computation has proved to be an efficient and low-cost alternative to the traditional multi-CPU strategies (Lacasta et al., 2015).

This paper presents a two-phase two-dimensional model for multi-grain tailings flows over nonuniform erodible beds. We first present the fundamental equations, and then we summarize the results of simulations of a real tailings dam break event using the quadratic rheological formulation suitable for relatively dilute tailings and the granular formulation appropriate for dry stacks.

Two-phase tailings flow model

The model for mud/tailings flow is based on that described in detail in Martínez-Aranda et al. (2022), and involves the following assumptions:

- A shallow-two-phase solid-water flow approach.
- A multicomponent flow: the mixture of water and sediment particles is described by using the continuum approach and assuming the same velocity for the liquid and the solid phase.
- The different sediment size-classes present in the flow are distributed uniformly in the flow column.
- The reference coordinate system is horizontal-vertical, but the pressure and stress forces act along the direction tangential to the bed surface.
- Dynamic pore-fluid pressures can be developed in the liquid phase, affecting the frictional shear stress between solid grains.
- The model formulation is physically based and has been thoroughly validated with experimental data and real events (Martínez-Aranda et al., 2022).
- The two-dimensional mud/tailings flow model over erodible bed consists of 3 + N + 1 partial differential equations, including the depth-averaged equations for the water-sediment mixture mass and momentum conservation:

$$\frac{\partial}{\partial t}(\rho h) + \frac{\partial}{\partial x}(\rho h u) + \frac{\partial}{\partial y}(\rho h v) = -\sum_{p=1}^{N} \rho_{b,p} \frac{D_p - E_p}{1 - \xi_p} \quad (1)$$

$$\frac{\partial}{\partial t}(\rho h u) + \frac{\partial}{\partial x}(\rho h u^2 + \frac{1}{2} g_\psi \rho h^2) + \frac{\partial}{\partial y}(\rho h u v) = -g_\psi \rho h \frac{\partial z_b}{\partial x} - \tau_{bx} \quad (2)$$

$$\frac{\partial}{\partial t}(\rho h v) + \frac{\partial}{\partial x}(\rho h u v) + \frac{\partial}{\partial y}(\rho h v^2 + \frac{1}{2} g_\psi \rho h^2) = -g_\psi \rho h \frac{\partial z_b}{\partial y} - \tau_{by} \quad (3)$$

the continuity equation for each sediment size-class p = 1, ...,N, expressed as:

$$\frac{\partial}{\partial t}(h\,\phi_p) + \frac{\partial}{\partial x}(hu\,\phi_p) + \frac{\partial}{\partial y}(hv\,\phi_p) = -(D_p - E_p) \qquad 4$$

as well as the mass conservation equation for the bed layer considering N sediment size-classes:

$$\frac{\partial z_b}{\partial t} = \sum_{p=1}^{N} \frac{D_p - E_p}{1 - \xi_p} \qquad 5$$

where ρ is the bulk mixture density, h is the flow depth, (u, v) are the components of the depth averaged flow velocity vector **u** along the x and y coordinates respectively, ϕ_p represents the depth-averaged volumetric concentration of the p^{th} sediment size-class, N is the number of sediment size-classes transported, and (τ_{bx}, τ_{by}) are the components of the basal resistance vector τ_b along the x and y coordinates respectively. Moreover, z_b is the bed elevation, ξ_p is the deposition porosity for the p^{th} sediment class and $\rho_{b,p}$ the associated bulk density in the bed layer, D_p and E_p are the size specific deposition and entrainment exchange rates respectively, and $g_\psi = g\cos^2\psi$ is the bed-normal projection of the gravity, g is the gravitational acceleration and cos ψ is the direction cosine of the bed normal with respect to the vertical axis (Juez et al., 2013). Accordingly, the normalized bulk density r is given by:

$$r = \frac{\rho}{\rho_w} = 1 + \phi^\chi \qquad \text{with:} \quad \phi^\chi = \sum_{p=1}^{N} \frac{\rho_{s,p} - \rho_w}{\rho_w}\,\phi_p \qquad 6$$

where ϕ_χ is the buoyant solid concentration, ρ_w is pore-water density and $\rho_{s,p}$ is the density of the sediment particles for each sediment size-class.

Rheological formulations

A detailed explanation of the depth-averaged non-Newtonian basal resistance models used for the RiverFlow2D MT model can be found in Martinez-Aranda et al. (2022). Here, only the most important points are summarized.

The rheological formulations available in RiverFlow2D MT are summarized in Table 1.

Table 1: Rheological basal resistance formulations used in RiverFlow2D MT

ID	MODEL	BASAL RESISTANCE	FLOW TYPE
1	Turbulent Manning	$\tau_b = \tau_f + \rho g_\psi \frac{n^2 \lvert\mathbf{u}\rvert^2}{h^{1/3}}$	Turbulent Newtonian
2	Full Bingham	$2\tau_b^3 - 3\left(\tau_y + 2\mu_B \frac{\lvert\mathbf{u}\rvert}{h}\right)\tau_b^2 + \tau_y^3 = 0$	Cohesive viscoplastic
3	Simplified Bingham	$\tau_b = \frac{3}{2}\tau_y + 3\mu_B \frac{\lvert\mathbf{u}\rvert}{h}$	Cohesive viscoplastic
4	Turbulent Coulomb	$\tau_b = \tau_f + \rho g_\psi \frac{n^2 \lvert\mathbf{u}\rvert^2}{h^{1/3}}$	Frictional turbulent with $\tau_f = \left(\rho g_\psi h - \mathcal{P}_b\right)\tan\delta_f$
5	Turbulent Yield	$\tau_b = \tau_y + \rho g_\psi \frac{n^2 \lvert\mathbf{u}\rvert^2}{h^{1/3}}$	Cohesive turbulent
6	Turbulent Coulomb/Yield	$\tau_b = \min(\tau_y, \tau_f) + \rho g_\psi \frac{n^2 \lvert\mathbf{u}\rvert^2}{h^{1/3}}$	Frictional/cohesive turbulent with $\tau_f = \left(\rho g_\psi h - \mathcal{P}_b\right)\tan\delta_f$
7	Quadratic	$\tau_b = \tau_y + \frac{k_0}{8}\mu_B \frac{\lvert\mathbf{u}\rvert}{h} + \rho g_\psi \frac{n^2 \lvert\mathbf{u}\rvert^2}{h^{1/3}}$	Cohesive viscous/turbulent with $k_0 = 24$
8	Granular	$\tau_b = \rho g_\psi\, h \tan\delta_f$	Dry pure-frictional
9	Viscoplastic Coulomb	$\tau_b = \tau_f + \left(\frac{2m+1}{m}\right)^m \mu_P \left(\frac{\lvert\mathbf{u}\rvert}{h}\right)^m$	Frictional shear-thinning $m < 1$ or shear-thickening $m > 1$, with $\tau_f = \left(\rho g_\psi h - \mathcal{P}_b\right)\tan\delta_f$

Numerical solution

The equations described in the above section are solved by a fully conservative finite-volume method, detailed in Martinez-Aranda et al. (2022). The spatial domain is divided into triangular computational cells using an unstructured mesh. The time step is limited by the Courant-Friedrichs-Lewy (CFL) condition. The numerical computation can take advantage of multiple-core Graphical Processing Units (GPU) that allow reducing model runs up to 1,000 times with respect to non-parallelized models.

Results

This application aims to illustrate the importance of selecting the rheological formulation that better captures the non-Newtonian behavior of the tailings we would need to deal with. Using a formula that is not appropriate for the type of tailings would require using values of the key parameters (e.g., viscosity, yield stress) that could be unrealistic. In this test we compared the results for two different rheological formulas, while keeping the same parameters for both cases. On 25 January 2019 (at 12:28 p.m.), Dam I at the Córrego do Feijão Iron Ore Mine, located 9 km north-east of Brumadinho in the state of Minas Gerais, Brazil, suffered a sudden and catastrophic failure, resulting in an extremely violent mud flow that traveled downstream for more than 10 km and reached the Paraopeba River. The initial failure extended across the face of the dam and the slope collapse was complete in less than ten seconds. Most of the dam material flowed out of the dam in less than five minutes. The tailings in the dam showed a sudden and significant loss of strength and rapidly became a heavy liquid that flowed downstream at a high speed (about 120 km/h

in some zones). The data used to characterize the tailings, and the main parameters used in the test, are summarized in Table 2.

Table 2: Parameters used in the simulations

Parameters used in the simulations						
Liquid density ρ_w (kg/m^3)	1,000					
Initial mixture density ρ (kg/m^3)	2,247.5					
Internal stability angle ϕ_b(°)	5

Pore press. excess coeff. γ_{pp} (–)	2.05					
Global critical Shields stress θ_c (–)	0.03					
Transport capacity parameter β_T (–)	0.5					
Number of solid phases	6					
Solid phase material	**Sand**	**Silt**	**Fe**	**Al**	**Mn**	**Ti**
Medium diameter d_p (mm)	0.4	0.075	0.075	0.075	0.075	0.075
Initial volume concentration ϕ_p (–)	0.19	0.224	0.075	0.009	0.0015	0.0003
Solid density ρ_p (kg/m^3)	2,700	2,700	7,874	2,700	7210	4,506
Bed fraction $F_{b,p}$ (–)	0.38	0.62	0.0	0.0	0.0	0.0
Deposition porosity p_p (–	0.35	0.45	0.45	0.45	0.45	0.45
Critical Shields stress $\theta_{c,p}$ (–)	0.020	0.067	0.067	0.067	0.067	0.067

Tailings were composed of a mixture of water, sediments and heavy metals, mainly iron (Fe) 264.9 mg/g, aluminum 10.8 mg/g, manganese 4.8 mg/g, and titanium 0.5 mg/g (Vergilio et al., 2020). The size distribution consisted basically of a mineral sand fraction (38%) and a fines fraction (62%), accounting for mineral silt-clay and metals particles. The water content before the failure was estimated to be around 50% by volume with a specific weight of 22 to 26 kN/m^3 (Robertson et al., 2019).

Figure 1 shows an aerial image of the mine site after the dam collapse, including the dam location and the original tailings elevation in meters above sea level.

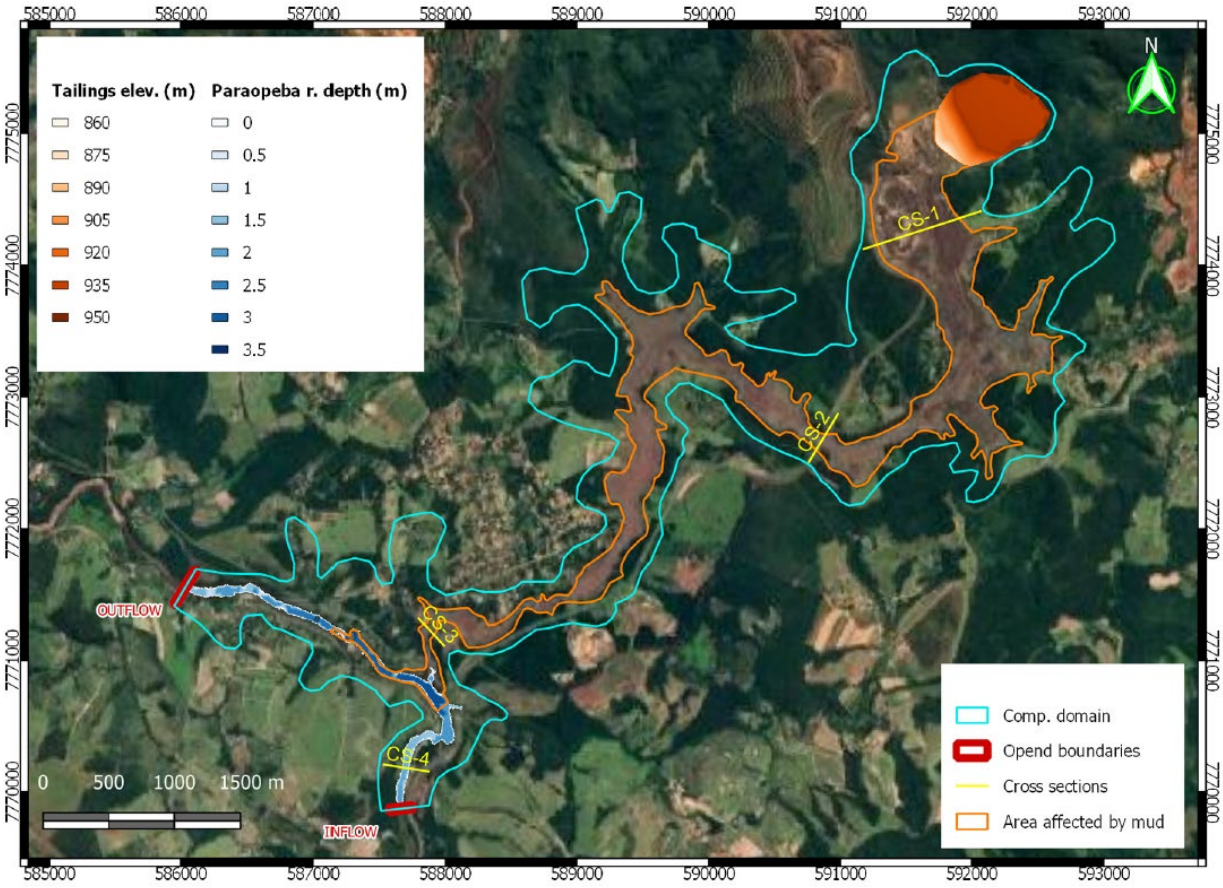

Figure 1: Aerial image of the area affected by the mud and the computational domain used in the simulation

The area affected by the mud was 3.3 × 106 m^2, not including the original dam area. In order to perform the simulations, a spatial domain of 10.396 × 10^6 m^2 is discretized using an unstructured triangular mesh, with the RiverFlow2D MT model containing approximately 20,000 cells ranging from 15 m to 50 m in size.

For the simulations the tailings mixture is considered fully saturated with an initial global volumetric concentration of solids φ_0 = 0.5, leading to a mixture density ρ = 2247.5 kg/m^3. The specific initial volumetric concentration for each solid phase φ_p is estimated from the available literature (Robertson et al., 2019).

Figure 2 shows the mud flow depth at 5 minutes, 10 minutes, and 35 minutes after the dam collapse, assuming the Quadratic and the Granular rheological formulation. Figure 3 depicts the volumetric concentration of the mixture.

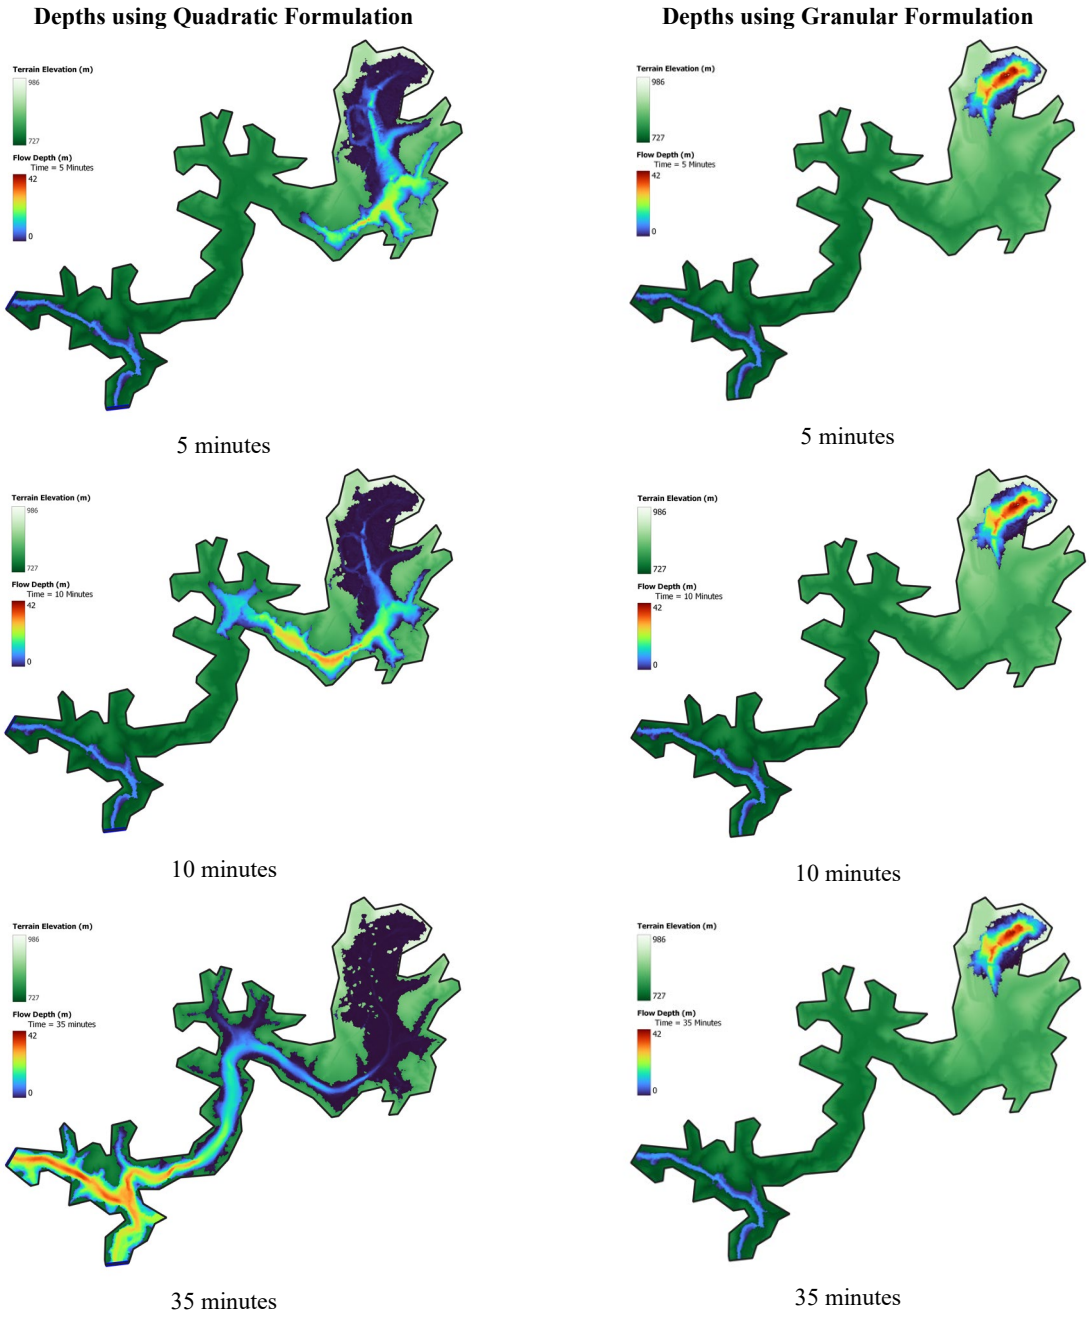

Figure 2: Flow depth maps at different times obtained using the Quadratic (left) and Granular (right) formulations

The numerical results using the quadratic formulation show that almost the entire initial tailings volume flowed out of the dam in the first five minutes after the dam collapse. The mud wave moved downstream with a computed height of more than 25 m and with velocities greater than 15 m/s (54 km/h) in some zones during the first minutes. On the other hand, assuming the granular formulation, the flow stops quickly at a short distance from the original deposits.

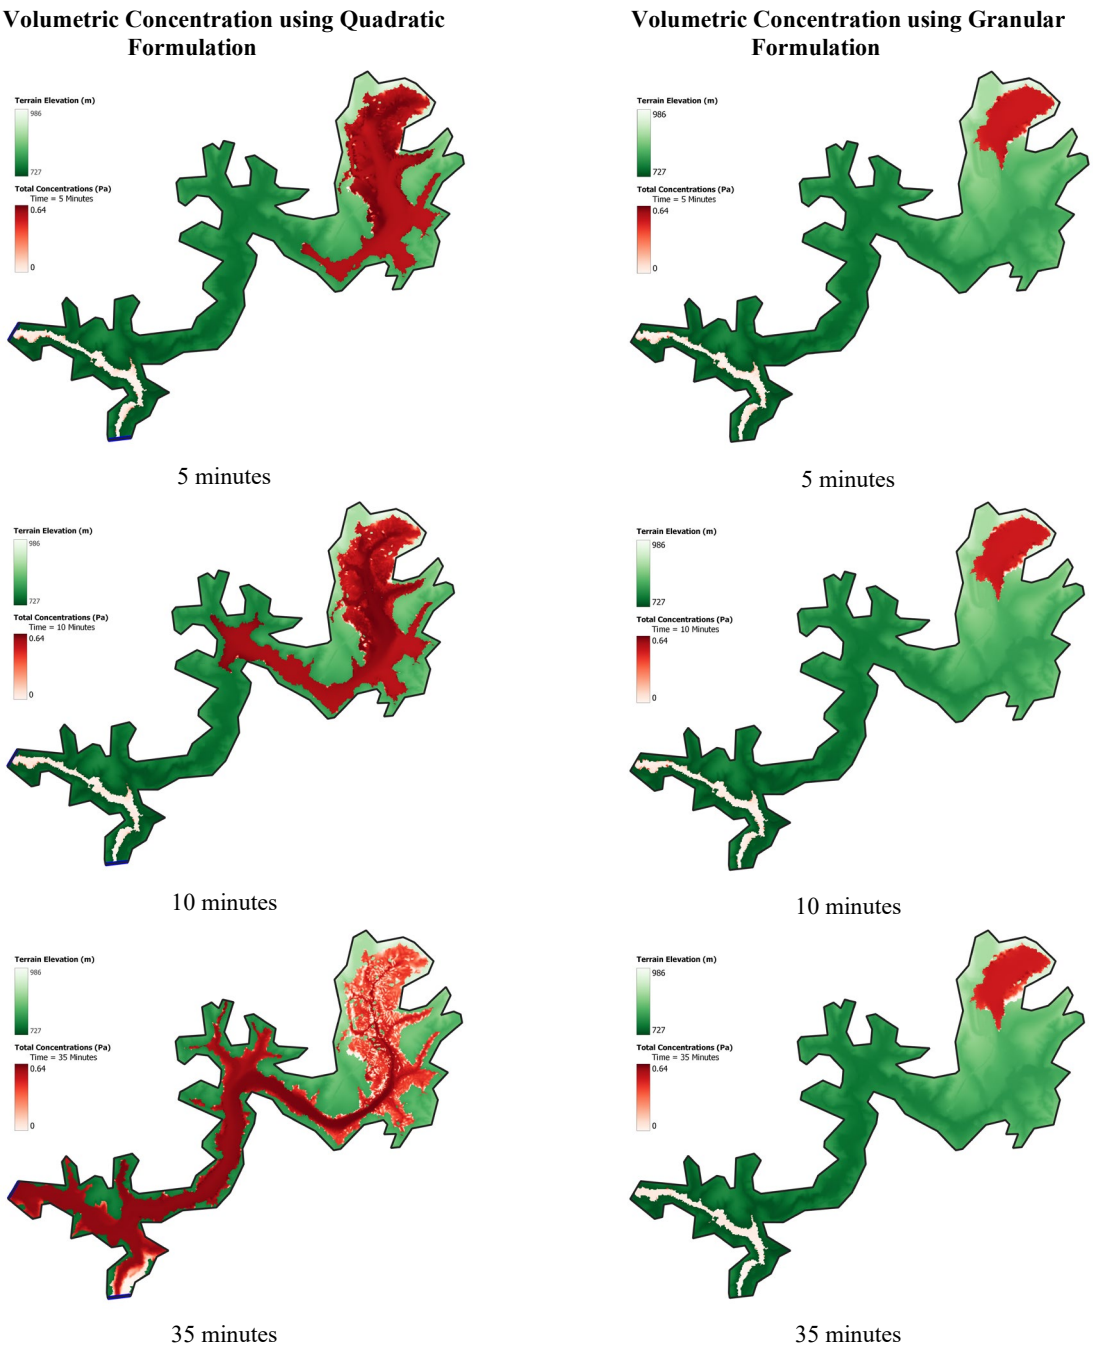

Figure 3: Material volumetric concentration maps at different times obtained using the Quadratic (left) and Granular (right) formulations

Conclusion

After mine tailings dam failures, the flowing fluid often consists of a mix of water and multiple solid phases with different sediment size classes, organic materials, chemical solutes, metals, and numerous sediment types from the dam itself. In turn, the high-speed flow can entrain soil from the existing terrain and, under

low energy conditions, can deposit or stop altogether.

To determine the areas that could be affected by tailings, it is critical to utilize models that consider rheology formulations that correctly represent the dam materials and tailings, whether dilute or dry. Also, if conditions require, the model should be able to incorporate the interaction of the tailings flow with existing water bodies such as water reservoirs or rivers.

This paper presents a practical application of the RiverFlow2D MT two-phase model for tailings dam risk assessments using as base data the case of the Córrego do Feijão dam break that occurred in Brazil in 2019. The simulations were performed with Quadratic and a Granular rheological formulation applicable to non-Newtonian fluids. The first one can be used to represent initially dilute tailings, while the latter can be used for those originating from dry stacks. The model considers the variability of the soil characteristics in the initial terrain and tailings as well as how fluid properties such as density, viscosity, and yield stress change in time and space as the materials flow and interact with terrain soils and other water bodies.

The application presented shows the importance of considering an appropriate rheological formulation for the tailings deposit and the dynamic interaction of tailings with their surrounding environment. Assuming the quadratic formula, the tailings flow several kilometers downstream from the dam location, while considering the Granular formulation the tailings flow only a few hundred meters from the initial deposit until they come to a full stop.

Abstract

One of the results of the tailings dam breach modeling process is the creation of a hazard map that classifies areas of the inundation into different hazard categories based on the depth and velocity of the flood. The hazard map is commonly used to estimate the Potential Loss of Life (PLL). Current industry practice is to employ hazard map categories and corresponding fatality rates developed based on water (Newtonian) flood properties. This paper presents a robust analytical framework for addressing the non-Newtonian characteristics of tailings floods, specifically focusing on its application in hazard mapping and fatality rate estimation. The case studies presented in this paper indicate that accounting for fluid density can significantly increase the estimated PLL; however, PLL is also dependent on the sediment concentration, location of the downstream residences, and depth and velocity of the flow. When the modeled flow is deep and fast, adjusting for density does not have a significant effect; however, where flows are wider, shallower, and/or slower, the differences can be substantial. The presented methodology offers a straightforward and practical tool for engineers and practitioners to estimate the true potential impacts of tailings dam breaches, leading to more informed decision-making and potentially saving lives.

Introduction

General

The non-Newtonian properties of tailings flows are typically considered during tailings dam breach modeling; however, current industry practice when estimating potential loss is to employ Newtonian methodologies and corresponding fatality rates that are available from the literature. Tailings flows typically have much higher sediment concentrations, densities, yield stress, and viscosity, than those associated with water floods. A higher-density fluid will result in a higher force exerted on objects in the flow path. In

general, a high density, yield stress, and viscosity flow causes more damage and is much harder for people caught within the flood to escape. This indicates that tailings flows should have higher associated fatality rates than those determined for water floods when all other variables are constant.

The United States Bureau of Reclamation (USBR, 2015) provides fatality rates that are based on case studies of water dam (Newtonian) failures that aggregate many factors. A similar case study for tailings dam failures that relates fatality rates to depth times velocity, warning time, and sediment concentration does not exist.

A sound mathematical approach to account for the non-Newtonian properties of tailings floods for hazard mapping and fatality rate estimates is summarized herein. This paper provides guidance on how the mathematical approach can be efficiently applied in practice and presents case studies supporting validation of the methodology and highlighting the potential severity of predicted impacts. The USBR fatality rate charts and other Newtonian-based analytical approaches to determining the impacts resulting from a hypothetical dam breach scenario can continue to be used, provided that the methodology described in this paper is followed and the depth times velocity values are adjusted to account for the fluid density of a specific tailings flow.

Derivation

The following methodology builds upon the concept discussed by Correa et al. (2021) and the previously developed procedure by Walden et al. (2022). The methodology utilizes the moment instability equation developed by Jonkman and Penning-Roswell (2008), as follows:

$$\boldsymbol{D \times V = \left(m \times \frac{2g \cdot cos(\alpha) \cdot L}{C_D \cdot B \cdot \rho} \right)^{0.5}} \quad (1)$$

Where, D × V is the critical depth times velocity of the flow, m is the mass of the person, B is the average body width exposed normal to the flow (m), L is the height of the person, C_D is the drag coefficient (unitless), g is the acceleration due to gravity (9.81 m/s^2), ρ is the density of the flowing fluid (kg/m^3), and α is the angle from the pivot point to the center of mass. A typical dam breach analysis assumes typical parameters for the theoretical population caught within the flood and m, B, L, g, α, and C_D can be combined into a single constant (K), and the resulting simplified equation is:

$$\boldsymbol{D \times V = \left(K \times \frac{1}{\rho} \right)^{0.5}} \quad (2)$$

Equation 2 clearly shows that the critical D × V is directly proportional to $\sqrt[2]{\boldsymbol{1/\rho}}$. The D × V of a non-Newtonian tailings (slurry) flood can be set equal to that of a clear water flood provided a conversion factor (X) is applied, as is depicted in Equations 3, 4, and 5.

$$\boldsymbol{D_{water} \times V_{water} = X \times D_{Slurry} \times V_{Slurry}} \quad (3)$$

(4) $$\left(K \times \frac{1}{\rho_{water}}\right)^{0.5} = X\left(K \times \frac{1}{\rho_{slurry}}\right)^{0.5}$$

(5) $$X = \left(\frac{\rho_{slurry}}{\rho_{water}}\right)^{0.5}$$

Where, X is the density ratio, V_{slurry} is the velocity of the non-Newtonian flood, V_{water} is the velocity of the Newtonian clear water flood, D_{slurry} is the depth of the non-Newtonian flood, D_{water} is the depth of the Newtonian clear water flood, ρ_{slurry}, is the density of the non-Newtonian flood, and ρ_{water} is the density of water.

The density ratio (X) can be applied to determine the equivalent clear water depth times velocity, which can be directly applied to hazard mapping as it is typically based on the depth times velocity values of the flood. The equivalent clear water depth times velocity equation (Equivalent Clear Water Hazard Map (ECWHM) equation) is as follows:

(6) $$ECWHM = D_{Slurry} \times V_{Slurry} \times X$$

Where the ECWHM equation can be applied to a dam breach model in order to convert a non-Newtonian hazard map into an equivalent Newtonian hazard map, as is described in the following section.

Application

The ECWHM equation can be applied through the use of a raster calculator once a tailings dam breach analysis model has been simulated. A raster is a matrix of cells (or pixels) where each cell contains a value representing information, such as the sediment concentration of the flood. Determining the slurry density raster is imperative for the accurate computation of the ECWHM, as defined by Equation 6. Conventional outputs from prevalent 2D dam breach modeling software, such as Riverflow2D, Flow2D, and HEC-RAS, do not include density rasters. Instead, these software packages typically produce a raster representing sediment concentration (C_v), and a conversion is necessary to transform the C_v raster into a density raster. This conversion is achieved through the application of the subsequent formula, which utilizes the specific gravity of solids (G_s):

(7) $$\rho_{slurry} = C_V \times (G_s \times \rho_{water}) + (1 - C_V) \times \rho_{water}$$

Case study

Background

The Brumadinho (Córrego do Feijão- Dam 1) tailings dam failure was selected for a case study to validate the previously presented ECWHM approach to fatality rate estimates. The Brumadinho failure released approximately 10 million (M) cubic meters (m^3) of mining waste and flowed at depths greater than 10 meters. The dam collapsed quickly and the peak flow (90,000 m^3/s) at the breach opening was estimated to

occur 5 seconds after the initiation of the failure. Images of Córrego do Feijão- Dam 1 pre- and during failure are presented on Figure 1. Loss of life resulting from the dam collapse has been estimated to be between 270 and 320 people (Lumbroso, 2021).

Results from previous dam breach modeling of the failure indicated that the computed results align with the observed data (Martinez-Aranda et al., 2022). The maximum depth times velocity raster from the previous study was used as a basis to validate the ECWHM methodology.

Figure 1: Córrego do Feijão Dam 1 pre-failure (left) and during failure (right)

Identification of structures and populations

The exact number of people residing within each inundated structure at the time of the failure are either not well documented or are not publicly available at this time. Therefore, inhabitable structures were identified using satellite imagery from the area prior to the failure. To estimate the number of persons within each flood hazard zone, it was assumed that three people resided within each structure, per the recommendations of the Department of Homeland Security (DHS, 2011). An estimated 200 individuals were present in the canteen immediately downstream of the facility (Lumbroso et al., 2021) at the time of the breach and were also accounted for in this study.

Methodology for estimating fatality rates

The generalized Reclamation Consequence Estimating Methodology (RCEM) approach (USBR, 2015) was utilized to estimate the fatality rate at each inundated location. The RCEM approach primarily considers flood severity (DxV) and warning time as the driving factors for determining the fatality rate associated with populations within the inundation area of a Newtonian flood. Although practitioners frequently apply the RCEM approach to individual structures, its primary design characterizes regional population fatality rates, offering a broad-scale assessment rather than structure-specific risks (Feinberg et al., 2016). Consequently, when using RCEM for individual structures, it is essential to adopt a conservative fatality rate limit from the relevant RCEM chart to avoid potential underestimation of fatality risks. The RCEM

methodology provides two charts that were developed for selecting fatality rates. One chart corresponds to failures that have little to no warning and the other corresponds to failures with adequate warning. The chart corresponding to little to no warning time was selected for use in this study as it best represents the actual event. The chart, presented on Figure 2, provides a suggested limit for estimating fatality rates corresponding to specific DxV values.

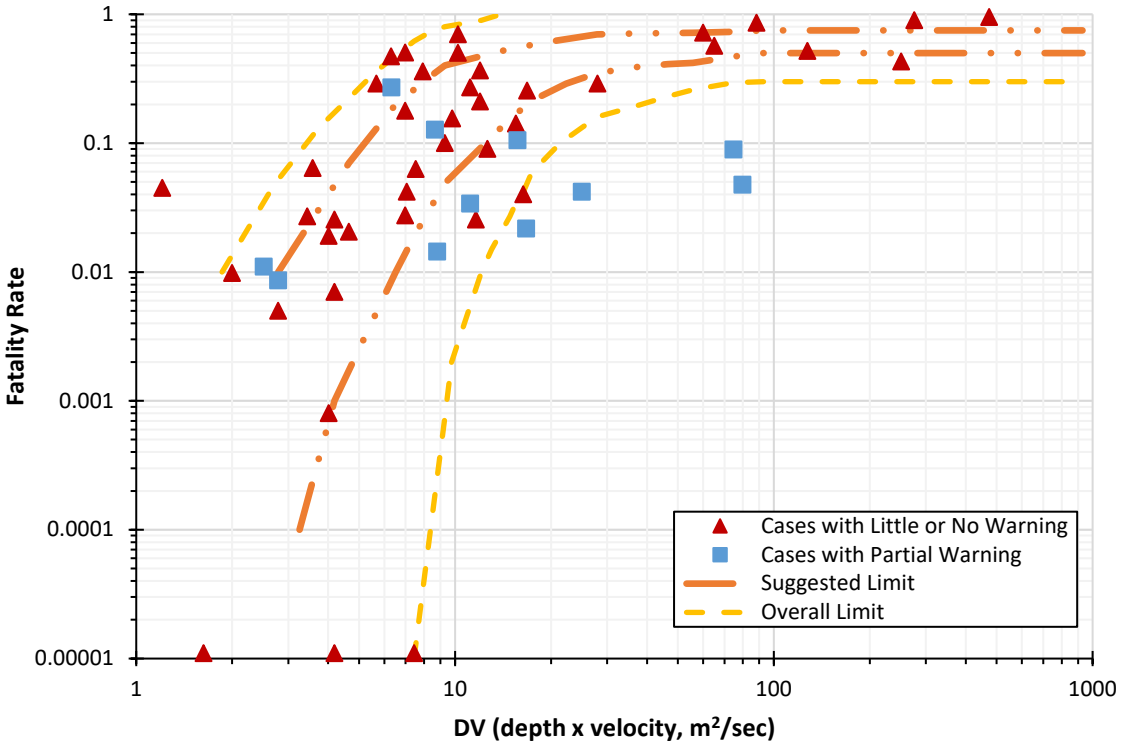

Figure 2: RCEM depth times velocity chart (adapted from USBR, 2015)

The suggested upper limit was used as a basis for estimating the fatality rates associated with the failure. For simplicity, ease of use, and efficiency, the DxV values were binned according to the flood hazard categories from Federal Emergency Management Agency (FEMA) Guidance for Flood Risk Analysis and Mapping (FEMA, 2020), which categorizes the DxV values based on flood severity. The categories are based on studies in Australia (Hawkesbury-Nepean Floodplain Management Steering Committee, 2006).

The bin listed by FEMA for extreme was considered to provide too large of a range in fatality rates and was further subdivided into four additional sub-categories. The categories and their corresponding DxV and fatality rates are presented in Figure 3 and are tabulated in Table 1. Although the fatality rates in Table 1 corresponding to the low and medium categories are listed as 0 because the associated fatality rates are so low (~0.00005) that they are unlikely to affect Potential Loss of Life (PLL) estimates.

Table 1: Depth times velocity zones and corresponding fatality rates

Category	Depth Times Velocity Range (m^2/s)	Fatality Rate
Low	<0.2	0
Medium	0.2-0.5	0
High	0.5-1.5	0.0001
Very High	1.5-2.5	0.005
Extreme I	2.5-5.2	0.05
Extreme II	5.2-9.3	0.25
Extreme III	9.3-27.9	0.55
Extreme IV	>27.9	0.75

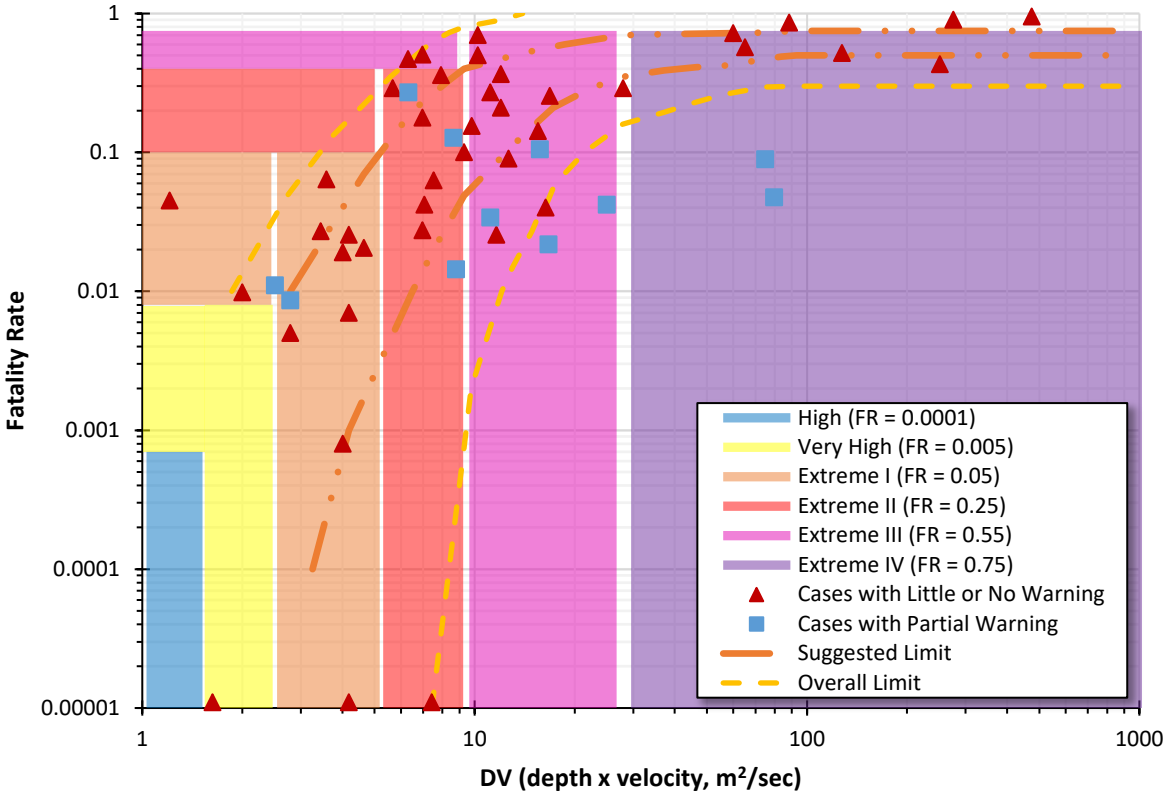

Figure 3: Zoned depth times velocity chart

Determining the tailings flood density

A raster of the maximum flood density during the breach was produced using Equation 7. The density raster for the tailings flow is presented in Figure 4. The densities of the tailings flood were found to range from

as high as 2,248 kg/m^3, representative of a thick mudflow, to as low as 1,001 kg/m^3, representative of clear water flow. The average density was 2,157 kg/m^3. Most areas impacted by the flood experienced flow densities between 2,100 kg/m^3 and 2,250 kg/m^3.

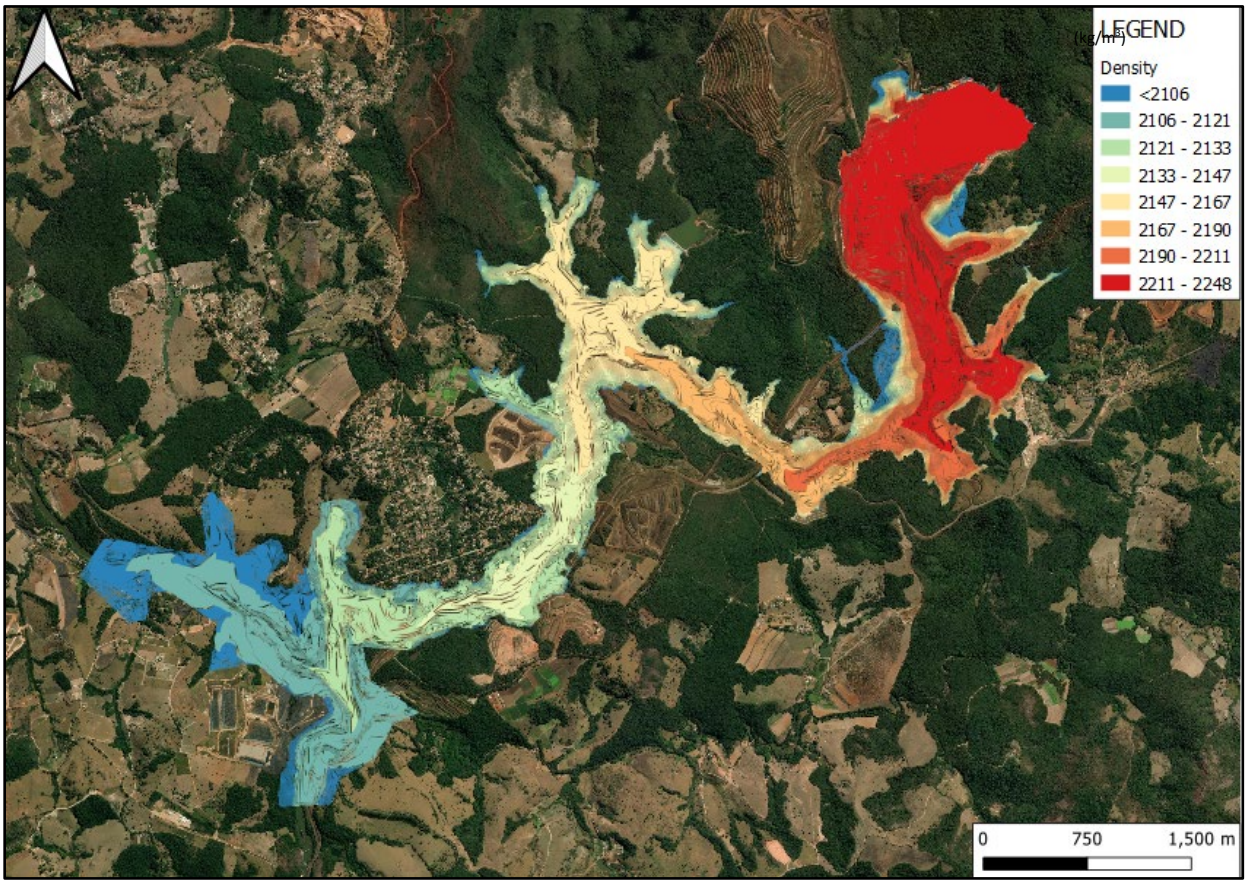

Figure 4: Brumadinho failure fluid density

Generating the equivalent clear water hazard map

The ECWHM was generated using the simplified approach previously described. In general, a raster calculator was used to produce the ECWHM using a raster of the density ratio and the original hazard map (depth times velocity raster) generated by the breach flow model. The density ratio, employed for the conversion of the original hazard map raster into an ECWHM, was determined utilizing Equation 5.

The density ratio values ranged from ~1.0 (indicating no change from the original raster) to as high as 1.5 (indicating a 1.5 times increase in the ECWHM depth times velocity value). The average value was 1.47, and approximately 99 percent of the values were above 1.40. In general, the density ratio indicates that the depth times velocity values in the original hazard map should be approximately 1.5 times greater to produce an equivalent clear water hazard map.

Results

Densities

The results indicate that Brumadinho tailings dam failure produced very high-density flows, generating instability at lower depths and velocities than equivalent Newtonian flows.

In the case of the Brumadinho tailings dam failure, the fluid densities were typically between 2,100 kg/m^3 and 2,250 kg/m^3 due to the large release of solid mine waste from the facility, lack of a significant supernatant pond, and lack of substantial dilution as the flood transitioned downstream.

Hazard mapping

The original hazard map is presented in Figure 5 and the ECWHM is presented on Figure 6. Each hazard map presents the breach location, hazard map, and location of inundated structures (presented as circles that are color-coordinated with their hazard rating). A high-level overview indicates that there is little difference between the two hazard maps, which is due to the very high flood depths and velocities associated with the failure. However, closer review indicates that notable differences are apparent on the fringes (outer 100 to 300 meters) of the floodplain, as presented in Figure 7.

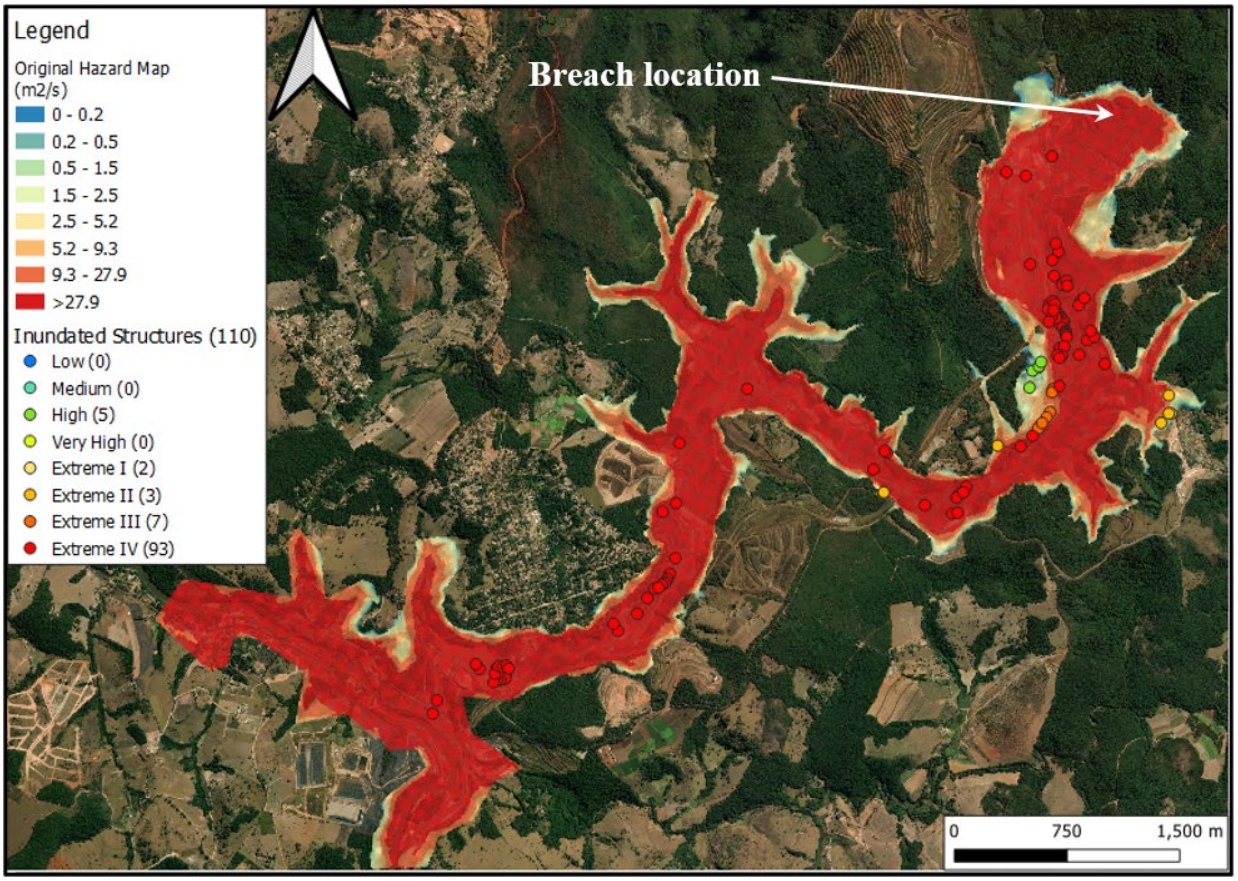

Figure 5: Original hazard map

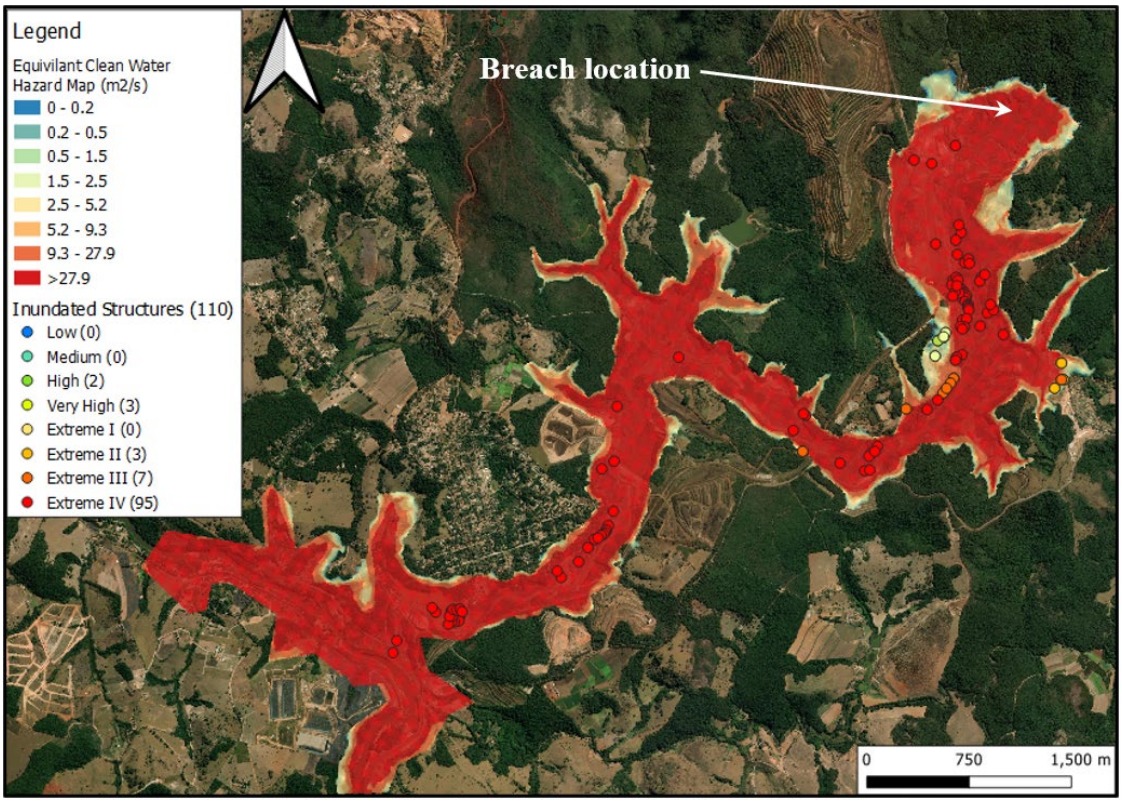

Figure 6: ECWHM hazard map

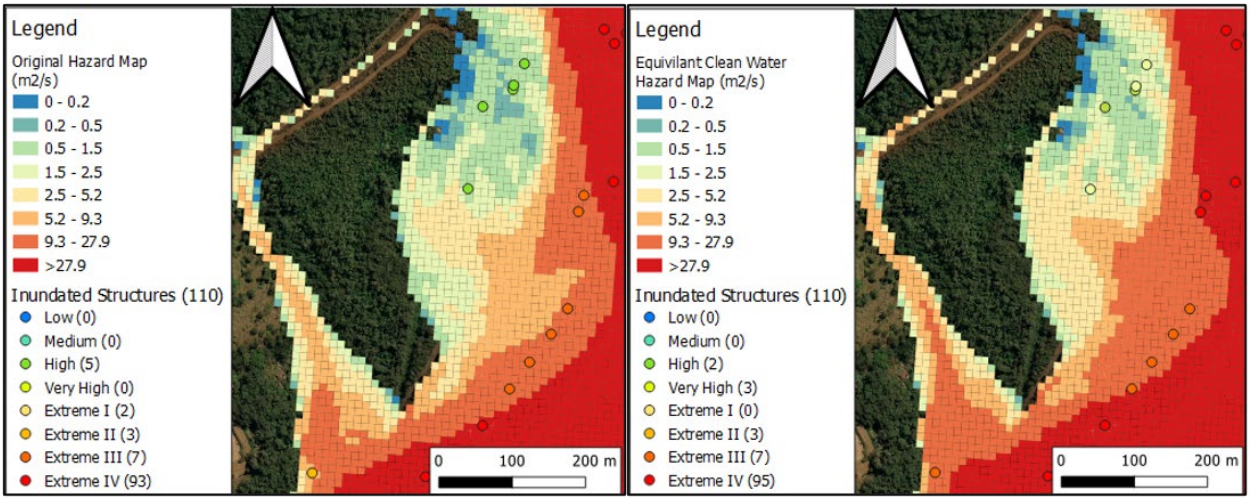

Figure 7: Original hazard map (left) vs. ECWHM hazard map (right)

The data from each hazard map was evaluated statistically to further investigate the differences between the results. Table 2 presents the average, maximum, minimum, and standard deviation depth times velocity values for each hazard map, along with the percent of raster values within each hazard class. As expected, the ECWHM has higher depth times velocity values, which represents higher associated hazard levels.

Table 2: Depth times velocity zones and corresponding fatality rates for the Brumadinho failure

Category	Newtonian	ECWHM
Average (m^2/s)	117	173
Minimum (m^2/s)	<0.01	<0.01
Maximum (m^2/s)	693	1,039
Standard Deviation (m^2/s)	123	182
Low Hazard (% of raster values)	<1%	<1%
Medium Hazard (% of raster values)	<1%	<1%
High Hazard (% of raster values)	3%	2%
Very High Hazard (% of raster values)	2%	2%
Extreme I Hazard (% of raster values)	5%	4%
Extreme II Hazard (% of raster values)	5%	4%
Extreme III Hazard (% of raster values)	14%	12%
Extreme IV Hazard (% of raster values)	70%	75%

Loss of life

The procedure for estimating the population at risk (PAR) and assigning fatality rates was previously discussed. Lumbroso et al. (2021) states that the total number of deaths from the dam failure ranged between 270 and 320 people. A comparison of the resulting difference in number of inundated structures, PAR, and PLL between the original hazard map and the ECWHM is presented in Table 3. The resulting hazard maps were previously presented in Figure 5 and Figure 6.

Table 3: Inundated structures, PAR, and PLL for non-Newtonian flood for the Brumadinho failure

Hazard	Structures		PAR		PLL	
	Original	ECWHM	Original	ECWHM	Original	ECWHM
Low	0	0	0	0	0.0	0.0
Medium	0	0	0	0	0.0	0.0
High	5	2	15	6	0.0	0.0
Very High	0	3	0	9	0.0	0.0
Extreme I	2	0	6	0	0.3	0.0
Extreme II	3	3	9	9	2.3	2.3
Extreme III	7	7	21	21	11.6	11.6
Extreme IV	93	95	476	482	357.0	361.5
TOTAL	**110**	**110**	**527**	**527**	**371.1**	**375.3**

Discussion

Case study summary

The case study resulted in an overall increase in PLL of approximately 4.2 people when the ECWHM methodology is compared to the standard Newtonian methodology. The total PLL for the ECWHM was 375.3, which is close to the high end of the range of estimated fatalities (270-320) and in general, indicates that the methodology used provides a reasonable and conservative approximation. The minor difference in PLL (~4.5 people) between the Newtonian and ECWHM methodologies indicates that, in the case of the Brumadinho failure, application of the ECWHM method does not have a significant impact on the resulting PLL. However, it should be noted that the minor difference in PLL can be attributed to the following:

1. **The unique and violent release of tailings during the dam failure.** The dam collapsed quickly and the peak flow of mine waste (estimated to be 90,000 m^3/s) from the breach opening was estimated to occur 5 seconds after the initiation of the failure (Lumbroso et al., 2021). The extremely high depth and velocity flood wave caused the majority of the depth times velocity values to be above 27.9 (the highest risk category (Extreme IV) associated with a 75% fatality rate) prior to adjustment with the ECWHM methodology. Therefore, although the ECWHM methodology increased the depth times velocity values, most remained in the Extreme IV hazard category.
2. **The location of the inundated structures**. The majority of the structures were located in the center of the flood path which falls in the Extreme IV risk category regardless of whether slurry density is taken into account or not. In countries with more stringent regulations for land development near rivers and floodplains the structures are more likely to be located on the fringes of the inundation due to regulatory requirements.

In scenarios beyond the scope of the present case study, the utilization of ECWHM may yield substantial differences compared to predictions derived from Newtonian methodologies, as is discussed in in the following section.

Impact of Implementation in other cases

The impact of applying the ECWHM methodology was evaluated for four hypothetical dam breach scenarios. These hypothetical Dam Breach Analyses were completed for mine sites at various locations around the world using appropriate standards, as described by the Canadian Dam Association (2021). The ECWHM methodology was not originally applied but was implemented to compare the original results to the ECWHM methodology. The results are presented in Table 4.

Table 4: ECWHM impacts on other tailings dam breaches

Case	Methodology	Average Slurry Density (kg/m³)	Structures	PAR	PLL	ECWHM Increase in PLL (%)
Case 1	Original	1,883	139	417	77.6	41
	ECWHM				109.6	
Case 2	Original	1,843	54	162	10.9	59
	ECWHM				17.3	
Case 3	Original	1,765	270	810	19.1	83
	ECWHM				35.0	
Case 4	Original	1,881	37	111	9.5	26
	ECWHM				12.0	
Brumadinho Case Study	Original	2,157	66	198	133.1	3
	ECWHM				137.6	

Note: All cases consider fair weather (sunny day) failure modes.

The impacts (regarding PLL) of applying the ECWHM to each of these cases are significantly larger than those established from the Brumadinho case study.

It should also be noted that use of the ECWHM method results in an increase in the PLL consequence classification (in terms of the Global Industry Standard for Tailings Management guidelines [Global Tailings Review, 2020]) for both Case 1 and Case 4. The PLL consequence classification for Case 1 would increase from Very High (10-100 PLL) to Extreme (>100 PLL), and the PLL consequence classification for Case 4 would increase from High (1-10 PLL) to Very High. Cases 2 and 3 had higher percent increases than Cases 1 and 4; however, the PLL consequence classification does not increase as the original PLL values were on the low end of the Very High consequence classification category and both scenarios require increases greater than 500% to transition to the Extreme hazard category.

The large difference in the PLL increase between the hypothetical cases and the Brumadinho case study can be best explained by the variance in the distribution of structures within each hazard zone. As indicated in Table 3, approximately 85% of the inundated structures were within the Extreme IV hazard zone without application of the ECWHM and have already been assigned the maximum fatality rate. In comparison, Table 5 presents the resulting difference in number of inundated structures, PAR, and PLL between the original hazard map and the ECWHM for Case 1. As indicated in Table 5, none of the inundated structures were within the Extreme IV hazard zone. This implies that the larger impact to PLL realized when the ECWHM is applied is due to either the populations being located further from the area of maximum depth and velocity (safer locations) and/or the flood generated from the DBA was of lower depth

and velocity than the Brumadinho failure. This result aligns with the fact that the violent Brumadinho failure was somewhat unique and the indication that many of the dwellings were constructed without much consideration for potential flood hazards, meaning that they were closer to the area of maximum depth and velocity. The results indicate that when the modeled flow is deep and fast, adjusting for density does not have a significant effect; however, where flows are wider, shallower, and/or slower, the differences can be substantial.

Table 5: Inundated structures, PAR, and PLL for non-Newtonian flood for Case 1

Hazard	Structures		PAR		PLL	
	Original	ECWHM	Original	ECWHM	Original	ECWHM
Low	14	12	42	36	0	0
Medium	8	6	24	18	0	0
High	20	14	60	42	0.1	0
Very High	14	16	42	48	0.4	0.5
Extreme I	33	27	99	81	5	4.1
Extreme II	27	26	81	78	20.3	19.5
Extreme III	23	38	69	114	51.8	85.5
Extreme IV	0	0	0	0	0	0
Total	**139**	**139**	**417**	**417**	**77.6**	**109.6**

Other methods of application

The ECWHM methodology can be applied to the USBR RCEM guidance as outlined in this paper, or any variation thereof. It should also be noted that the methodology could also be applied to LifeSim (2021) models, which utilizes depth and velocity measurements to evaluate flood impacts. Specifically, the ECWHM methodology can be used to understand the economic impacts of the inundation and evaluate the potential damage to inundation structures.

Engineering judgement

The methodology outlined in this paper is intended to be a tool to help account for the impacts caused by high-density non-Newtonian flows and should not be utilized without the application of sound engineering judgment. There are many ways that the assumptions utilized in the methodology can be adjusted for specific cases. For example, the case study presented here-in estimated that three people resided within each of the inundated structures. However, there may be some cases where it is appropriate to assume more, or less, than three people reside within each structure. Accurate structure type classification is also a crucial

consideration, as engineered structures are generally more resilient to collapse. Transient populations can be another area of uncertainty, requiring additional consideration.

Consideration of the time step that the maximum depth, velocity, and sediment concentration (density) occur is also important. The flow model results provide the spatial variability of each of these metrics over the entire simulation, and maximum values inherently occur at different times of the simulation. Using the maximum of all three variables would produce conservative results; however, it would be more accurate to use the depth, velocity, and sediment concentration values from the timestep that produces the most critical results.

Conclusion

Non-Newtonian tailings properties are typically considered during tailings dam breach modeling, but are not commonly accounted for when estimating PLL since there is limited guidance on how these properties influence fatality rates. When determining the consequences of the impacts of a tailings dam breach the current standard of practice is to employ Newtonian-based methodologies, which can lead to underestimating the true potential impacts of the breach. Tailings flows typically have much higher sediment concentrations and fluid densities than those associated with water floods, which in turn leads to greater impacts at equivalent Newtonian depths and velocities.

This presented procedure provides a reasonably simple methodology for adjusting the depth times velocity values such that the existing Newtonian methods for estimating PLL can be utilized.

It should be noted that, although the approach outlined in this document is technically feasible, it has only been validated based on a single real-world case study. Further work should be completed in this area to further refine and build upon the methodologies outlined in this paper. The authors recommend completion of the following to support further development and refinement:

1. Additional back-analysis case studies should be completed to further validate the work and assumptions outlined in this paper.
2. Additional studies should be completed to assess the impacts of using this methodology in consequence-estimating software such as LifeSim.
3. Additional studies should be completed to further validate this methodology in terms of application to damage to structures and economic impact.

In general, more tools directly related to non-Newtonian tailings floods, rather than Newtonian water floods, are essential for continual development and improvement in predictive dam breach modeling. The procedure presented herein is a positive step in that direction.

Multi-model Analyses of Tailings Impoundment Failure and Runout: Part III

Armin Saeedi, Carleton University, Canada
Mario Martinelli, Carleton University/Deltares, Canada/Netherlands
Paul Simms, Carleton University, Canada

Abstract

Continuing the line of research presented previously at Tailings and Mine Waste 2022 and 2023, in order to better understand and eliminate uncertainties associated with tailings impoundment failures and the prediction of subsequent runout characteristics, the Merriespruit case study is re-analyzed using a geomechanics-based MPM software employing Norsand in undrained conditions. Work reported in the earlier papers did not employ Norsand in MPM, nor did it consider pore-water pressure. Parameters were constrained by element test data. The MPM model employing Norsand is able to accurately describe the progressive nature of the failure, and is also able to capture other features, for example the shallower failure zone upstream of the main failure. The state parameter that best matched the retrogression pattern produced a runout considerably shorter than reported (500 m compared to > 1.2 km). It is argued that this is at least partially an artefact of 2D conditions, hypothesized for two reasons i) the less sheared tailings trap a substantial amount of mobilized tailings, which would not necessarily occur in 3D, ii) the shallow part of the failure extends much wider than the breach in reality; therefore, there is a lower volume of low strength tailings available to flow in the 2D simulation compared to the real 3D case. It is also clear that the shape of the CSL at low stresses will have a strong influence on the volume of flowable tailings, whereas the CSL is usually defined using laboratory and/or field data obtained at much higher stress than runout conditions.

Introduction

Approaches to numerical modeling of both the initial failure of a tailings impoundment and the subsequent runout are being developed by many researchers. The initial failure is often simulated using geomechanics-based software, taking into account complex constitutive behavior, pore-water pressure coupling, 3D geometry and appropriate mechanical and hydraulic boundary conditions (e.g. Zabolotnii et al., 2022), whereas runout is simulated in practice using flow models with various rheological constitutive models, most of which use a depth-average solution of the momentum equation (as summarized by Rana et al.,

2021). This simplification allows for inundation mapping over a real topography. These two types of models probably define the ends of the spectrum of available tools, whereas a number of other models try to consider both rheology and geomechanics, usually providing additional complexity at the cost of increased computer resources, or simulating only 2D profiles of the runout.

This paper is the continuation of research presented at the Tailings and Mine Waste 2022 and 2023 conferences (Saeedi et al., 2022, 2023), where three different models (FLAC3D, Anura 3D, and UINTAH-VBR) were applied to analyze the failure and the subsequent tailings runout i) at the Merriespruit mine, as well as ii) in centrifuge and small flume experiments for clayey tailings. The models were a 3D geomechanics model (FLAC3D) using the Norsand constitutive model and considering 3D geometry; a 2D geomechanics model (Anura 3D), using the material point method numerical approach (MPM), and simulating the tailings failure using a Mohr-Coulomb constitutive model but ignoring pore-water pressure; whereas the third was a 3D viscosity bifurcation rheology model (also implemented in a MPM framework. The finding of the first paper (Saeedi et al., 2022) was that the more geomechanics-based models could apparently reproduce the failure surface and mobilized volume for a reasonable set of parameters, but substantially underpredicted both the runout distance and overpredicted the speed of the runout. By contrast, for a reasonable set of parameters, the rheology model could give a good approximation of the observed runout speed and extent, but overpredicted the volume of tailings mobilized during the failure and could not correctly simulate failure initiation, and would therefore require an independent estimate of the "hydrograph" of mobilized tailings.

The second paper in the series (Saeedi et al., 2023) focused on analyzing a centrifuge test on a 3 m tall clayey tailings embankment using a rheology and a geomechanics-based constitutive models: both constitutive models simulated degradation of strength from a peak to a residual value. In the rheological model this occurred as a function of strain rate; in the geomechanics model strength decreased through accumulated plastic strain. Both constitutive models, calibrated to the same laboratory data, gave very similar predictions of runout. It was concluded from the relatively small height (3 m) that momentum of the mobilized tailings was dissipated in each model by the de-structuration process; and that the flow during the runout phase was slow enough that either method could reasonably describe the deceleration of the flow.

The present paper returns to the analysis of Merriespruit, but now employs a more sophisticated constitutive model in the MPM software, namely the Norsand constitutive model implemented to allow undrained simulations that consider existing pore-water pressure. Some effort is made to explain what the Norsand model actually does, from a practical perspective.

Numerical formulation and constitutive model (Norsand)

MPM formulation

In the current study, the Anura-Deltares MPM software is employed. The MPM implementation is described by Martinelli and Galavi (2022) and verified for several constitutive models. It uses an explicit dynamic formulation, and an automatic adaptation of time step size based on the Courant–Friedrichs–Lewy (CFL) criterion, to promote computational stability and numerical efficiency. The CFL criterion is very common and was originally used in computational fluid dynamics to maintain numerical stability. This and other features that promote numerical stability allow for the efficient use of more complex constitutive models, such as Norsand. While 3D simulations are possible, at present they take considerable time and are less stable. This paper only reports 2D analyses.

Norsand implementation

Here we include a brief qualitative description of Norsand, in an attempt to convey some understanding of how it actually works. The Norsand model is based on critical strength concepts, where during undrained shear the geomaterial will approach an ultimate shear stress that is a function of the friction angle and the critical state line in void ratio (e) and mean effective stress (p') space. Conventionally, where the critical state line is expressed in a semi-logarithmic relationship, $e_c = \Gamma - \lambda \ln(p')$, e_c being a void ratio on the CSL, the ultimate undrained strength will then be $M/2 \exp((\Gamma - e_c)/\lambda)$, M being the slope of the critical state line in q (deviatoric stress) – p' space. This ultimate strength therefore depends on the friction angle and the slope of the CSL, increasing with density; and importantly, is therefore independent of stress path. But more important is the initial state of the soil before undrained loading. If the soil, at a given e, is at a higher mean effective stress than the CSL, the peak strength will be higher than the residual, leading to the possibility that a particular tailings impoundment is susceptible to brittle failure, which may contribute to substantial acceleration of the tailings as the resisting forces decrease during failure.

Figure 1 gives an idea of how the model functions. This group of figures shows the stress path under undrained loading for three samples, one starting on the CSL, and two others starting at void ratios above and below the CSL, but starting at the same mean effective stress. If we consider the points on the right as three initial possible states in a tailings impoundment – each has been arrived at by presumably some combination of depositional stress history, including consolidation, potentially desiccation, or perhaps some alteration due to compaction; all three have the same identical initial condition in terms of stress. For undrained loading, the loading path is horizontal in e -p' space (no volume change), and the final shear strength depends only on the initial value of e. But how the stress the path progresses in terms of shear depends strongly on the initial state, and to a lesser degree on the elastic and plastic parameters of Norsand.

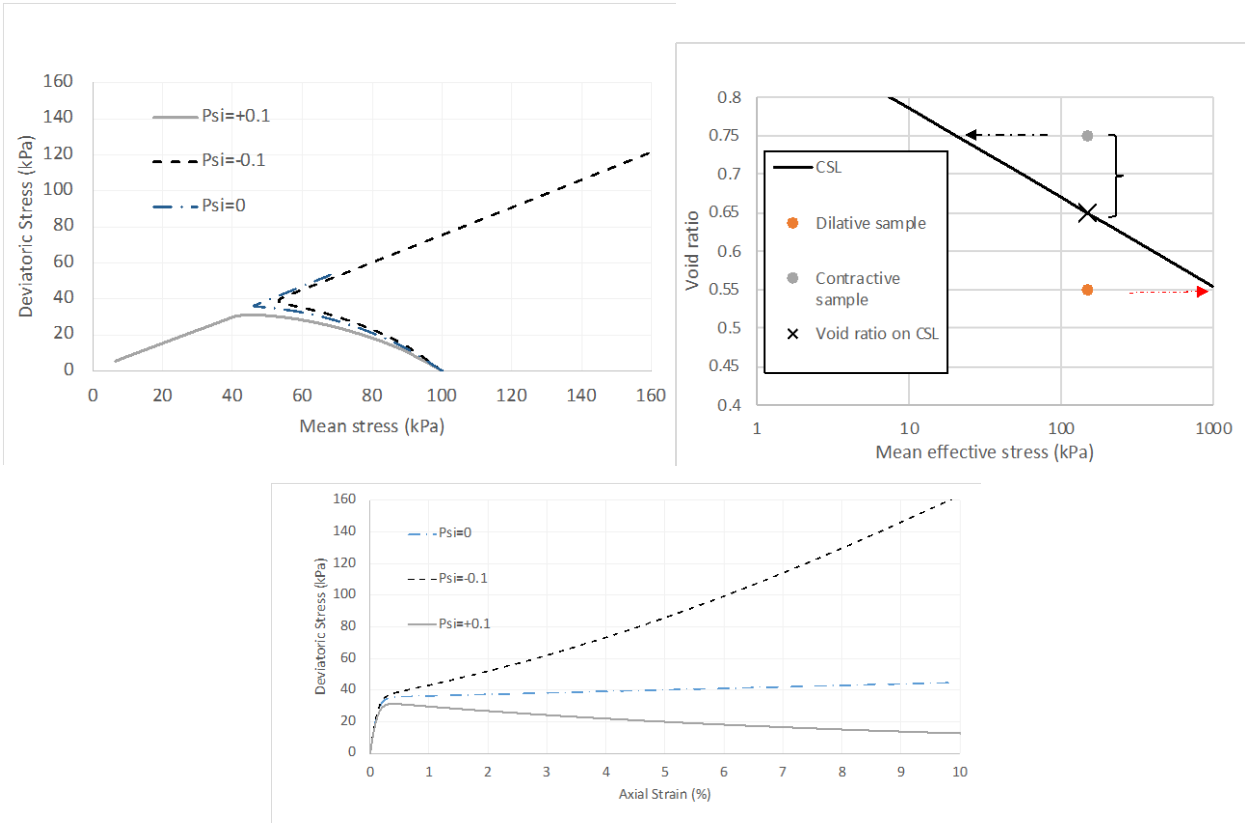

Figure 1: Basic function of Norsand model

The initial state of the geomaterial is described by the state parameter (ψ), which is the vertical change of void ratio between its initial value, and the void ratio on the CSL at the same mean effective stress, as shown in Figure 1. For example, consider the stress path of the sample with ψ = 0.1. This contractive sample moves towards the CSL to the left in e-p' space, arriving at its unique (and low value of) p'. This is reflected in Figure 1 b, where the critical state is reached at a value of q = M p'. The peak strength is also the lowest among these example samples, though the variance between peak strengths is much smaller than the variance in the critical state strengths. Thus, Norsand and similar models transit the geomaterial between a peak strength largely dependent on the initial stress state; to the critical state, largely dependent on void ratio.

The field case

The Merriespruit dam failure is a relatively well documented case (Fourie et al., 2001; Fourie and Papageorgiou, 2001; Wagener, 1997). The failure is generally attributed to an overtopping trigger, while the length of the runout is thought to be due to static liquefaction as the failure progressed, possibly exacerbated by the presence of a significant pond of water that accumulated near the dam, co-incident with the

overtopping event. The height of the tailings near the breach was 30 m, and the width of the breach was approximately 150 m. Cross-sections of the impoundment geometry before and after the breach are shown in Figure 2.

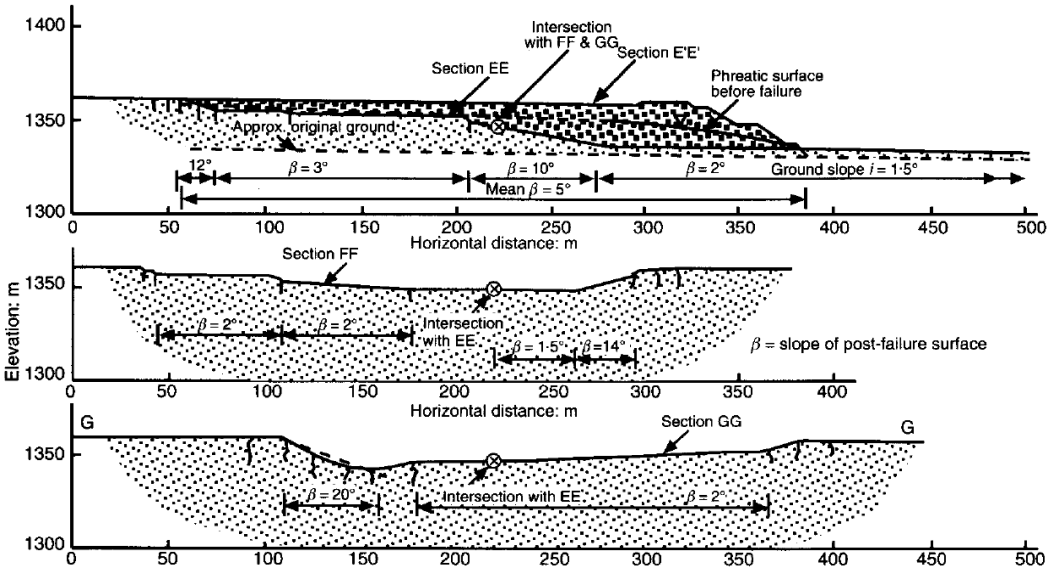

Figure 2: Failure surface, redrawn from Fourie et al. (2001)

The runout of the tailings is variously reported as between 1.2 km, 1.96 km, 2 km in 5 minutes, and 3 km (Wagener, 1997; Niekerk and Viljoen, 2005; Rana et al., 2021; Fourie et al., 2001). Some spreading parallel to the dam is evidenced in several pictures after the failure, appearing to be no more than twice the breach width. Evidence from damaged buildings points to a maximum thickness of the flow of 2.5 m at 300 m from the breach. Eyewitness accounts suggest the travel time to reach the maximum distance was approximately five minutes (Fourie et al., 2001).

From in-situ measurements (such as reported in Strydom and Williams, 1999), an in-situ void ratio of 0.8 appears to be representative of about the bottom two-thirds of the tailings. The critical state line and critical state friction angles are obtained taken from the triaxial tests conducted by Fourie and Papageorgiou (2001) on reconstituted samples from their M4 samples. The CSL fit is shown in Figure 4 (from Fourie and Papageorgiou, 2001). Comparing with the in-situ measurement of void ratio of 0.8, we can show the implied distribution of void ratio with mean effective stress by the choice of state parameter. The chosen state parameter values of 0.035 and 0.1 seem to bracket the reported void ratio of 0.8 for the range of effective stresses likely for the bottom 20 m of the impoundment. The remainder of the Norsand parameters are obtained by calibrating to the M4 triaxial experiments, using average values reported by Been and Jeffries (2015) as the initial parameter set. We find a good fit to these triaxial tests by only varying the H parameter, with all others kept at their initially assumed mid-range value.

Table 1: Calibrated and typical Norsand parameters

Parameters	Description	Calibrated Merriespruit	Typical range for sands/tailings
G_{ref}	Shear modulus factor	200	100-500
ν	Poisson's ratio	0.2	0.1-0.3
A	Exponent of the stiffness relation	0.5	Fixed
e_{cs0}	Critical state void ratio at p=0	0.8	Measured independently
λ	Slope of the critical state line	0.05	As above
M	Exponent of the critical state line	0.6	As above
M_{tc}	Critical state q/p' line at failure	1.58	As above
N	Dilatancy parameter	0.3	0.2–0.5
H	Hardening modulus	75	25-500; Estimated by 103-9810 ψ_0
X_{tc}	Hardening/softening coefficient	3	2-5

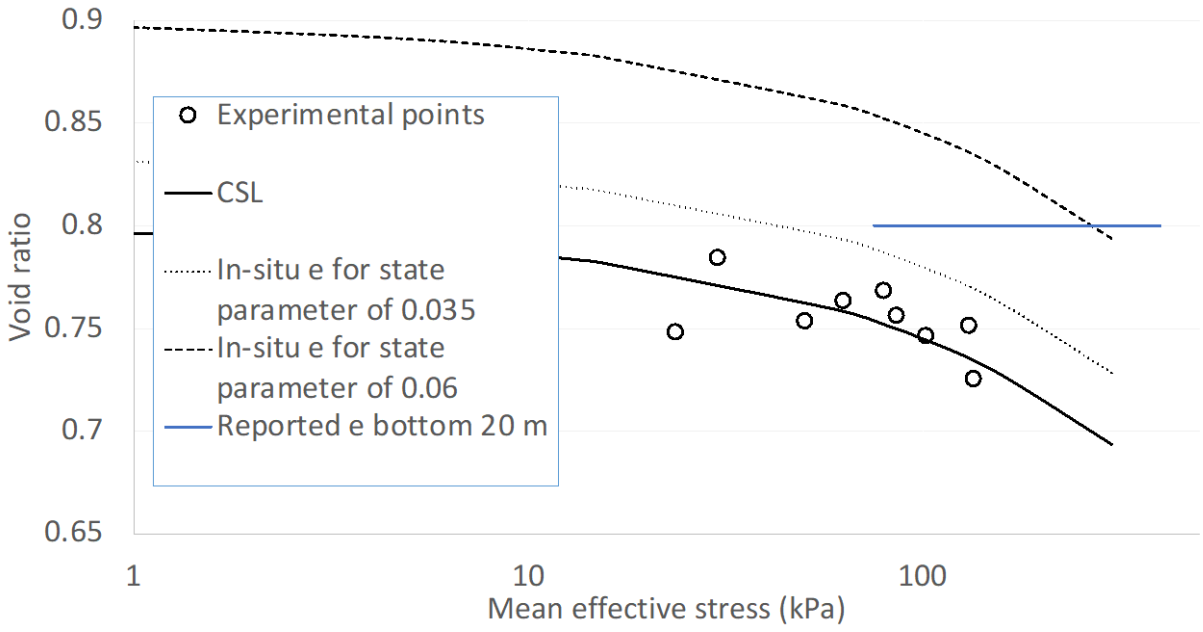

Figure 3: The CSL in e-p' space, the distribution of void ratio with effective stress implied by two different state parameters, and estimated void ratio in bottom 2/3 ratio of the impoundment

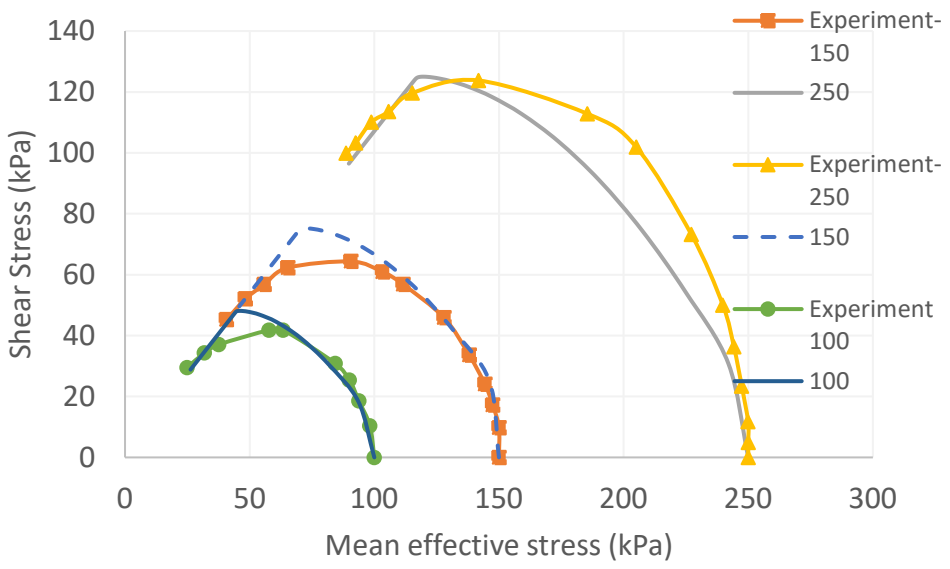

Figure 4: Calibration of Norsand using triaxial data on M4 samples from Fourie and Papageorgiou (2001)

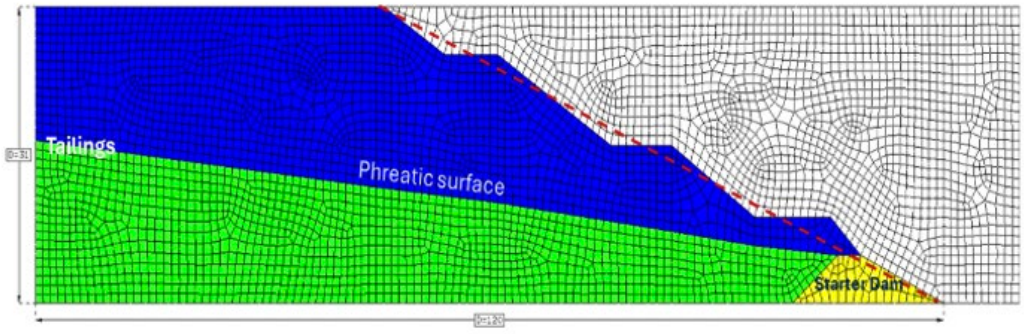
Model geometry and boundary conditions

The model uses a simplified version of the geometry. Except for the starter dyke, the whole of the section is modeled as the tailings, using the Norsand parameters. The starter dyke is modeled as a Mohr-Coulomb material with an initial friction angle of 30°. This is progressively reduced to initiate the failure, to simulate the erosion of the front dyke due the supposed overtopping trigger. The phreatic surface is a simplified version of initial surfaces estimated in other studies (e.g., Figure 2). The bottom boundary condition is fixed. The mesh size is in the order of 1 m, and it was not possible to substantially reduce the mesh size while keeping a stable model. The back boundary is fixed. The assumed geometry downslope from the toe is a plane that dips downwards at 1.5 °, for the whole distance of the flow. The presence of buildings or any other geometric features are ignored.



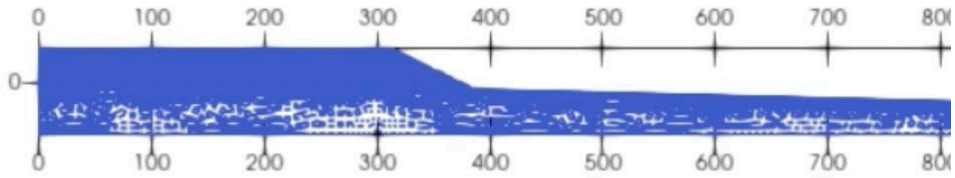


Figure 5: Idealized 2D geometry and mesh

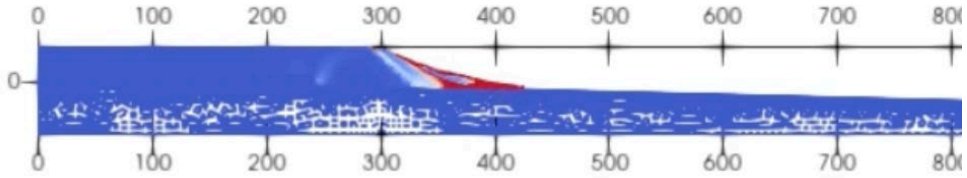
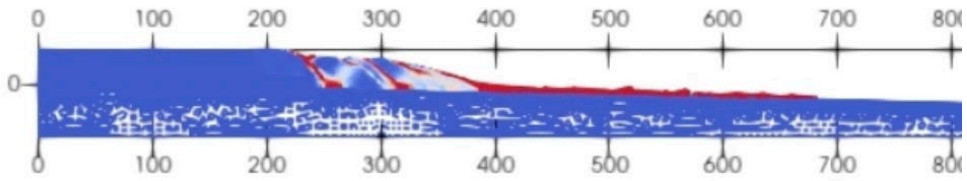


Results

We performed simulations using state parameters ranging from 0.02 to 0.1. We found a good reproduction of the postulated progressive failure geometry and the tailings mobilized during retrogression using a state parameter of 0.035. For lower values, the tailings do not retrogress to the same extent; for higher values the retrogression exceeds that reported; and for state parameters greater than 0.06 the whole deposit in the modeling domain is mobilized, with the runout not stopping before the domain boundary is reached.



The simulation for $\psi = 0.035$ is shown in Figure 6. The failure is progressive, showing an initial failure closer to the toe in Figure 6 (b), but then developing two additional slip planes father back from the original toe in Figure 6 (c). These slip planes result in two zones of unsheared tailings. Tailings mobilized by further retrogression seem to flow on top of these unsheared zones. Unlike the true event, the unsheared zones "trap" material between themselves and the eventually stable face of the post-failure impoundment. This is an artifact of the 2D model, and it is likely that fracturing in 3D would in reality allow the mobilized tailings to drain. The runout predicted for this state parameter is 550 m, much less the observed value (>1.2 km), but this trapping of the material obviously reduces the predicted extent.

Figure 6: Simulation for state parameter of 0.035, which has the best agreement with a) initial geometry; b) initiation of first flow slide; c) initiation of 2 more slip surfaces, material already mobilized flows in front of toe; d) shallow regression behind initial failures, tailings continue to flow on top of unsheared slope remnants; (e) final geometry, runout from the toe about 500 m; the remnants have been pushed about 25 m

Figure 7: Photograph showing the accumulation of material near the breach (photograph supplied by Andy Fourie, personal communication)

The accumulation of unsheared material seems to play a role in shaping the actual failure surface. The portion of the failure surface furthest back from the toe is very shallow, and it possibly remains shallow due to some stability imparted by the less sheared material in front. Again, the presence of unsheared material, or at least stronger material in the immediate area of the failure, seems to be clear in Figure 7.

The chosen initial state assuming $\psi = 0.035$ indicates a range of initial void ratio, most less than 0.8, but with a range in 10 kPa effective stress or less with $e > 0.8$. Given the formulation of the CSL, this material greater than 0.8 will never touch the CSL in undrained loading in e-p' space; though it will follow the M line in q-p' space, q decreasing as the tailings thin out during their flow. For reference, the critical state strength at $e = 0.798$ is 300 Pa, at $e = 0.775$ it is 20 kPa, at $e = 0.75$ it is 60 kPa.

Considering that this case has been modeled by rheometry models with yield stress of 300 Pa (e.g., Saeedi et al., 2022) or even less, this points to the tailings contributing to flow as those being in the relatively shallow zones of the impoundment. This would seem to also provide some indication of where to focus remediation /better control of deposition, given that the "dangerous tailings" are easily classified.

Interestingly, this also points to another explanation of the low runout. As can be seen from Figure 7, the zone of shallow failure behind the dam extends to a greater width than the breach, especially to the left from the perspective of the reader looking at Figure 7. Converted into a 2D situation, there would be a greater volume of shallow mobilized tailings, which could flow over the remnants and contribute to longer runout. As mentioned previously, in 3D the tailings trapped behind the remnants would likely be able to flow out and also contribute to longer runout. This requires further investigation: as pointed out by an

anonymous reviewer, 3D effects associated with the sides of the breach might have an inhibiting effect on the runout.

Summary and conclusion

To summarize the analyses and the discussion:

1. The Merriespruit failure was analyzed using MPM, employing the Norsand constitutive model in an undrained condition
2. The CSL in e-p' and p-q' space was determined using the M4 sample of triaxial tests undertaken by Fourie and Papageorgiou (2001).
3. Other plasticity parameters were obtained by starting with mid-range values and calibrating to measured triaxial stress paths. Agreement could be obtained with the mid-range values suggested by Been and Jeffries (1985).
4. A range of state parameters (0.035 to 0.1) were considered, based on the fitted CSL in e-p' space and the reported void ratio of 0.8 at depth by Strydom and Williams (1999).
5. Using 0.035, the nature and location of retrogressing failure surface could be well captured. Using higher state parameters pushed the retrogression back beyond what was reported. State parameters > 0.06 resulted in full mobilization of all tailings in the domain.
6. For the ψ=0.035 simulation, the runout is well short of the reported range (~ 500 m compared > 1.2 km). This is hypothesized to be an artefact of 2D conditions, such as the remnants of unsheared trapping in some of the mobilized tailings, which would be less likely to occur in 3D. Also, in the real failure, the shallow zone extended to greater width than the breach.
7. It is demonstrated that critical state theory implies that the shallow tailings would be the ones mobilized to larger distances, which is reproduced in the model.
8. It is clear that the shape of the CSL at low effective stresses will bear strongly on the generation of flowable tailings.

Abstract

The "failing forward" project is conducted at Carleton University and the University of Alberta to assess the risk of flowability and egress of clayey tailings off-site at different stages of the tailings facility (pre- and post-closure). The research is conducted using physical experiments at different scales (flume tests, multi-meter high prototype embankments, and centrifuge tests) to verify understanding of possible failure mechanisms and post-failure runout behavior. The physical experiments are interpreted using geotechnical and rheological characterization tests, in concert with a suite of numerical analysis tools. The latter includes both geotechnical and rheological based large deformation software. Preliminary results and analysis of experiments on both oil sands tailings and a soft clay analogue are reported.

Introduction

The "failing forward" project is conducted at Carleton University and the University of Alberta, funded by Canada's Oil Sands Innovation Alliance (COSIA), a research consortium of the oil sands surface miners. The goal of the project is to develop criteria for tailings flowability. Flowability can be defined as the capacity of tailings to flow substantial distances off-property in the event of breach, but also speaks to other safety hazards, such as those that might be encountered during reclamation, where a loss of strength may result in a serious accident, even though no breach occurs. The scope of the project is aimed at clayey tailings, similar to various treatments of oils sands fines dominated tailings, but also other clay tailings such as bauxite red muds.

The "failing forward" clause refers to experiments at various scales that physically model the failure of tailings. These experiments are required as the number of failures are relatively few, and/or not characterized sufficiently to establish criteria related to flowability on themselves. The physical experiments replace, in essence, large databases on well documented failures, that provide clear geotechnical information on what type of failure can result in landslides of substantial volume and runout. As an example, correlations have been developed for failures of Eastern Canadian Clays, as shown in Figure 1, in terms of sensitivity and remolded shear strength. The failures are divided into "retrogressive" and "landslides," the first pertaining to failures generating substantial runouts.

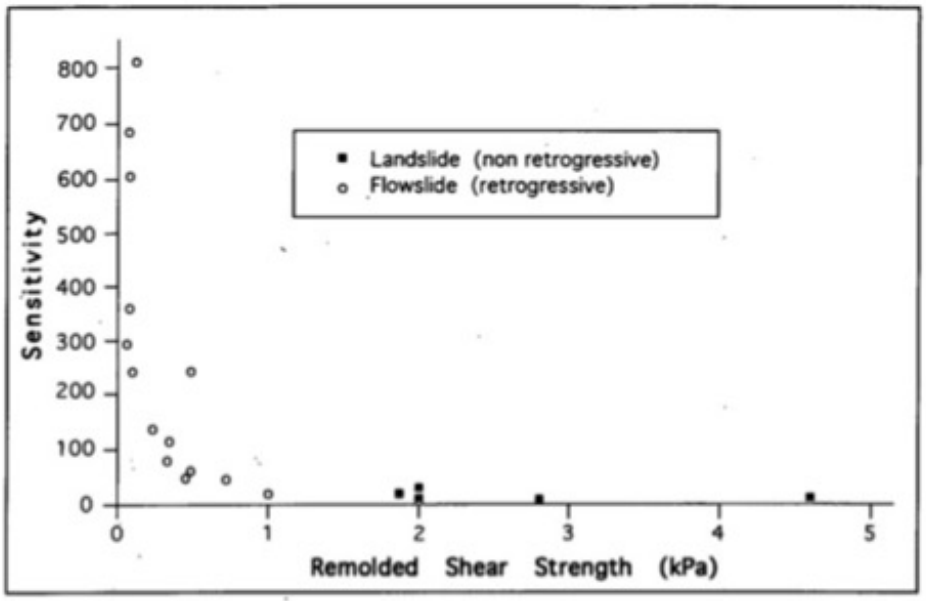

Figure 1: Example of a flowability criteria build on database of real slope stability failures (Lefebvre, 1981)

The different types of physical experiments are shown in Figure 2. Due to tailings availability, most tests on oil sands tailings are restricted to the flume and centrifuge experiments, with a clay analogue being used for the largest experiments.

The physical tests are then used as targets for different types of numerical simulations, including FLAC and material point methods (MPM) codes, incorporating both geotechnical and rheological constitutive models of varying complexity, supported by shear strength and rheology testing. Combining these physical tests and numerical analyses, we hope to better understand clayey tailings flowability. The characterization of tailings flowability is crucial for oil sands operators to design closure progression, to ensure minimal risks and/or consequences for long-term reclamation plans (Miller et al., 2022).

In this paper, we report select analysis on centrifuge and flume tests, using also a subset of numerical analyses.

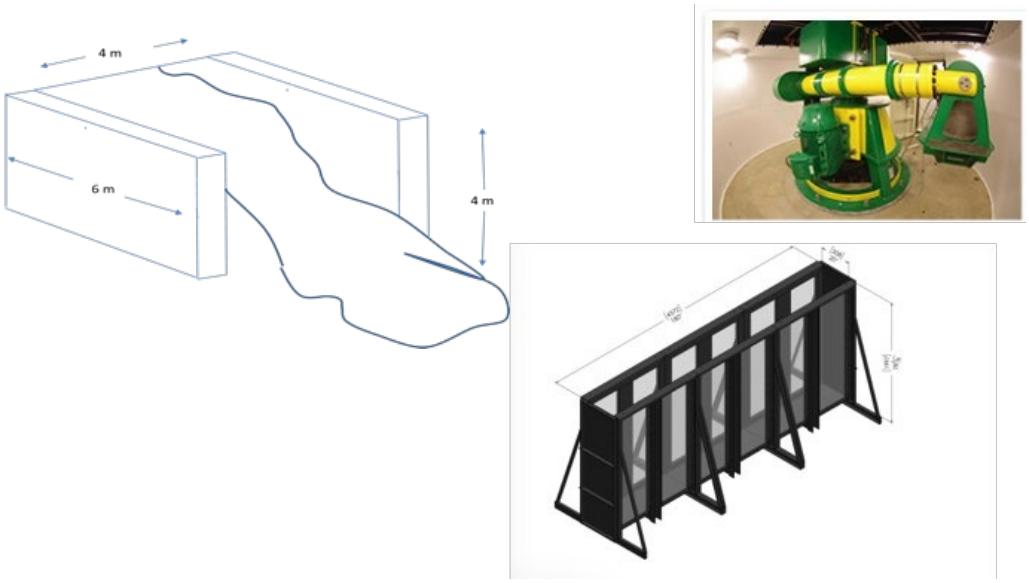

Figure 2: Physical models used in the project, including 4 m high test pit, 8 m long flume (bottom), and centrifuge tests in various configurations

Methods

Numerical models

In this paper, we show simulations using MPM codes, using two relatively simple constitutive models. Both models are explained in more detail in other publications (Saeedi et al., 2022; Simms et al., 2023). Both models essentially transition the material between a peak strength and a residual strength. In the geotechnical constitutive model (Mohr-Colomb Strain Softening or MCSS), strain softening occurs through accumulated plastic shear strain:

$$S = S_{residual} + (S_{\max} - S_{residual})e^{-\eta\varepsilon_{pd}} \quad \text{(Equation 1)}$$

Where S, the shear strength, is reduced from the peak value of S_{max} as a function of plastic shear strain (ε_{pd}), the limiting value being the residual shear stress $S_{residual.}$ The parameter η, the shape factor, regulates the decrease in strength with plastic shear strain. The shape factor can be obtained by fitting Equation 1 to element test data; however, the application of Equation 1 is affected by strain localization (Zabolotni et al., 2022), and therefore the shape factor that will predict a given runout distance may change with mesh size (Martinelli and Remmerswaal, 2023). One strategy to calibrate the shape factor is to simulate an element with the same mesh size as would be used in the failure and runout simulation.

In the rheology model (viscosity bifurcation or VBR), the change in shear strength is a result of incremental changes in the state of the model as a function of strain rate as opposed to accumulated shear strain. For low strain rates, the material will build structure and increase in viscosity and strength, the high strain rates, the material will disintegrate and viscosity and strength will degrade. Aside from the peak and

the residual shear strength, the model also requires rheology test data ,which provides i) the viscosity at the fully sheared state, and ii) rate of viscosity increase or decrease at a given strain rate. The VBR model is described more fully in Saeedi et al. (2022). Its practical advantage is its strain rate dependency limits issues of localization, and it is more stable in 3D. The geotechnical strain weakening model, however, is more intuitive to those with a geotechnical perspective.

Experiments

All of the tests reported employ Leda Clay as an analogue to clayey tailings. The LL and PL are 52% and 27% respectively, the clay mineralogy predominantly Illite (80%) with some Kaolinite (10%). Leda Clay, also called Champlain Sea Clay, is extensively studied in the geotechnical literature.

Here we report tests from a i) small flume tests, and ii) centrifuge experiments, as pictured in Figure 3. The flumes are 0.3 m high by 0.15 m wide, where a reservoir 0.3 m long is failed by gate lifting. The centrifuge experiment was tested at the 2-m radius beam centrifuge at the GeoCERF facility at the University of Alberta. The model was 0.3 m high, 0.3m wide, and 0.5 m long, with a bench 0.1 m long at the top. The embankment was failed when it was spun up to a prototype height of 2.8 m (18 g).

Figure 3: Picture of Flume Test 4

The flume tests are performed at water contents approximately 1.85 × LL, but are performed at different rest times. Each test has the same residual shear strength (0.265 kPs), but the peak shear strength varies with rest time. The shear strength development during the rest time is monitored by fall cone using. a special frame to allow testing of the surface of the material in the reservoir. This frame also allows for shear strength measurements in the tailings or clay after failure. Pore-water pressure is monitored at two depths as well during the rest time.

The centrifuge tests were performed at 1.1 × LL, and a rest time sufficient to generate a peak strength of 7 kPa, while the measured residual strength was 2 kPa. Peak strength, as well the strength in the flowed material after failure, was tested using a fall cone supported by a similar apparatus as in the flume tests.

To date, there are about twenty flume tests, and two centrifuge tests. Three of the flume tests have been performed on oil sands tailings, but all the remaining tests have been performed using Leda Clay. The tests reported in this paper are summarized in Table 1.

Table 1: Tests reported in this paper

Type of test	Rest time	Water content	Residual, peak strength (kPa)
Flume test 4	< 5 minutes	1.89 x LL	0.265, 0.27
Flume test 9	24 hours	1.86 x LL	0.28, 1.3
Centrifuge test 1	3 weeks	1.1 x LL	2, 7

Results

Flume test 4

The post-failure geometry of this test is shown in Figure 3. It is typical of such tests done on high water content / unconsolidated soft soils or tailings, the runout being higher than would be predicted by simple analytical methods based on yield stress alone (for example, see the lubrication theory equations in Henriquez and Simms, 2009), due to the momentum generated by the mode of failure. However, this test can be well-simulated by the MCSS model using the measured shear strength (peak strength = residual strength), as shown in Figure 4.

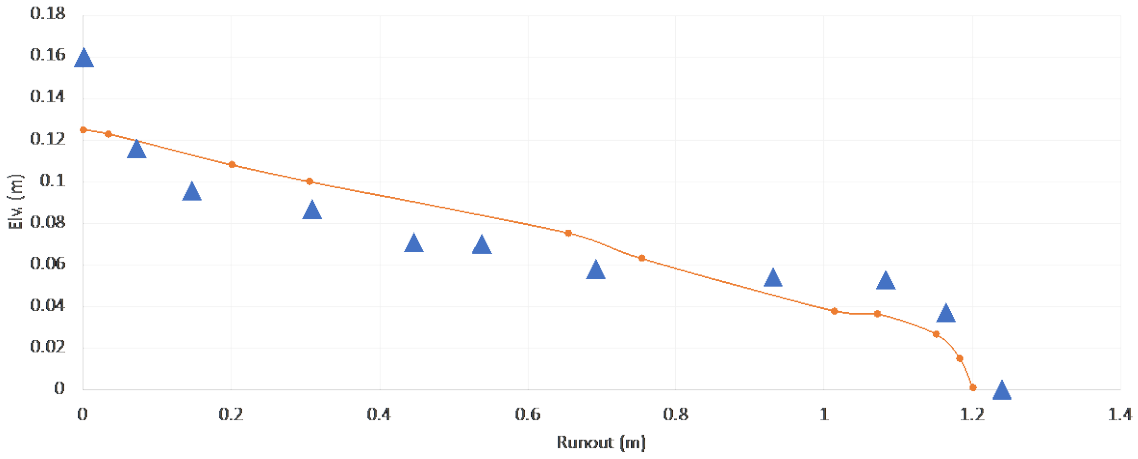

Figure 4: MCSS model simulation of Flume Test 4 using $S_{peak} = S_{residual} = 0.27$ kPa

Flume test 9

This test presents more complex behavior. Pictures of the flume test are shown in Figure 5 along with simulations snapshots at similar times using the MCSS model. The consolidation time of 24 hours has

generated sufficient peak strength that there are regions at the bottom and at the top that do not yield, and after initial yielding and deformation, a slip surface forms, and part of the top of the samples slides on this failure surface, some of it remaining effectively a rigid body, while the bottom part subsequently de-structures and joins the leading yielding material at the front of the toe.

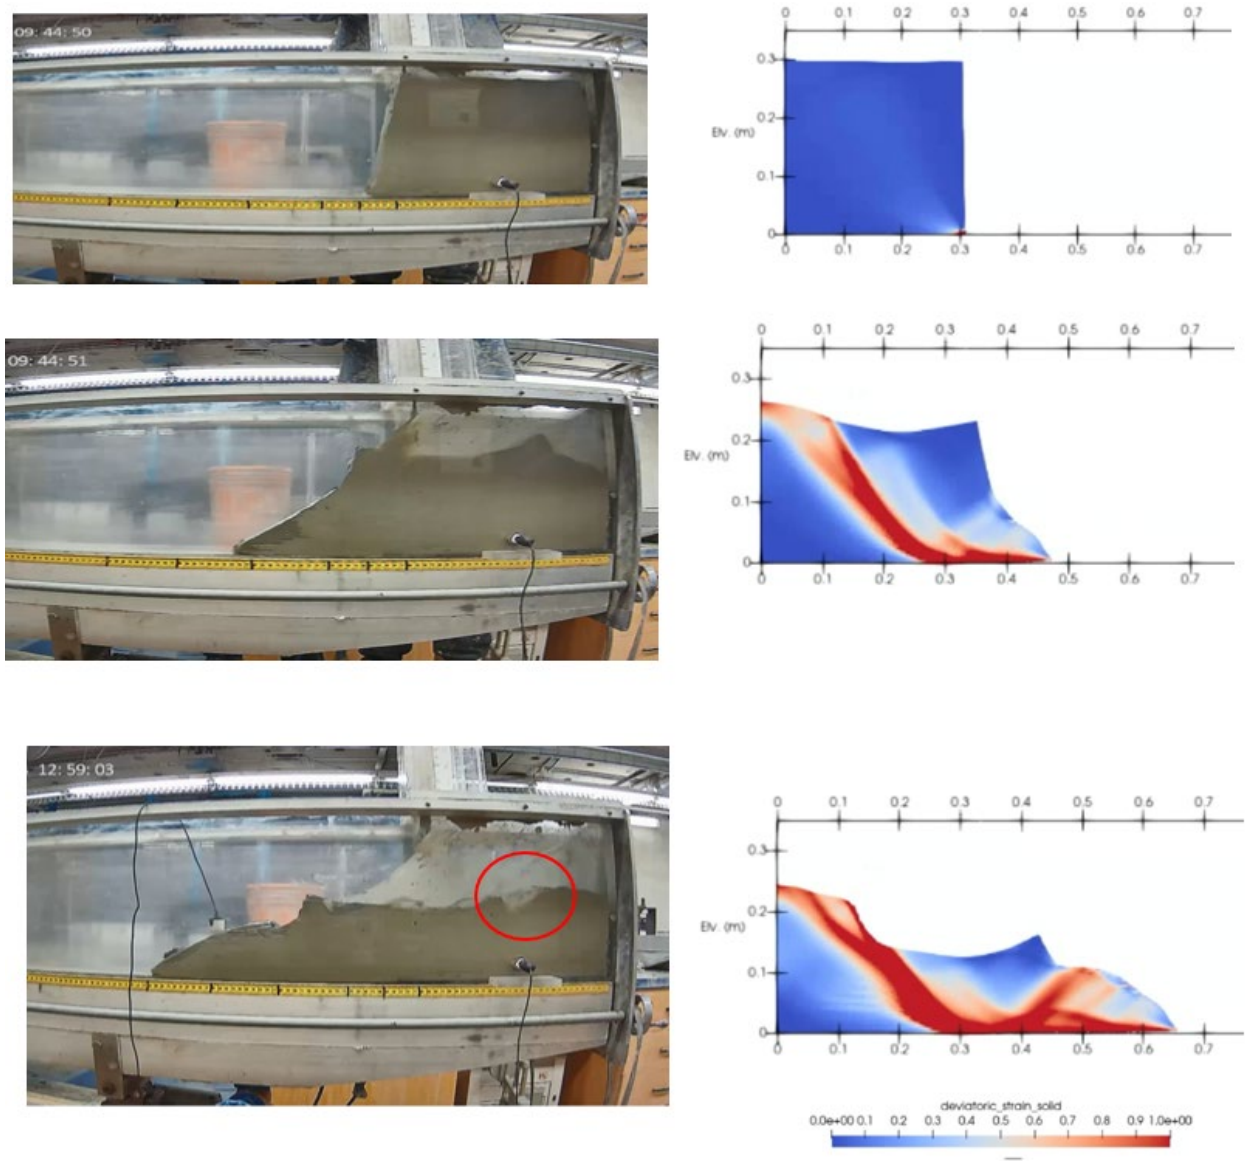

Figure 5: Pictures of Flume Test 9 paired with simulation results at similar times. MCSS model using a shape factor of 5

Most of this behavior is captured by the MCSS model, a notable exception is that the real material separates readily from the back wall, but this does not occur in the model, where the backwall is a boundary condition fixed in the x-direction. Still, the shape during failure, the final profile, and the runout are well-

captured by the model, as shown in Figure 6. The best agreement with runout is provided by a shape factor between 5 and 10 (Figure 7).

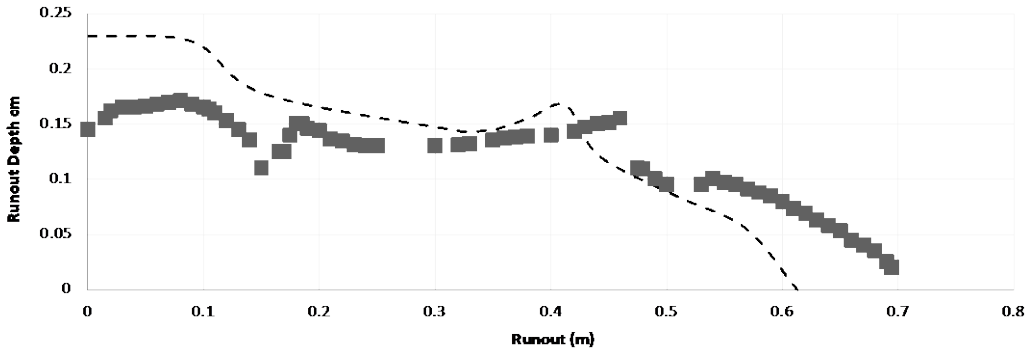

Figure 6: MCSS simulation of Flume test 9, final profile, shape factor of 5

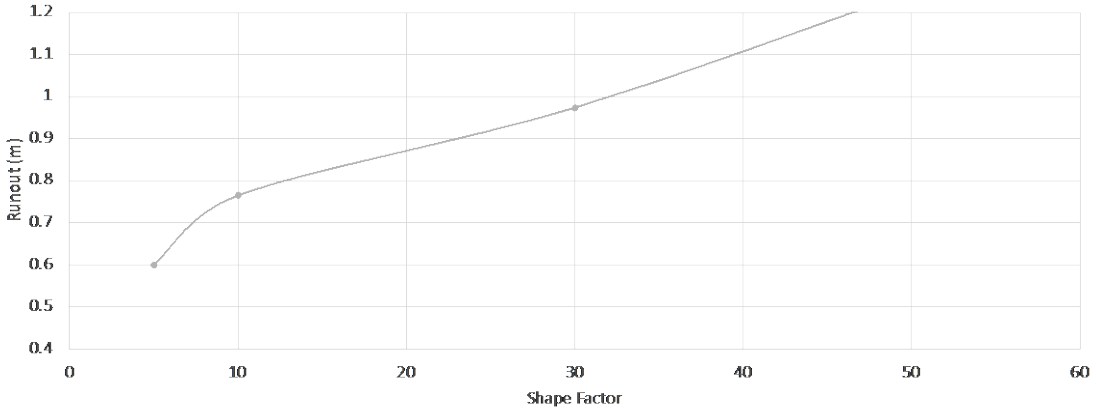

Figure 7: Sensitivity of runout to shape factor in simulations of Flume Test 9

VBR model

Figure 8 shows snapshots from the 3D VBR model. Its relative better stability and speed in 3D allow us to study effects such as the finite time of raising of the gate, and the influence of sidewalls. The raising of the gate time (< 0.5 s) makes very little difference compared to instantaneous removal (~ 1 cm of runout). The sidewalls, however, can have a significant influence, depending on what boundary condition is used. Using a no flow / full stick boundary condition could result in a decrease in runout by as much as 5 cm. However, as discussed later, this does not seem to be the case in the flume tests, where the effect of sidewalls was investigated experimentally.

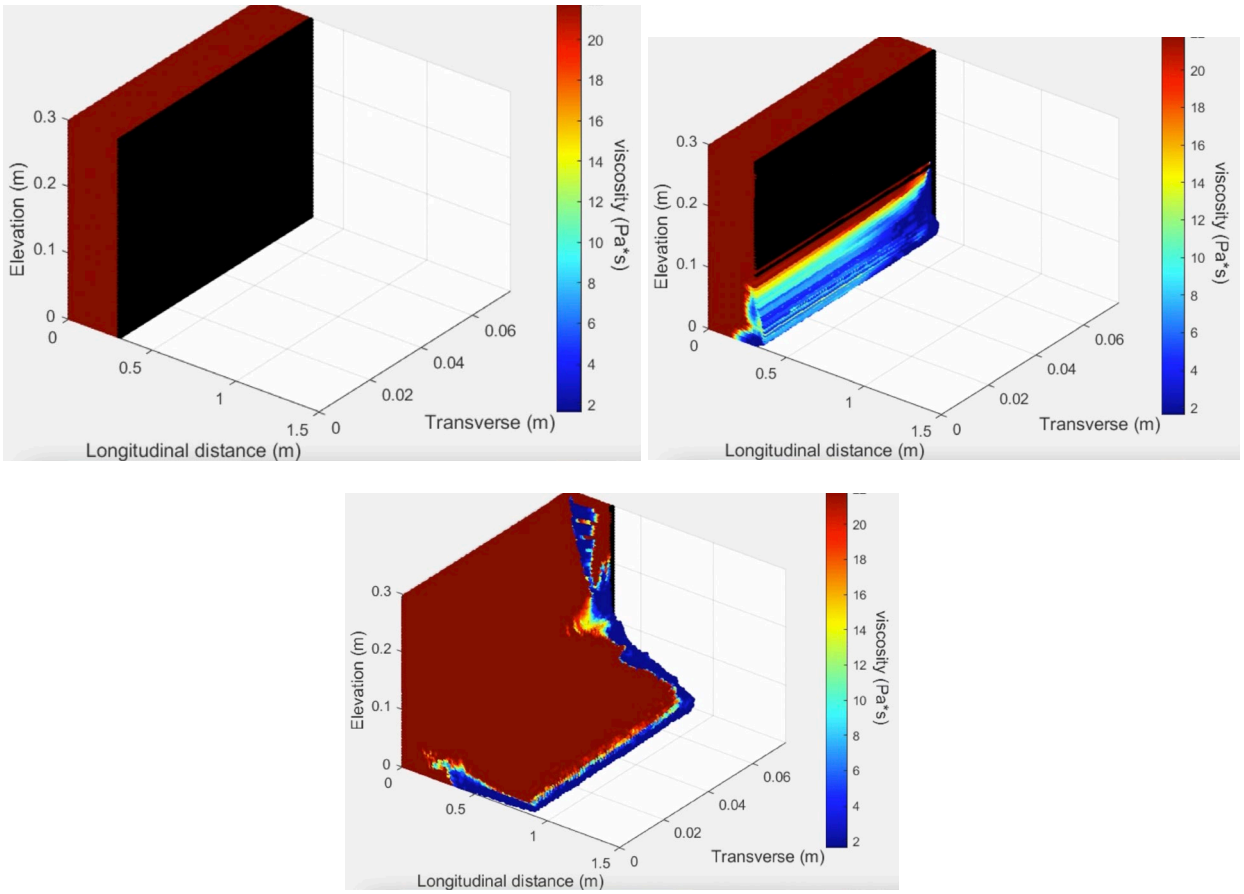

Figure 8: 3D rheology model simulation of flume test 4, showing its capacities to simulate raising of the gate, and simulation of the sidewall boundary conditions

Centrifuge Test 1

The centrifuge test, previously discussed in Saeedi et al. (2023), is shown in Figure 9 in its pre-flight and post-failure state. The reader should remember that the height is actually less than 0. 3 m, spun up to its prototype height of 2.8 m at the time of failure.

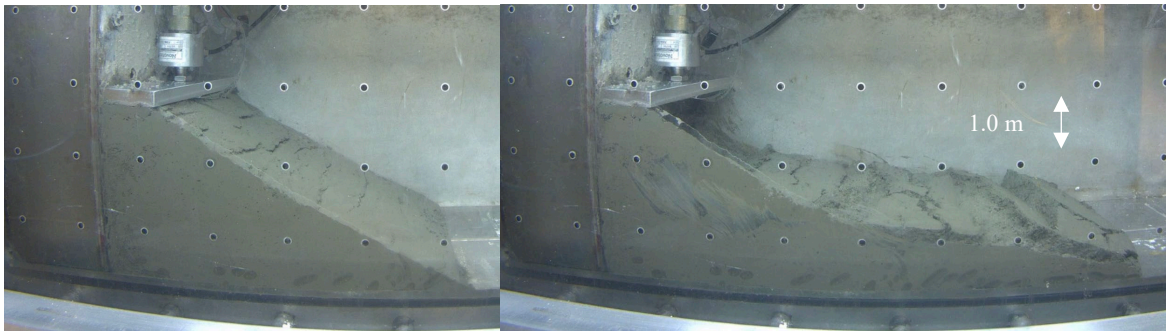

Figure 9: Centrifuge model test of aged clay at 1.2 LL, (2.8 m high, 5 m long with 1 m bench in prototype), intact strength 7 kPa, remolded strength 2 kPa

This centrifuge test experiences failure in a successive pattern, an original failure surface forming before much deformation occurs. and then after the tailings start to move, two successive shear bands or zones of shear bands form, coincident with the material farther from the toe stopping, while material towards the toe continues to move. This behavior is evident in the real tests by the large cracks that form at the surface. The behavior is replicated in the model, as evidenced by the pattern shown in Figure 10.

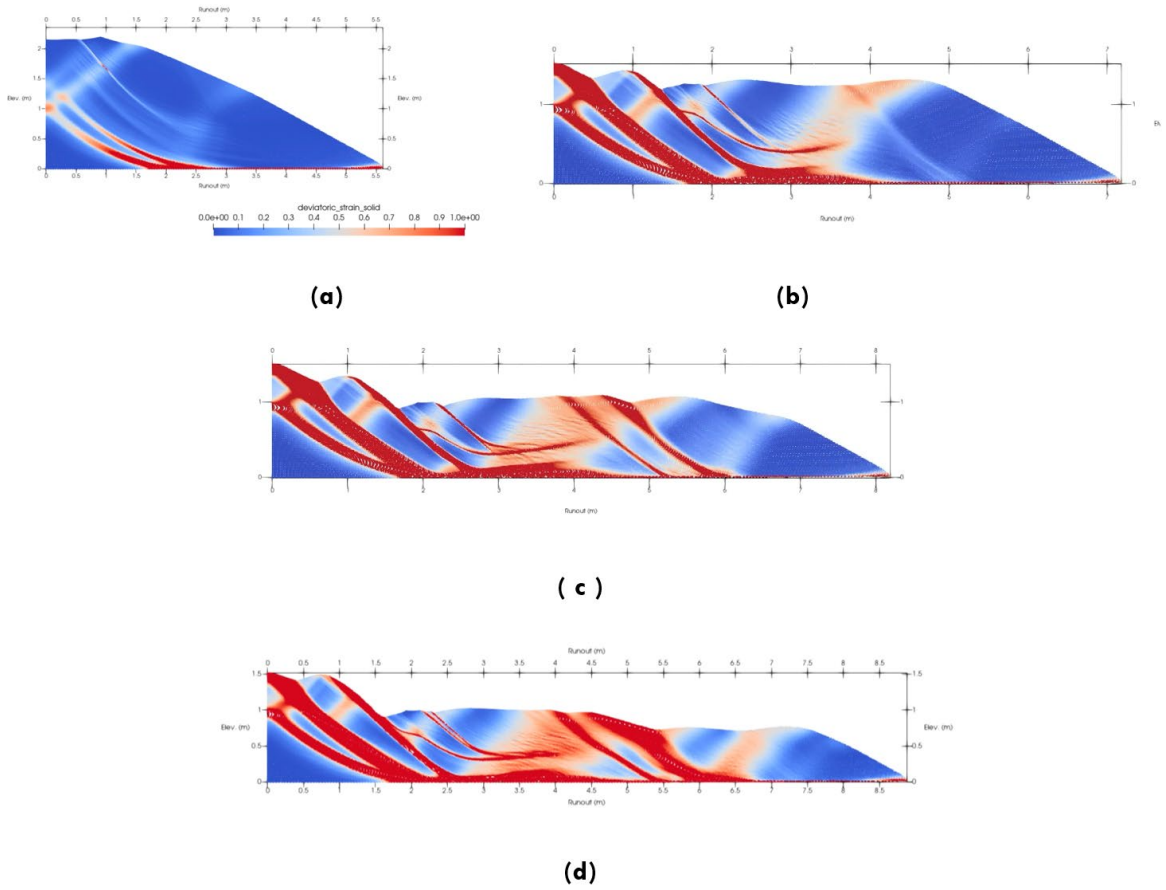

Figure 10: Best centrifuge simulation with MCSS , shape factor of 0.5 (a) initial shear band formation, (b) translation of material in front of initial shear band (c) formation of secondary shear bands (d) material in front of new shear bands translates, material behind has stopped

With the formation of the initial shear band, the whole material in front of the shear band moves, but then a secondary series of bands develops. Thereafter the material in front of the new shear bands continues to move, but the material between the old and new zones of shear bands stops.

This behavior is again quite different from the previous two flume tests. Here, the initially relatively stronger material experiences most of its deformation as successive translations of rigid body elements, sliding over relatively discrete shear zones. While Flume Test 4 experiences almost uniform degrees of shear strain, Flume Test 9 exhibits a combination of behaviors in Flume Test 4 and this centrifuge test.

Discussion on the shape factor

The flume test was best fitted with a shape factor between 5 and 10, while the runout in the centrifuge test was best fitted using a shape factor of 0.5 or 1. The higher range of shape factors in the flume test are more realistic: a value of 10 implies 2/3rd s reduction in strength by 10% shear strain, a value of 1 implies only a 10% reduction in shear strength by 10% shear strain. As discussed in Saeedi et al. (2023), it was thought that this low shape factor might be parameterizing the effects of the sidewalls. Evidence collected in the flume tests by varying width suggest minimal action by the sidewalls. However, the interaction between the clay and walls could be quite different for the initially stronger clay material in the centrifuge: investigations are ongoing.

Conclusions and ongoing work

Physical modeling studies are ongoing to study failure and runout at different scales, to properly characterize flowability in clayey tailings. Preliminary tests have used a well-studied clay as an analogue. The physical experiments have been interpreted using multiple models. In this paper, we report on the analysis of two flume tests and a centrifuge test using an MPM code using the MCSS model. The following conclusions are made:

1. The two flume tests and centrifuge test use material of different initial water contents, and different "rest times" to change the sensitivity as a function of consolidation. All three tests exhibited distinct behaviors as a result of these differences. The weakest material yielded throughout homogeneously, whereas the strongest material was dominated by translation of zones of unyielding material over discrete shear bands.
2. The relatively simple MCSS model could replicate the qualitative evolution of shape in all these tests, despite these strong differences in initial state and consequent behavior.
3. The flume tests runout is best replicated by a shape factor of 5 to 10, while for the centrifuge this value was 0.5 or 1. This large discrepancy is thought be due to substantial interaction with the sidewalls in the centrifuge test where the material is stronger, but this requires further investigation.

Ongoing and future work includes expanding the physical tests to larger tests in 1 g (up to 3 m height) as well as much larger prototype heights in the centrifuge. Modeling work includes simulation of the expanding database of physical tests with the suite of models already described, but also beginning to use critical state models for clays (such as the SCLAY family) to compare with the straightforward but relatively simple MCSS model.

Abstract

The mining industry is constrained by available qualified professionals to perform detailed risk assessments for tailings storage facilities. As such, a suite of simple spreadsheet models and guidance to support assessment of tailings dam risk using a combination of failure statistics and engineering judgment is being developed by the authors. The objective of this work is to complement expert-based quantitative or semi-quantitative risk assessment methods and accelerate the adoption of risk-informed decision making in all phases of tailings dam management. Designers and dam owners can apply this framework to improve consideration of risk in site selection and preliminary design; support rapid screening and prioritization of large portfolios of dams; inform expert-based assignments of failure mode probabilities; help assess the reasonableness of risk assessment results generated using more rigorous methods; and inform the range of dam breach analysis scenarios that should be conducted in consideration of the risk drivers.

The current work, and the focus of this paper, is estimating tailings release volume using a statistical approach to assign preliminary probability distributions of the release volume by failure mode. Guidance is provided for adjusting the baseline release volume distributions according to site conditions, such as impounded tailings volume, pond volume, liquefaction susceptibility, dam height, fill materials, and dam configuration.

Introduction

Best practice guidance for the tailings dam industry includes requirements to perform and regularly update risk assessments, including identification and characterization of potential failure modes (Global Tailings Review [2020] and International Commission of Large Dams [ICOLD, 2022]). Best practices have been adopted from the water dam industry and include expert-based quantitative or semi-quantitative risk

assessment; however, these efforts are constrained by limited availability of personnel with the required expertise to support assessment for the global inventory of tailings storage facilities (TSFs), which exceeds 20,000 (Rana et al., 2022). In addition to the number of TSFs that require an assessment, substantial effort is needed to prepare each risk assessment, including conducting tailings dam breach assessments (TDBAs) that allow for the evaluation of consequences associated with the potential failure modes.

While there is industry guidance to base a TDBA on so called "credible flow failure scenarios," they are often based on conservative assumptions leading to results representing "worst-case" scenarios that manifest the most extreme consequence. This approach does not lend itself well to the risk assessment process as it focuses only on a single scenario. To support a risk assessment, TDBAs would need to be performed for each failure mode, or at least the risk driving scenarios, recognizing that the probability associated with each failure mode is unique and dam breach characteristics related to each failure mode vary.

Considering these constraints, there is a need to develop tools to assist with the risk assessment process associated with TDBAs. Previous work by Porter et al. (2023) involved the development of a screening-level tool to support expert-based assignment of probability of failure estimates for common failure modes. This work included developing simple spreadsheet models based on review of recent publications on tailings dam inventories and failure databases (including Rana et al., 2022; Stark et al., 2022). Baseline failure probabilities by dam raise method and failure statistics were then used to identify the average relative contribution of common failure modes to the total probability of failure. Guidance is provided to adjust the industry-average probability of failure estimates based on site conditions, design criteria, and level of governance practice.

Expanding on the work by Porter et al. (2023), the authors have developed a framework for an extension of this screening-level tool to support the selection of tailings dam breach volumes to assist with screening-level assessments and TDBAs. The statistical approach outlined by Porter et al. (2023) has been adopted to assign a preliminary baseline probability distribution to release volumes for common failure modes. Preliminary guidance has also been developed to adjust the baseline release volumes according to site conditions, which is described in this paper.

This work is part of an overall screening-level risk tool envisioned by the authors to complement expert-based quantitative or semi-quantitative risk assessment methods and accelerate the adoption of risk-informed decision making in all phases of tailings dam management. The probability of failure and probabilistic release volume tools can feed into other simplified models to estimate runout extents and flow velocity, providing a spatial probability estimate. Combined with other exposure models, life loss and economic loss could be estimated, leading to an estimate of total annualized risk that can be plotted on a

plot of frequency of event vs. number of fatalities (i.e., F-N) and compared against established risk tolerance criteria.

Development of preliminary baseline probability distributions for dam breach release volume by failure mode

While statistical relationships for TDBA release volumes have been explored by others (including Rico et al., 2008; Larrauri and Lall, 2018), few have explored the relationship between release volume and failure mode. This has, however, been recently explored by Lin et al. (2022) who present proportion of sand burst (proportion of released volume to impounded volume, referred to as release volume proportion hereafter) by common failure modes, as shown in Figure 1.

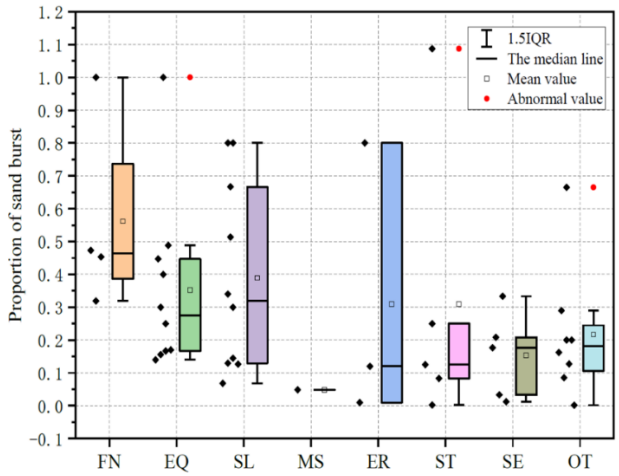

Figure 1: Dam breach release volume proportion by failure mode, as reported by Lin et al. (2022). Failure modes include Foundation (FN), Earthquake (EQ), Slope Instability (SL), Mine Subsidence (MS), Erosion (ER), Structural (ST), Seepage (SE), and Overtopping (OT)

The data by Lin et al. (2022) has been used in conjunction with expert judgement to develop baseline probability distributions for dam breach release volume proportions for each failure mode. For this work, the authors have adopted a Beta probability distribution using the dam failure data summarized by Lin et al. (2022), which was chosen because it is bounded between 0 and 1, and due to its flexibility in shape. These baseline distributions are summarized in Table 1 and are considered preliminary for the purposes of developing the framework for the screening-level tool. Future work is planned to use an expanded dataset, and to use a more objective implementation of expert judgement such as through Bayesian statistics.

The Beta family of distributions is defined by two parameters, $\alpha > 0$ and $\beta > 0$, and has density

$$f(x) = \frac{x^{\alpha-1}(1-x)^{\beta-1}}{B(\alpha,\beta)}$$

for $0 < x < 1$, where $B(\alpha, \beta) = \Gamma(\alpha)\Gamma(\beta)/\Gamma(\alpha + \beta)$ is the beta function, and $\Gamma(z) = \int_0^\infty t^{z-1}\, exp(-t)\, \mathrm{d}t$ is the gamma function for $z > 0$. When compressed to have a minimum of x^* and a maximum of 1, the density function becomes

$$\frac{1}{1 - x^*} f\left(\frac{x - x^*}{1 - x^*}\right).$$

Table 1: Parameters (α, β, minimum) defining the Beta distributions for release volume proportion for two failure modes under consideration for this paper. The median and interquartile ranges of the distributions are also included

Failure mode	α	β	Minimum	Median	Interquartile range
Foundation (FN)	2.40	3.88	0.25	0.53	0.43 – 0.63
Overtopping (OT)	1.86	4.31	0.01	0.29	0.18 – 0.42

Development of preliminary guidance to adjust baseline volume distributions for site-specific conditions

Guidance was developed to adjust the baseline dam breach release volume proportion distributions for site-specific conditions. A preliminary list of site conditions was developed based on judgement and includes impounded tailings volume, pond volume, liquefaction susceptibility, dam height, fill materials, and dam configuration. These conditions were incorporated into 4 site factors as summarized in Table 2. Preliminary guidance has been developed for each site factor relating to foundation and overtopping failure modes. These failure modes were selected for initial development of the tool as they are commonly investigated failure modes and some of the site factors, specifically dam fill configuration, affect each quite differently.

Table 2: Site factors

Site Factor	Inputs	Description
Release Potential	Impoundment Volume (V), Dam Height (H)	Adopted from Piciullo et al. (2022) and provides an indication of the release potential during a breach. A high dam doesn't necessarily mean a large release potential if there is a small impoundment volume behind it, and vice versa: the potential is dependent on both variables.
Liquefaction Susceptibility	High, Low	Based on tailings susceptibility to liquefaction and provides an indication of tailings mobility. Preliminary estimates are based on judgement of how much of the tailings deposit is contractive, and how high the phreatic level is within the deposit.
Pond Ratio	Surface Area (Pond, Impoundment)	Defined as pond surface area ÷ impoundment surface area. This factor relates to the erosional potential to transport tailings sediments from the deposit through the failure process. If tailings liquefaction susceptibility is low, then pond ratio becomes a factor.
Dam Type / Fill Configuration	Construction Method (Upstream, Centerline, Downstream, Water Retention); Fill Material (Tailings, Rockfill, Earthfill)	Considers construction methods and dam fill materials and configurations that are typically used with each method. Different configurations have different susceptibility to failure, and corresponding magnitude, especially for failure modes involving erosion.

Scaling factors are proposed as a method of adjusting a baseline distribution of release volume proportion, V_U. However, as V_U cannot be scaled without potentially exceeding the 100% release proportion limit, the *release volume excess ratio,* V_E is scaled, which is the release volume (V_U) divided by the volume not released ($1 - V_U$), as shown below. After scaling, the release volume proportion can be back-calculated.

$$V_E = \frac{V_U}{1-V_U} \quad \text{(Equation 1)}$$

The baseline volume (V_U) distributions for the foundation and overtopping failure modes, as developed from the data provided by Lin et al. (2022), are shown in black in Figure 2. Distributions of V_U after scaling V_E by 0.5 and by 2 are also shown. Scaling by 0.5 moves the baseline distribution towards smaller values, while scaling by 2 moves the baseline distribution towards larger values. Note that the scaled distributions are no longer Beta distributions.

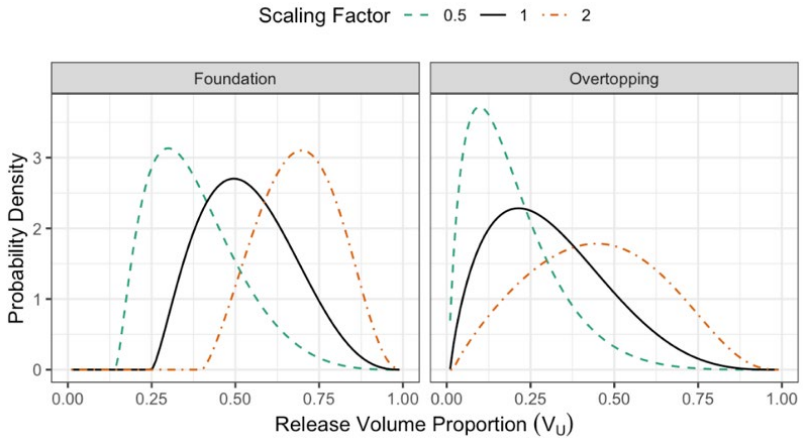

Figure 2: Preliminary probability distributions for dam breach release volume proportion by failure mode based on data provided by Lin et al. (2022). Baseline distributions are presented in black. Adjustment to baseline distributions by applying a scaling factor of 0.5 and 2 are also presented

At this stage of the development of the tool, the objective was to develop a framework for which scaling factors could be developed for each site factor. Scaling factors presented in this paper have been developed using a combination of empirical evidence (Piciullo et al., 2022) and engineering judgement, and require refinement as part of future work. Specifically, the selection of site conditions, inputs, and scaling factors should be refined through discussion with subject matter experts. Additionally, scaling factors should be refined following a process that involves testing the tool on tailings dam failure case histories. The baseline distribution should also be refined (narrowed) to more accurately represent sites with a scaling factor of 1, rather than representing the full spread of release volume proportions. This can be achieved through investigation of the residuals of a regression analysis for the failure database used to develop the baseline probability distributions.

Scaling factors developed for the proposed site factors (Table 2) are presented in the following sub-sections. The geometric mean of the four scaling factors is proposed to be considered for adjusting the baseline release volume proportion distributions for site-specific conditions, akin to an ensemble mean of four separate models. The resulting distribution of V_U is then issued as the predictive distribution, and the median is taken as a deterministic prediction.

Release potential

An empirical relationship of release volume (R in m^3) was established by Piciullo et al. (2022) using the impoundment volume (V in m^3) and dam height (H in m), which has been used to inform a preliminary empirically-driven scaling factor for the release potential. The relationship is

$$log_{10} R = 0.330 + 0.611\, log_{10} V + 0.944\, log_{10} H + \varepsilon. \quad \text{(Equation 2)}$$

The non-ε terms make up the mean log release volume, whereas the ε term is a random variable capturing the volume distribution with mean zero. To inform the scaling factor, the release volume excess ratio V_E, has been defined as

$$V_E = \frac{\mathrm{R}}{\mathrm{V-R}}. \quad \text{(Equation 3)}$$

Scaling factors can be calculated for sites with different dam heights and release volumes as the site-specific predicted V_E divided by the average predicted V_E across all sites considered in the failure database used to generate the baseline probability distribution, as

$$\text{Scaling Factor} = V_{E,\text{Site-Specific}}/V_{E,\text{Average}}. \quad \text{(Equation 4)}$$

Further work is required to improve the empirically driven scaling factor for the release volume, such as limiting release volumes to less than or equal to the total impoundment volume, which has not been accounted for in the relationship developed by Piciullo et al. (2022).

Liquefaction susceptibility

Preliminary scaling for liquefaction susceptibility is determined using engineering judgement. If the tailings are highly susceptible to liquefaction, then scaling factors of 2 and 1.5 are applied as preliminary scaling factors for foundation and overtopping failures, respectively. The authors judged that the release volume proportion for tailings susceptible to liquefaction would be higher for a foundation failure, compared to an overtopping failure. The rationale is that a foundation failure results in a sudden loss of confinement, and with that, liquefiable tailings would become very mobile. Overtopping failures generally tend to be more gradual with a progressive loss of confinement, and so may result in tailings being less mobile. These values could be refined by adding more granularity to the scaling range based on estimated percentages of contractive tailings within an impoundment and the degree of saturation.

If the liquefaction susceptibility of tailings is low, then no scaling factor is proposed. In this case, the pond ratio site factor should be considered, as described in the next section.

Pond ratio

The volume of tailings that may be released during a potential dam breach is influenced by the size and location of ponded water stored withing the TSF. Generally speaking, the volume of tailings released increases as the volume of stored water and/or the ratio of pond area to tailings area increases as the stored water provides increased erosive effects, increasing tailings mobility, during the breach. Furthermore, the closer the pond is to the TSF dam the larger the release potential becomes. Integrating the scaling relationship associated with pond location is outside the purview of this work. Instead, the authors focused on developing a relationship between pond area versus tailings surface area. Proposed scaling factors are presented in Table 3.

Table 3: Site-specific input assignment

Pond Ration (PR)	Scaling factor	Comment
PR<0.1	0.5	A low PR suggest lower release volume proportions
0.1<PR<0.4	1	Considered to represent average conditions
0.4<PR<0.8	1.5	A higher PR suggest higher release volume proportions
0.8<PR<1.0	2	

It was assumed that the same pond scaling factors can be used for foundation and overtopping failure modes. Future work will explore the efficacy of the proposed scaling factors over the range of possible pond ratios.

Dam type/fill configuration

Dam fill configurations were considered for upstream, centerline, and downstream construction methods, as well as water retention dams, which typically do not have a tailings beach present (Table 4). Judgement was used to assign relative rankings based on how susceptible the configuration is to external erosion. A downstream-constructed dam zoned with a rockfill shell is deemed to be the least susceptible, whereas an upstream-constructed dam with a tailings shell is deemed the most susceptible. Preliminary scaling factors for overtopping are proposed to range from 0.5 to 2 as presented in Table 3. No scaling factor is proposed for the foundation failure mode, as in this case the full dam is involved in the failure process and therefore assumed not susceptible to subsequent erosional processes.

Table 4: Dam type/fill configurations and preliminary scaling factors

Dam type	Dam fill configuration	Preliminary scaling factor
Upstream	Tailings Shell	2
	Rockfill Shell	1.7
	Wide Compacted Tailings Zone	1.3
Centerline	Tailings	1.5
	Earthfill	1.0
	Zoned with Rockfill Shell	0.7
Downstream	Tailings	1.3
	Earthfill	0.8
	Zoned with Rockfill Shell	0.5
Water Retention Dam (No Beach)	Earthfill	1.2
	Zoned with Rockfill Shell	0.8

Example use of probabilistic release volume tool

The following section presents results using the preliminary probabilistic release volume tool for three tailings dam failure case histories: Mount Polley, Brumadinho, and Merriespruit. These failure case histories were selected considering they are well-documented and represent a range of release volume proportions from failure modes of focus within this framework development.

Compared to the failure case histories in Lin et al. (2022), Mount Polley represents a typical foundation failure (FN), that had a pond present at the time of failure; the resulting outcome of the failure was a large volume; however, it is generally a lower value within the range of release volume proportion for this failure mode.

Brumadinho is considered a relatively extreme failure case study in that a high release volume proportion occurred, even with no pond present in the impoundment. Although this failure is categorized as a slope instability (SI) failure mode, the authors have included it for this assessment and consider it reasonable to compare as a foundation failure (FN).

Merriespruit represents a typical overtopping failure (OT) and although it had catastrophic consequences, it had a relatively low release volume proportion for the failure mode.

Table 5 summarizes the site-specific input assignments for each dam and Table 6 presents the calculated scaling factors following the framework presented in this paper, along with the resulting median estimated release volume proportion compared to the actual release volume proportion reported in case history literature.

Table 5: Site-specific input assignment

	Mount Polley	Brumadinho	Merriespruit
Impoundment Volume, V (Mm^3)[1]	74	12	7
Dam Height, H (m)	40	87	31
Liquefaction Susceptibility	Low	High	High
Pond Ratio	0.4 – 0.8	0 – 0.1	0.4 – 0.8
Dam Type	Centerline	Upstream	Upstream
Dam Fill Configuration	Zoned with Rockfill Shell	Tailings Shell	Tailings Shell

Table 6: Preliminary results for three tailings dam failure case histories

		Mount Polley		Brumadinho		Merriespruit	
		FN	OT	FN	OT	FN	OT
Release Potential	Release Volume, R (Mm^3) (Eq. 2)	5.4		4.4		1.1	
	Release Volume Excess Ratio, V_E (Eq. 3)	0.08		0.58		0.15	
	Release Volume Proportion, V_U (Eq. 1)	0.07		0.37		0.13	
Scaling Factors	Release Potential (Eq. 4)	1.0	0.9	7.7	6.6	2.1	1.8
	Liquefaction Susceptibility	1	1	2	1.5	2	1.5
	Pond Ratio (Table 3)	1.5	1.5	1	1	1	1
	Dam Type / Fill Configuration (Table 4)	1	0.7	1	2	1	2
	Combined Scaling Factor (Geometric Mean)	1.12	0.99	1.98	2.11	1.43	1.52
Predictions after Scaling	Release Volume Proportion, V_U (median, Interquartile Range)	0.55 (0.46–0.66)	0.28 (0.17–0.42)	0.69 (0.60–0.77)	0.46 (0.31–0.60)	0.61 (0.52–0.71)	0.38 (0.24–0.52)
	Release Volume, (Mm^3)	41	21	8.3	5.5	4.3	2.7
Reported from Case Histories	Actual Release Volume Proportion	0.32		0.80		0.09	
	Predicted Exceedance Probability	0.99	0.43	0.18	0.04	1	0.96
	Actual Release Volume (Mm^3)	23.6		9.57		0.6	
	Failure Mode	FN		SI		OT	

[1] The convention 1 $Mm^3 = 10^6$ m^3 is used here, as opposed to the metric system convention, following common use in the industry.

Model performance can be evaluated through investigation of exceedance probabilities. These are calculated as the predicted probability of exceeding the observed V_U; if f is the predictive (scaled) density function, then the exceedance probability is $\int_{V_U}^{1} f(x)\mathrm{d}x$. If predictive distributions are calibrated, then exceedance probabilities should be uniformly distributed. Table 6 shows that exceedance probabilities tend to be closer to 0 or 1, indicating the need for further calibration of expert judgement and integration of data. Despite this, predictions are more certain than random guessing (i.e., the Uniform distribution), as seen from the interquartile ranges spanning roughly 0.2 to 0.3 units compared to the Uniform distribution's 0.5. A metric to consider during the refinement stage is the Continuous Ranked Probability Score, which combines calibration with prediction certainty.

The probability distribution from the tool produces an exceedance probability of nearly 100% compared to the actual value for Mount Polley, which is expected considering the failure was at the lower bound of release volume proportions in the failure case dataset.

The predicted value for Brumadinho (using a foundation failure for simplicity in this framework) is lower than the actual value, but it is recognized that Brumadinho was considered a relatively extreme failure scenario. The probability distribution from the tool produces an exceedance probability of 18% compared to the actual value, which aligns with the expected result.

The predicted value for Merriespruit is higher than the actual value, with a corresponding 96% exceedance probability compared to the actual value.

These values, in general, are considered reasonable though they do suggest additional refinement of the scaling factors should be completed through comparison to additional failure case studies. Additional refinement can be achieved by considering additional site factors in case the selected ones are not sufficient at capturing the characteristics of failure case. Additionally, other interaction effects may need to be considered; for instance, in the current model, the pond ratio effect is only applied when liquefaction is low.

Discussion

Applications

This paper outlines the authors vision to develop a screening-level risk tool which could be used to support improved consideration of risk in site selection and preliminary design, rapid screening and prioritization of large portfolios of dams, and assessment of the reasonableness of risk assessment results generated using more rigorous methods.

Independent of full risk screening, the probabilistic release volume tool has some interesting applications, including informing the range of TDBA scenarios that should be conducted in consideration of the risk drivers. The probabilistic release volume tool when used in combination with the previously

developed probability of failure calculator (Porter et al., 2023) can help identify the risk driving breach scenarios and prioritize the number of TDBA scenarios. For example, depending on the unique site conditions, the probability of failure due to a foundation and seepage failure may be identified as contributing the most to the dam's overall total annual probability of failure. Based on the estimated dam-specific release volume distributions for these two failure modes, one may observe that the release potential for a foundation failure is significantly greater than for a seepage failure. This could allow for an informed decision to prioritize assessment of the foundation failure mode, Additionally, generating probability distributions for release volumes allows practitioners to make informed decisions on what release volume to use in a TDBA, such as the 50^{th} or 90^{th} percentile, based on a consideration of uncertainty in characterizing the failure. This method also highlights the full range of release potential rather than relying on average values as is often seen in current practice.

Further work is also planned by the authors to extend the tool to include a probabilistic framework for breach hydrograph development as discussed in the following sub-section.

Extending to a probabilistic breach hydrograph framework

While there is uncertainty associated with characterizing credible failure modes and mechanisms (especially in absolute terms), the physical processes that lead to a failure are generally understood. However, the way in which the failure evolves and releases stored material is complex and still a maturing science (Clohan and Kidner, 2020). As such, there are currently no physically based models that are capable of accurately estimating the rate of tailings released over time (i.e., tailings breach hydrograph). Instead, empirically/semi-empirically based models that are based on clear-water breach events are used to develop tailings dam breach hydrographs using estimates of breach bottom width (BBW) and time of failure (ToF).

The Canadian Dam Association (CDA, 2021) provides high-level guidelines on the development of tailings dam breach hydrographs using estimates of BBW and ToF. However, there are no industry specific technical standards for determining these parameters, and the typically referenced equations used to estimate embankment breach parameters are, in most cases, empirical (DSO, 1998) and largely based on past failures of water-retaining dams less than 30 m high, which is not particularly applicable to large tailings dams or tailings dams in general (Clohan and Kidner, 2020).

The current state-of-practice for determining BBW's and ToF's is to use one of the following techniques:

1. Use a single correlation between estimates of release volumes and dam characteristics. For example, use DSO (1998) to estimate the BBW and ToF.
2. Assume that discrete estimates of BBW and ToF represent a range of potential estimates and develop a probability distribution function over the range of estimates.

The validity of the first technique is generally undisputed as there is an implicit correlation between the BBW and ToF that suggests the parameters should not be mixed and matched. However, as one equation can predict a relatively larger BBW with a relatively longer ToF and another equation can predict a relatively smaller BBW with a relatively shorter ToF for the same inputs, it is often unclear which equation is the most conservative or which generally represents an "average" condition.

The authors acknowledge some may contest the mixing and matching of breach parameters and that technique 2 may not be valid. However, Ahmadisharaf et al. (2016) has shown that the correlation between BBW and ToF is relatively weak, and that mixing and matching breach parameters is a useful approach for developing a probabilistic framework to selecting a breach hydrograph.

By understanding the probability of a given hydrograph, a connection with the probably of failure and the probability of release volume can be made to develop a true probabilistic breach hydrograph.

Limitations of screening-level risk tools

The use of a screening-level tool must be used for the appropriate application and in consideration of the limitations of the tool at its current stage of development. The risk screening-level tool described is meant to complement more rigorous risk assessment methods such as quantitative or semi-quantitative assessments that are supported by subject matter experts.

The development of baseline distributions and adjustment factors presented in this paper are considered preliminary and will be refined as part of future work planned by the authors, as described in the above sections. For example, an investigation as to what scaling factors are empirically achievable would facilitate the selection by expert judgement. The expectation is that the tool will improve over time as more data becomes available to support a statistical basis and by the incorporation of more expert involvement and testing.

Volumes of Dam Material Mobilized by Erosion During Tailings Dam Failure Events

Daniel Adria, Knight Piésold, Canada
Violeta Martin, Knight Piésold, Canada
Heleman Wong, Knight Piésold, Canada

Abstract

The breach size and shape, and the rate at which it is formed, are key characteristics that must be estimated for conducting a dam breach analysis. A frequently used simplification in such analysis is that the breach channel through a dam is trapezoidal in cross section. This convention allows for consistent comparison between historical dam breaches (water and tailings dams alike) and is useful for numerical modelling of the breach hydrograph and downstream flood wave or runout propagation. However, a breach channel is three-dimensional, and an assessment of the volume of the dam material mobilized for a given two-dimensional trapezoidal breach geometry represents an additional useful parameter to consider when conducting the breach analysis.

The breach geometry and the mobilized dam volumes in a tailings dam breach event could vary substantially depending on the construction type, the dam geometry, and the construction materials used. The breach characteristics can also be impacted by the breach mechanism, which appears to be different for erosional type mechanisms (i.e., overtopping and internal erosion) compared to non-erosional type mechanisms (e.g., slope instability, foundation failure, liquefaction). It is important to include such considerations when conducting tailings dam breach analyses, as they may present physical constraints for the breach development.

Two empirical equations for calculating the eroded dam volume and the dam erosion rate are presented in this paper. Multiple linear regression equations were developed for a combination of historical erosional breach events of water and tailings dams, which use the breach height and the breach outflow volume as inputs. Also presented is a method to estimate whether the supernatant pond volume is sufficiently large for an erosional breach to progress to the foundation based on these equations.

Introduction

The breach size and shape, and the rate at which it is formed, are the key characteristics that must be

estimated when conducting a tailings dam breach analysis (TDBA). A frequently used simplification is that the breach channel through a dam is trapezoidal in cross section. This convention allows for consistent comparison between historical dam breaches (water and tailings dams alike) and is useful for numerical modelling of the breach hydrograph and downstream flood wave or runout propagation using the parametric breach approach (Froehlich, 2008; Wahl, 1998). The parametric breach approach is available in commonly used software for TDBAs (e.g., HEC-RAS, FLO-2D, RiverFlow2D). Many empirical equations developed for water retaining dam breaches use this convention as well.

A breach channel is three-dimensional, however, and an assessment of the volume of the dam material mobilized for a given two-dimensional trapezoidal breach geometry represents an additional useful parameter to consider when conducting the breach analysis. The breath or thickness of tailings dams can range substantially between facilities and dam construction methods (e.g., upstream, centerline, or downstream). All else being equal, it is intuitive that a larger breach channel would develop in a narrower upstream or centerline constructed dam compared to a wider downstream constructed dam (Figure 1), as the same amount of energy would be available for eroding through a much larger dam volume.

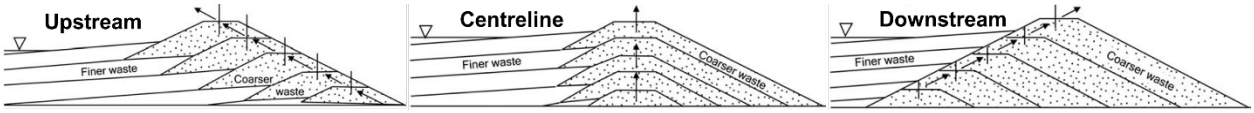

Figure 1: Comparison of tailings dam geometries (adapted from Blight, 2010)

Despite this, most common empirical equations would suggest the same formation time and breach width for both tailings dams, which limits the inclusion of either adverse or favorable site-specific conditions such as the dam size and geometry. Furthermore, these empirical equations are not appropriate to use when the failure is caused by non-erosional mechanisms (e.g., slope instability, foundation failure, liquefaction, etc.), because they were developed for overtopping and internal erosion type failures. The outflow volume, breach geometry and formation time, as well as the peak flow and hydrograph shape are strongly impacted by whether a dam is breached through erosional or non-erosional mechanisms, as discussed in this paper.

Adria et al. (2023a) presented a paper at the 2023 Canadian Dam Association (CDA) conference, in which they introduced two empirical equations for calculating the eroded dam volume and the dam erosion rate for erosional breach scenarios. While these equations are applicable to both water and tailings dams, their applicability to tailings dams and some of the examples presented in that paper are further discussed herein. These examples include specific considerations such as a method to estimate whether the supernatant pond volume is sufficiently large for an erosional breach to progress to the foundation. Additional work is ongoing to expand on the understanding and the dataset related to erosional breaches of tailings dams.

Dam breach processes

Deep understanding of the physical processes during the breach and subsequent flood wave propagation are key requirements for conducting successful breach studies (Rana et al., 2021a). For context within this paper, these processes and existing conventions are summarized below.

Breach geometry conventions

The breach geometry is typically represented with a trapezoid (Figure 2), using the breach height, the average breach width (B_{Avg}), and the breach side slopes (Z_L and Z_R). The bottom breach width (B_B), or alternatively the top breach width (B_T) could be used. The ultimate breach geometry for erosional breaches can be formed by a V-shape cut that progresses downwards until it encounters materials that are substantially less erodible than the dam material, after which it starts widening until the outflow no longer has the capacity to further enlarge the breach opening. The period from when the V-shape begins cutting down into the dam to when the ultimate breach geometry is reached is considered the breach formation time. The formation time excludes the comparatively minor head-cutting phase that occurs during the initial overtopping or internal erosion development (Wahl, 1998), prior to the main breach progression. The breach geometry for non-erosional breaches appear to have more rounded shapes (e.g., U-shapes), but could be reasonably approximated with the same trapezoidal convention (Adria et al., 2023b).

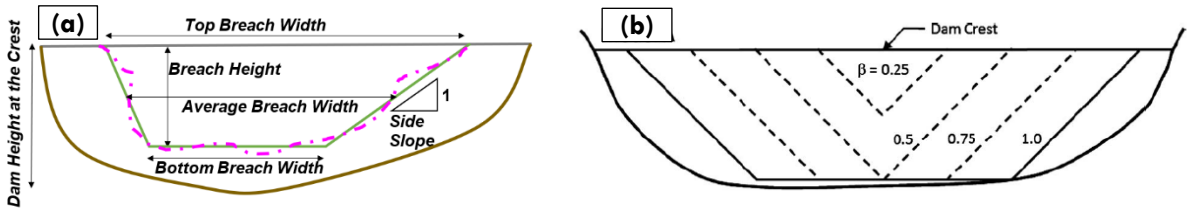

Figure 2: Trapezoidal breach: a) geometry and b) breach formation (Froehlich, 2008)

Breach and outflow processes

Breach processes and characteristics developed through internal erosion and overtopping of water retaining dams are well understood and documented (e.g., USBR, 1988; Wahl, 1998; Froehlich, 2008; Wahl, 2014; Walsh et al., 2021). These processes primarily involve erosion of the dam materials by water flowing over the crest or through the dam over a period of minutes to hours. Failures can also be caused by slope instability, foundation failure, structural failure, liquefaction, or other mechanisms that could remove the containment structure within seconds to minutes. In such "non-erosional" type failures, erosion does not play a key role, as these failures are dominated by geotechnical characteristics (e.g., slip surfaces, residual undrained shear strength ratios, etc.) rather than pond volumes.

The breach outflow volume for tailings dam breaches depends on whether there is a pond present in the TSF, and whether the tailings are susceptible to liquefaction (Small et al., 2017; CDA, 2021). The CDA

TDBA guidelines (2021) further identify two processes to qualitatively describe the discharge mechanisms associated with the outflow of the supernatant pond and/or flowable tailings. Process I is the discharge of the supernatant pond that carries tailings and dam materials mobilized through erosion, which can often be analyzed using Newtonian fluid approximations. Process II is the outflow of flowable tailings that are mobilized due to liquefaction or progressive slumping of unsupported tailings until a stable tailings slope is achieved (backscarp). The outflow from Process II would be primarily comprised of tailings solids and interstitial water, and therefore would have a much lower water content (i.e., higher solids content) compared to Process I. Process II outflows must be analyzed using non-Newtonian fluid approximations and associated rheological properties for the tailings material. A breach can, but does not have to, include both Process I and Process II outflows, which can occur in either order, or simultaneously.

As the breach opening develops and the outflows propagate downstream, the physical impacts of the two discharge mechanisms typically are notably different. Process I breach outflows have a relatively low solids content and are highly erosive, as was observed in the Mount Polley failure in 2014 with the erosion of Hazeltine Creek (Morgenstern et al., 2015; Cuervo et al., 2017). In contrast, Process II runouts have a high solids content and typically result in limited erosion. For example, the liquefied tailings outflow from the Prestavèl TSF in Italy (i.e., Stava) had a high fluidity and an intensive destructive power, but the downstream creek channel itself did not undergo much erosion or deposition (Berti et al., 1988). Takahashi (2014) stated that no erosion occurred because the solids fraction inside the water-sediment mixture of the Prestavèl tailings was so high (approximately 48% by volume) that the flow could not become denser through additional erosion. Hungr et al. (2005) similarly stated that flows with lower sediment concentrations can be expected to be more erosive than flows with higher sediment concentrations.

In this paper, the focus is on erosional breach processes through the embankment, which is considered separate from the downstream erosion of stream-channels and their floodplains.

Development of eroded dam volume equations

Adria et al. (2023a) developed two empirical equations to estimate the eroded dam volume (V_{ED}) and the mean eroded dam volume rate (M), which make use of the combined and verified databases for water retaining dam breaches from Wahl (1998, 2014) and erosional tailings dam breaches from Adria et al. (2023b). The proposed relationships are based on multiple linear regressions (MLRs) of dam height and outflow volume. MLRs have better predictive capabilities than the methods in which each input is used individually or combined (as in the height-volume product in MacDonald and Langridge-Monopolis, 1984). The two MLR equations are defined as follows:

$$V_{ED} = 1.26 {H_W}^{1.803} {V_{Out}}^{0.338} \quad (1)$$

$$M = \frac{V_{ED}}{T_f} = 415\ {H_W}^{2.296} {V_{Out}}^{-0.098} \quad (2)$$

In these equations V_{ED} is the volume of the eroded dam material [m³], H_w is the height of water above the breach [m], V_{Out} is the volume of breach outflow that typically includes the supernatant pond and the eroded tailings material [m³], M is the mean eroded dam volume rate [m³/hr], and T_f is the breach formation time [hr]. The variable V_{ED} is the same as V_M or V_{Er} used by MacDonald and Langridge-Monopolis (1984) or Wahl (1998), however, the labelling is changed to prevent confusion with eroded tailings volumes, or dam materials that mobilize through non-erosional breach processes. The events used to develop the empirical equations are compiled in Tables A1 and A2 of the Appendix to this paper.

Figure 3, reproduced from Adria et al. (2023), compares the predicted values for: (a) the eroded dam volume using Equation 1, and (b) the mean eroded dam volume rate using Equation 2 with observed values, while the insets show a box and whisker plot of the predicted to observed ratios. The dashed lines represent half an order of magnitude above and below the 1:1 line, indicating the approximate range of the error. Ideally, the boxplots have a mean and median close to unity (indicating little error on average) and a narrow interquartile range (indicating lower variability in estimated value accuracy). The interquartile ranges for the two equations are comparable to or are smaller than observed in earlier equations, indicating good predictive ability (Wahl, 2004).

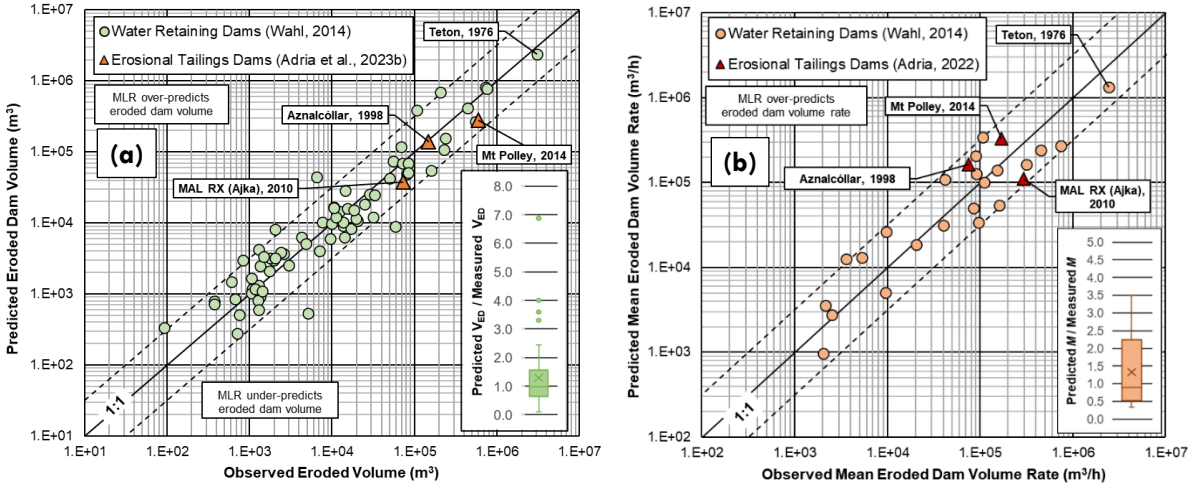

Figure 3: Comparison of observed and predicted values for: (a) eroded dam volume, and (b) mean eroded dam volume rate (from Adria et al., 2023)

For Equations 1 and 2, the volume of tailings that are eroded with the supernatant pond during Process I outflows is included in V_{Out}, while the liquefied tailings volume discharged in Process II outflows is not included in V_{Out} in consideration of the limited erosive potential of Process II flows (this can be changed depending on project-specific conditions). Equations 1 and 2 are not meant to be applied to non-

erosional breach events, for which the breach develops due to drivers other than erosion. For the tailings dam breach events that were included in the development of regression equations shown in Figure 3, the estimated volumes of tailings eroded during the supernatant pond discharge (i.e. Process I) were included in the analysis. A Process II outflow volume may be estimated separately after the breach geometry is selected, and the runout from Process II either evaluated separately or included in the final outflow hydrograph, as appropriate for the project-specific conditions.

The eroded dam volume rate varies during the breach development, with higher rates occurring during the peak outflow and lower rates during the rising and receding limbs of the breach hydrograph. The value predicted by Equation 2 represents the average or the mean rate. The mean eroded dam volume rate itself cannot be used as an input for most dam breach hydrograph modelling approaches, but needs to be combined with an estimate of the eroded dam volume to inform the breach formation time. The eroded dam volume can be estimated either by using Equation 1, or by using other regression equations to determine the breach width and side slopes (e.g., Froehlich, 2008; Xu and Zhang, 2009), and then converted to the eroded dam volume using relatively simple geometric equations. The Washington Guidelines (2007) include discussion on these geometric equations, or 3D CAD modelling can also be used to calculate the eroded dam volume based on the estimated breach geometry for more complex dam geometries if required (e.g., buttresses, or varying slopes). The primary advantage of estimating the mean eroded dam volume rate is to support the selection of both the breach geometry and the breach formation time.

Applications of eroded dam volume equations to tailings dams

Adria et al. (2023a) presented several examples that illustrate the impact of outflow volume or dam geometry on the breach size or the rate of breach development. They also included examples to demonstrate how topographic constraints may impact the breach development, and a discussion on how to use sensitivity analysis to support the final selection of breach parameters. Some of those examples relevant to tailings dams are included herein.

Determining breach widths and breach heights

Breach analysis ideally considers the dam geometry in a rational, non-subjective way. The characteristics of three TSFs that are 50 m tall are summarized in Table 1. These TSFs are hypothetical, but the geometries and pond volumes are comparable with the range the authors have observed for real TDBAs. TSF 1 and TSF 2 have the same pond volume, but TSF 1 has a thinner geometry (i.e., smaller crest width, steeper downstream slope, and a centerline dam construction with nearly vertical upstream slope). TSF 2 and TSF 3 are both downstream constructed dams with the same dam geometry, but the supernatant pond volumes are different. The tailings are considered non-liquefiable (i.e., they would represent Case 1B according to CDA,

2021); however, a portion of the tailings would be eroded and mobilized during the breach development. The eroded tailings volume in Process I was calculated using a 30% volumetric solids concentration in the outflow and a void ratio of 1 for the tailings material (Fontaine and Martin, 2015; CDA, 2021).

In Table 1, Equation 1 was used to calculate the Eroded Dam Volume for all three dams, which was then used to estimate the breach height and the bottom width given the outflow volume. The assumed breach side slopes for all three dams are 1H:1V. TSF 1 and TSF 2 are used to demonstrate how Equation 1 can be used to quantitatively consider the dam geometry (i.e., the dam thickness), rather than relying on subjective adjustments to empirical equation results. For both TSFs the same volume of dam material is predicted to erode (as the pond volumes, and thus, the breach outflow volumes, V_{Out}, are identical); however, the breach width for the downstream constructed dam must be narrower to erode the same dam volume given the same breach height.

Table 1: Comparison of estimated breach heights for different TSF characteristics

Parameter	TSF 1: Large pond centerline dam	TSF 2: Large pond downstream dam	TSF 3: Small pond downstream dam
Supernatant Pond Volume (m^3)	1,800,000	1,800,000	400,000
Eroded Tailings Volume (m^3)	2,700,000	2,700,000	600,000
Total Outflow Volume (m^3)	4,500,000	4,500,000	1,000,000
Crest Width (m)	5	20	20
Upstream and Downstream Slopes (xH:1V)	0 and 2	1 and 4	1 and 4
Calculated Eroded Dam Volume (m^3)	258,000	258,000	62,000
Calculated Breach Height (m)	50	50	30
Calculated Breach Bottom Width (m)	60	0	0

The second pair of TSFs (TSF 2 and TSF 3) that have different supernatant pond volumes is used to demonstrate the relationship between the breach outflow volume and the possible breach height to reach the predicted eroded dam volume from Equation 1. In this process, the breach height can be determined as follows:

1. The required volume of the dam that must be eroded for a breach to reach a given elevation is calculated using the geometric relation between breach geometry and eroded dam volume as per the Washington Guidelines (2007). The breach geometry uses a breach side slope of 1H:1V (or alternate as selected), a bottom breach width of 0, and a given dam geometry (i.e., crest width, upstream dam slope, and downstream dam slope). The calculation is performed at regular breach depth intervals, moving downwards from the crest elevation, to represent a V-shape erosion progression from Froehlich (2008).

2. The potential eroded dam volume that could be eroded for each breach height is calculated using Equation 1 for the same intervals using the predetermined outflow volume and varying the breach height.
3. The two eroded dam volume curves are plotted, and the breach elevation where the required eroded dam volume (Step 1) exceeds the potential eroded dam volume (Step 2) (i.e., the intersection of the two curves) represents the ultimate breach height. If the two curves do not intercept, the breach could progress down to natural ground.

This process is shown in Figure 4 (reproduced from Adria et al., 2023), using the hypothetical example of TSF 2 and TSF 3 from Table 1. The eroded dam volumes are placed on the x-axis to align the breach elevation (y-axis) vertically with the breach geometry schematic; the eroded dam volume remains as the independent variable in this procedure. The small pond is unable to erode the dam to its foundation, while the large pond is sufficient to erode it to the foundation. A pond larger than 1,800,000 m³ would be able to erode the downstream constructed dam to foundation and proceed to lateral erosion and breach widening, as described by Froehlich (2008). Dam features that also could arrest breach should be identified to support an estimated breach elevation that is above the foundation elevation. For example, a large buttress or bench is a plausible cause for the vertical breach progression to be slowed or stopped.

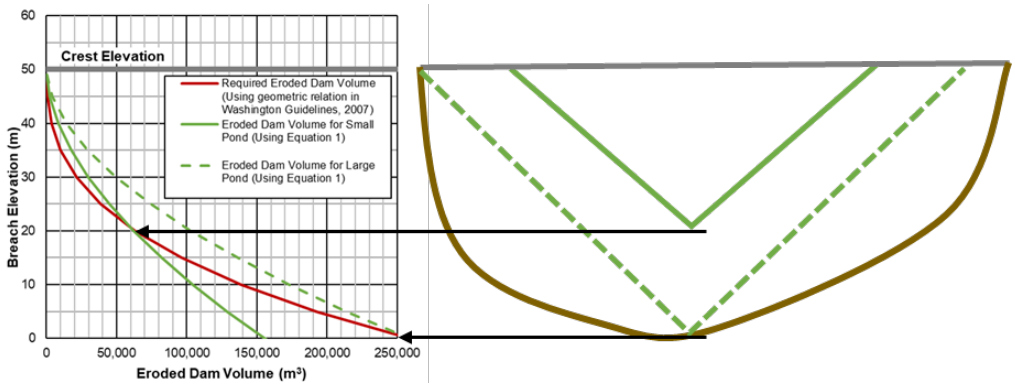

Figure 4: Comparison of the calculated eroded dam volume against the dam volume that would need to be eroded to reach a specific breach height with the V-shape breach

Refining formation times for sensitivity scenarios

A practitioner may ultimately choose more conservative inputs than what is estimated from any one regression equation; however, the combination of these conservative choices should remain within reason, which can be supported using the mean dam erosion rate equation. A larger breach, faster breach, or a combination of a larger and a faster breach could be assessed; however, these scenarios could result in physically impossible and extreme breach outflows. By using Equation 2 and the scatter in Figure 3b, an upper and lower bound on the mean eroded dam volume rate can be estimated for the sensitivity scenarios.

Using TSF 1 from Table 1 as an example, a breach bottom width and a breach formation time were estimated for the base case using Froehlich (2008). The values selected for the sensitivity scenarios (wide or fast breach) were based on the results from Froehlich (2008), and adjusted using the error guidance for these parameters from Wahl (2004). The selected breach side slope for this example was 1H:1V. The example results are shown in Table 2 (from Adria et al., 2023), where the breach width and formation time were calculated using Froelich (2008), V_{ED} was calculated using the geometric relations in Washington Guidelines (2007), and M was calculated using the dam breach formation time from Froehlich (2008) and the eroded dam volume from Washington Guidelines (2007).

Table 2: Mean eroded dam volume rates for sensitivity scenarios for a centerline dam

Parameter	Base Case	Wide Breach	Fast Breach	Wide and Fast Breach
Average Breach Width (m)	55	110	55	110
Bottom Breach Width (m)	5	60	5	60
Breach Formation Time (hr)	0.24	0.24	0.12	0.12
Eroded Dam Volume (m^3)	110,000	260,000	110,000	260,000
Eroded Dam Volume Rate (m^3/hr)	458,000	1,080,000	917,000	2,170,000

In comparison, Equation 2 predicts a mean eroded dam volume rate of 736,000 m^3/h. The maximum error for Equation 2 is approximately 0.5 orders of magnitude, therefore the maximum and minimum M values could be as high as 2,327,000 m^3/h and as low as 233,000 m^3/h, respectively. The base case values, as predicted using Froehlich (2008), result in an M value that is less than the predicted value from Equation 2. This is due to the implicit assumption in Froehlich (2008) that the dam would be downstream constructed and would have more dam material that could be eroded during a breach. A simple change from a centerline dam to a downstream dam that has an upstream dam slope of 2H:1V would result in a similar M value when using Froehlich (2008) to that calculated using Equation 2.
